The greatest reduction in the gap for males resulted at the end of the sustained expansion throughout most of the 1960's. Virtually all of these gains appear to have been wiped out in the early 1970's, for the gap for males has returned to the levels of the mid–1950's. Indeed, the recent decline in labor force participation rates for nonwhites suggests that the increased gap in the unemployment rate understates the extent to which the gains of the 1960's have been erased, for many potential labor force members have given up seeking work, believing jobs to be unavailable. Black males are disproportionately represented among these discouraged workers who are not counted as being unemployed and therefore are not reflected in the gap.

For adult females, while the unemployment rate for whites has varied from 8.0 to 3.2 percent, that for blacks has ranged from 11.8 to 5.4 percent. The unemployment gap had been lower for females than for males prior to the mid–1960's but became larger than for males in the late 1960's as men gained more than women from the prolonged expansion in that period. By mid–1975, the gains in the reduced gap for females were also extinguished.

For teenagers, the gap in unemployment rates has been continuously worsening over the two decades. While the white teenage unemployment rate has fluctuated between 18.3 and 9.1 percent, the black rate has varied between 39.8 and 13.5 percent. The gap has grown from 4 percentage points in the mid–1950's, to 14 in the mid–1960's, to 20 in the mid–1970's. The economic ebullience of the 1960's merely tempered the persistent trend up-

ward in the black-white teenage unemployment gap.

## II. The Pace of Recovery and the Unemployment Gap

A central question then is what can be done to reduce unemployment rates generally, as well as the gap between the rates for blacks and whites. It is therefore of interest to ascertain the contribution that might be made by a more rapid recovery than the modest ones often contemplated in current popular forecasts.

Since the recent recession has been unusually severe, a return from current rates of unemployment of above 8 percent to a low level by 1978–IV, say to 4.5 percent, would require very high average annual rates of growth in the real *GNP* approximating 7.5 percent. This in turn would be consequent to highly expansionary fiscal and/or monetary policy or to a vigorous upswing in demands from the private sector, for example, a decline in the saving rate, or a boom in capital spending or in net exports. There is no evidence of such strong sources of forthcoming private demand. A recovery averaging a real growth rate of 5.5 percent annually is more consistent with past experience over a three year period. Such a growth rate would leave the unemployment rate at between 6 and 7 percent by the end of 1978. There are of course other possible growth paths for the economy.

The trade-off with inflation from more rapid rates of recovery is difficult to project. Because of the persistence of inflation, it is quite probable that even the more moderate recovery would still be accompanied by annual increases in the consumer price index of about 6 percent by 1978. Accelerating the average annual growth rate from 5.5 percent to 7.5 percent until 1978 through stimulative fiscal policy with less than fully accommodating monetary policy could increase the rate of inflation by another percentage point. It can be argued that as long as there is excess capacity and unemployment remains about 4.5 percent, added inflationary pressures will be moderate. On the other hand, as our report states, "the psychological consequences of adopting a new, highly expansionary fiscal strategy are uncertain, and one cannot rule out the possibility of a new round of price increases that could be set off by inflationary expectations." The depth of the current recession and the concurrence of high unemployment together with inflation combine to increase the hazards of applying models based on past experience to the current recovery.

TABLE 2—PROJECTED RANGE OF SELECTED UNEMPLOYMENT RATES FOURTH QUARTER, 1978

| | Alternative Macroeconomic Policies | |
|---|---|---|
| | Faster Recovery Strategy 1978–IV | Moderate Recovery Strategy 1978–IV |
| Unemployment rate (in percent) | | |
| Total | 4.5 | 6.6 |
| Nonwhites[a] | 8.0–8.8 | 11.4–12.2 |
| Whites | 3.9–4.1 | 5.8–6.0 |
| Difference between nonwhite and white unemployment rates (in percentage points) | 3.9–4.9 | 5.4–6.4 |

*Source:* The unemployment rates and differentials were estimated by *CBO*, assuming a continuation of recent historical patterns. The levels of the nonwhite and white unemployment rates relative to the national unemployment rates were reviewed and particularly for recent periods when the national rate approached those projected for both recovery paths. The estimates were also compared to the mid-points produced in two models using microsimulation modeling of the labor market at the unemployment rates of 4 and 5 percent at 1978–IV. The microsimulations were made available to *CBO* by The Urban Institute.

[a] Negro and other races, 89 percent of whom are Negro. See *Employment and Earnings: October 1975*, U.S. Department of Labor, Bureau of Labor Statistics, p. 161.

Shown in Table 2 are the unemployment rates by race and the racial gap consistent with the two recovery paths. The moderate recovery path leads in 1978–IV to a national unemployment rate of about 6.6 percent. The associated range of unemployment rates for whites has a midpoint at 5.9 percent in contrast to 11.8 percent for blacks, leaving a racial gap of between 5.4 and 6.4 percentage points in 1978–IV.

A more rapid recovery could be brought about by cuts in the personal income tax, increased government purchases of goods and services, or by a combination of the two at a cost of a greater federal deficit and, as we have seen, added inflation. It would produce a 4.5 percent unemployment rate in 1978–IV, according to *CBO* simulations. In contrast to the moderate recovery strategy, this strategy would reduce the overall unemployment rate in 1978–IV by 2.1 percentage points. The midpoint of the range of associated unemployment rates for whites would be lowered by 1.9 percentage points, and for blacks, by 3.4 percentage points. More rapid recovery would therefore narrow the gap by about 1.5 percentage points, or by about one-fourth, a not inconsiderable magnitude. Even so, a gap ranging from 3.9 to 4.9 percentage points would still remain between the black and white unemployment rates in 1978–IV.

## III. Conclusion

Over the last 20 years, the gap between the unemployment rates of blacks and whites has ranged from 2.9 to 6.8 percentage points and was close to the high end of this range in 1975–III when the gap was 6.1 percentage points. The gap varies by sex and age. The substantial gains made in the 1960s in reducing the racial gap for adult males and for adult females had been virtually wiped out by mid–1975. For teenagers, the gap has become progressively wider over the last twenty years. Adjusting unemployment rates to include the effects of discouragement would increase the overall racial gap in 1975–III from 6.1 to 7.7 percentage points. No adjustments were made to adjust the data for underemployment.

A major factor affecting the level of unemployment and perhaps the gap is the pace of the recovery. Two growth paths over the next 36 months were reviewed. The real *GNP* expands at an average annual rate of 5.5 percent in the moderate growth model and by 7.5 percent in a faster growth model. The moderate growth strategy reduces the overall unemployment rate from 8.3 percent in November 1975 to 6.6 percent by 1978–IV, but it would either not close the racial gap at all or not by much. The faster growth strategy reduces the unemployment rate to 4.5 percent by 1978–IV and narrows the racial gap by one-fourth, at a cost of some added inflation and a higher deficit. Even with the faster growth strategy, a gap between the black and white unemployment rates of between 3.9 and 4.9 percentage points remains unclosed.

Ongoing research is focusing upon alternative selective fiscal policies for further narrowing the gap. Alternatives such as countercyclical revenue sharing, public works, public service employment and other public programs that are targetable will be analyzed for their impact on the gap in the short run and their costs. Other research at the Congressional Budget Office analyzes what is known about the effectiveness of a wider range of programs—including job creation strategies, human capital development and regulatory efforts aimed at combatting discrimination—that would impact on the racial gap over a longer time period.

# Capital Problems in Minority Business Development: A Critical Analysis

*By* KENNETH E. KNIGHT AND TERRY DORSEY*

The authors have examined the federal government's strategy of economic development for minority groups through the development of minority enterprise as a function of capital availability. (See Knight and Dorsey for complete analysis.) The demand for capital is defined as a function of asset parity with nonminority business to be achieved over a twenty year period. Capital availability is estimated through examination of three sets of institutions which provide capital to minority business: (1) minority and nonminority banks; (2) the availability of equity capital through the Minority Enterprise Small Business Investment Company (*MESBIC*) program; and (3) the Small Business Administration (*SBA*).

Based upon an estimate of the annual capital requirements needed to achieve asset parity over time, the magnitude of available capital is assessed for adequacy. In aggregate, the three sets of institutions appear to provide less than 10 percent of the yearly amount required to reach asset parity. This capital shortfall is viewed as the result of a more generalized capital shortage in the United States today.

Between 1960 and 1973, the *U.S.* average level of total output devoted to fixed investment was lower than in any of the other 11 most industrialized countries, including Italy and Great Britain (U.S. Treasury Department). Estimates of capital shortage expected over the next ten years range from approximately $200 billion by James S. Duesenberry and Bosworth (*Business Week*) to $646 billion by a New York Stock Exchange study. While it is not possible to estimate the impact of this shortage for minority enterprise, it is appropriate to conclude that the shortage can do little except make the lack of available capital for minority enterprise even worse. The current programs, while significantly larger than efforts in the past, fall far short of what is required to achieve asset security within 20 years.

## I. The Demand for Capital by Minority Business

Estimating the demand for capital by minority business from the goal announced by Secretary Stans in 1970—double the number of minority firms between 1970 and 1990—is inadequate as an operational goal. The inadequacy of this goal stems from its failure to enumerate the types and sizes of firms that would most benefit minority groups. R. Yancy describes the results of an unfocused program to assist minority enterprise:

> The types of industries which blacks have entered under federal assistance programs are no different from the industries they enter without federal assistance. These industries . . . do not offer optimum opportunities for economic growth and success. Few of the industries where blacks are concentrated offer excellent opportunities for large scale activity, for capital accumulation or for growth . . .

* The University of Texas at Austin.

TABLE 1

| Firm Size (Yearly Receipts) | Receipts Per Employee | |
|---|---|---|
| \$0–\$49,999 | \$12,269 | |
| \$50,000–\$99,999 | \$21,198 | |
| \$100,000–\$199,999 | \$25,191 | |
| \$200,000 or more | \$36,570 | |
| | Total *U.S.* Firms | Minority Firms |
| Number of all firms | 7,489,000 | 322,000 |
| Gross sales | \$1,498 bil. | \$10.6 bil. |
| Average sales | \$200,027 | \$32,919 |
| Total nonfinancial (corporate) assets | \$859 bil. | \$2.6 bil. |

> The ideal federal strategy, then, should be to encourage blacks to enter larger scale businesses which employ greater numbers of employees and which offer potential for growth within the business community. [pp. 67–68]

Potential benefits accruing to the minority community from development of larger ventures rather than small or "mom and pop" operations is highlighted by data from the 1969 census of minority-owned businesses with paid employees (p. 152). (See Table 1.)

If one asserts that the objective of minority business development is parity of total minority business assets over a twenty year period, it is necessary to make a yearly capital investment of approximately \$7.3 billion. (Minorities constitute approximately 17 percent of the *U.S.* population; \$859 billion x 1/20 x 17% = \$7.3 billion.) The overall debt/equity ratio for all nonfinancial *U.S.* corporations in 1971 was 2.57 (*Statistical Abstract of the U.S.*, 1974); thus, it may be inferred that approximately \$2.04 billion should be invested or generated each year as equity and \$5.24 billion as debt.

## II. The Availability of Capital for Minority Enterprise

Next the supply of capital for minority business relative to the demand is evaluated.

### A. The Banking System

Examination of capital availability for minority business through commercial banks is conducted by analyzing the roles of minority and nonminority banks.

Andrew Brimmer succinctly describes characteristics of black banks: "The typical black bank is about one-third the size of the typical bank in the country at large, the former having average deposits of roughly \$10 million in 1969 compared with \$33 million for the latter . . ."

Other factors diminish black banks' ability to loan capital to business even further. High losses and inexperienced management have combined to produce (1) high operating costs and low efficiency, (2) one-quarter to one-third the percentage profit of the average bank, (3) loans of a smaller proportion of the bank's available funds, and (4) investments of a large proportion of total assets in government securities.

Despite the almost insignificant size of minority banking relative to the commercial banking system as a whole, its role through 1970 in financing minority businesses

> . . . had been disproportionately large: As recently as 1971, it has been reported, minority banks, with combined assets less than one tenth of one percent of those of all commercial banks, had extended \$60 million in loans to minority enterpreneurs —more than a third as much as the \$150 million granted by nonminority banks. [D. Fisher, p. 37]

However, in 1970 the banking industry announced a program to invest \$1 billion in the new financing of businesses planned or owned by members of minority groups by 1975 (*Burroughs Clearing House*). Statistics released by the American Bankers Association (*ABA*) in July

1973 revealed that 351 member banks had placed minority loans totaling $758 million since 1970. While lack of suitable data prohibits precise comparisons, it is useful to note that $758 million represents 2.93 times $258.8 million, the total assets of black banks in 1969 and 9.12 times $83.1 million, the total amounts of loans by black banks for commercial, industrial and real estate purposes in 1969. However, if $758 million were invested in only one year, it would represent 14 percent of the amount of debt capital needed in that year to achieve parity over a twenty year period.

### *B. Availability of Equity Capital: The MESBIC Program*

The availability of long-term debt and equity capital for minority business is examined by analyzing the *MESBIC* and, to a lesser extent, the Small Business Investment Corporation (*SBIC*) program. This approach is undertaken because minority groups own negligible financial assets to serve as the basis of equity capital.

By April 1972, *MESBIC*s had invested $7.6 million in 422 firms, averaging $18,009 per firm (Richard H. Klein); assuming 6 percent annual inflation, average investment size in 1975 dollars would be $21,449. In February 1975, there were 73 licensed *MESBIC*s whose combined private and government capital was $68.1 million.

Experience from the *SBIC* indicates that smaller investment firms are more prone to make debt rather than equity investments. Because of their small sizes, it is estimated that firms in the *MESBIC* program probably can furnish no more than $14.73 million in equity funds *if they were fully invested.* Using an estimated average investment size of $21,500, it is inferred that the current *MESBIC* program is likely to furnish equity capital to approximately 650 ventures.

The entire *MESBIC* program, consisting of $68.1 in capital equals approximately 3.5 percent of the yearly need for almost $2 billion in equity. If the *SBA* requirement of 15 percent equity is used, the entire *MESBIC* program can support $454 million in *SBA* loans or 6.25 percent of the needed yearly investment.

Samuel Doctors and S. Lockwood have proposed that entry by minority enterprise into growth industries, especially technology-intensive ones, would permit the most economic benefits to minority enterprise. Thus, it is useful to evaluate the availability of venture capital (*VC*) and to note that the small size of the *MESBIC* industry derives not so much from inadequate support by government as it does from the total amount of funds currently available as equity capital for new nonminority enterprise.

Stanley Rubel, editor of *Venture Capital,* estimates that the approximately 600 *VC* operations listed in his directory have access to about $400 million which can be invested as *VC;* he also estimates that these operations will invest approximately $150–250 million this year. If in 1975 the entire *VC* community made all its investments in minority enterprise, $250 million would still represent only 12.3 percent of the amount needed this year to achieve asset parity. Moreover, the total $400 million estimated to be available is only 19.6 percent of the $2.04 billion needed each year as equity.

Just as smaller loans made by *SBA* seem to have higher probabilities of failure, evidence also indicates that large *VC* investments have higher probabilities of success than smaller ones. A study of more than 350 such investments reveals that investments which resulted in very successful growth ventures averaged more than $800,000 each, while those which produced failures averaged $400,000 (Dor-

TABLE 2—MINORITY ENTERPRISE LOANS
(Millions of dollars)

| Year | Total *SBA* Involvement[a] | *SBA* Direct (37.5%) |
|---|---|---|
| 1968 | $ 54 | $ 20.25 |
| 1969 | 131 | 49.13 |
| 1970 | 176 | 66.0 |
| 1971 | 231 | 86.63 |
| 1972 | 309 | 115.88 |
| 1973 | 317 | 118.88 |
| 1974 | 238 | 89.25 |

[a] 1968–72 from Yancy, p. 72. 1973–74 from 1974 Annual Report of *SBA*.

sey). Because of statutory limitations on maximum investment size as a function of private capital invested, there are no *MESBIC*s which can make investments of even $400,000 or more, much less the larger investments.

Thus, the availability of equity capital through the *MESBIC* program is inadequate: (1) the size of the program is too small; (2) the size of individual *MESBIC*s is likewise too small to finance firms with high probabilities of success. However, the effectiveness of *MESBIC*s is limited not by the program itself as much as by the limited availability of equity capital for all new firms.

### *C. Small Business Administration*

Analysis by Yancy indicates that direct investment by the *SBA* in business is somewhat less than claimed because *SBA* includes participation loans and loan guarantees when it publishes data on loan investment. Using Yancy's data to adjust published *SBA* data, the authors are able to estimate the amount of capital actually loaned to minority business between 1968 and 1972. See Table 2.

The $238 million *SBA* claims to have invested in minority business in 1974 is 4.47 percent of the yearly amount required to achieve parity over time; the adjusted estimate of $89.25 is only 1.67 percent of the needed yearly amount.

# INTERNATIONAL CAPITAL MARKETS AND FOREIGN EXCHANGE: NEW DIRECTIONS OF RESEARCH

# Portfolio Choice and the Demand for Forward Exchange

*By* MICHAEL ADLER AND BERNARD DUMAS*

The development of the so-called "modern theory" (*MT*) of the forward exchange market summarized in Herbert G. Grubel and Hans R. Stoll (1968) purported to offer at least three contributions. First, it established that forward exchange market equilibrium could occur at a forward rate which did not correspond to interest rate parity (*IRP*). Second, it predicted usefully for forecasting purposes that the equilibrium forward rate would invariably fall in between the *IRP* forward rate and the expected future spot rate. And third it supplied a theoretical foundation for government policies of intervention in the forward market which were deemed—given certain assumptions regarding speculators' expectations as to the results of the intervention—to be potentially successful even under market demand conditions that were such as to produce *IRP*. As we shall show, the first claim survives but for reasons other than those proposed by the *MT*, while the second and third do not.

The main conceptual difficulties of the *MT* deserve brief mention. The urge to identify the equivalent of demand and supply sides in the foreign exchange market forced many authors, e.g., Sho C. Tsiang, Egon Sohmen and Grubel, to posit an artificial segmentation of forward market transactions as between pure arbitrage and pure speculation: arbitrageurs never speculate and vice versa. Because interest arbitrage involves equal and opposite spot and forward transactions, this putative segmentation led some to the misleading supposition of a direct quantitative link between the volumes of forward and spot market transactions and an incorrect specification of the response of spot, short-term capital flows to monetary policy.[1] The segmentation also forced the *MT* largely to exclude hedging, an important motive of transaction, for which the linkage necessarily breaks down (E. Ray Canterbery, Donald Schilling). But the exclusion of hedging is actually unnecessary. The link is generally indirect and will be established by the simultaneous equilibria in the international markets for stocks, bonds and currency.

Our main objective in Section I is to derive an individual's demand function for forward exchange under general uncertainty in a two-country model which includes international markets for stocks, bonds, and forward contracts and which allows for default risks. Peter B. Kenen, using a certainty model of an individual

* The authors are Professor and Assistant Professor, respectively, at the Graduate School of Business, Columbia University. Financial support was provided by the Rockefeller Foundation which, however, bears no responsibility for any opinion expressed herein.

[1] Jerome L. Stein provides an exception to this rule.

firm, was the first to argue that a single economic unit might trade, hedge, and speculate all at once. Similarly, our investors, who may trade to an unspecified degree, will transact simultaneously in the several financial markets.

Our analysis of Section II reveals that the demand for forward contracts cannot be decomposed linearly into additive component demands for the purposes of arbitrage and speculation. The usual *MT* rendition is therefore demonstrably wrong. The arbitrage motive operates multiplicatively: it amplifies the demands for other motives and need not involve interest arbitrage at all. Arbitrage will occur between *any* two linearly dependent sets of risky assets. Further, a demand for hedging purposes, excluded from the *MT*, arises here as a result of the availability of forward contracts as an extra risky asset into which the investor can diversify to reduce his total real portfolio risk. Perhaps surprisingly, hedging in our model has nothing to do with definitions of the exposure of assets or investment returns to exchange risk. An investor maximizing the expected utility of his real consumption of a mix of goods, as in F. Grauer-Robert H. Litzenberger-R. Stehle, will not convert forward his foreign investment returns and exchange receipts into his own currency—i.e. cover his exposure. He would do so, as Kenen's firm and B. A. Solnik's individuals are assumed to do, only if he desired to consume his own country's goods exclusively. Instead, he will seek to reduce his real purchasing power risks, arising from exogenously specified relative price and exchange rate changes. This can be achieved by diversifying into risky forward contracts when the spot rate is not perfectly correlated with the real returns on stocks and bonds.

The equilibrium results developed in Section III are useful for confronting the empirical literature and the predictions of the *MT*, most of which seeks to explain why forward rates deviate from *IRP*. Three strands of explanations have been offered.

Our explanation of departures of forward rates from *IRP* is founded on the existence of risks and the associated costs of default on bonds and forward contracts. Others have offered similar suggestions but without rigorous proof. Stoll (1972) and Grubel have argued that default risk in arbitrage transactions will make the (hypothetical) pure arbitrage function inelastic. Robert Z. Aliber surmises that probably political risks (i.e., of restrictions on convertibility) are enough to do the trick: this is not the case, however, as we show below.

Other authors largely rely on specific market imperfections. Paul A. Einzig, followed by Sohmen and Canterbery argue, after Keynes, for institutional constraints on the availability of arbitrage funds which, in the language of the *MT*, cause the arbitrage net-demand curve for forward contracts to become inelastic with respect to the forward rate. Martin F. Prachowny and Jacob A. Frenkel identify as the culprits capital market imperfections, in the form of borrowing rates which rise in an unspecified (and unmeasurable) fashion with the volume of arbitrage; Kenen makes a similar assumption. Such accounts are basically unsatisfactory in the sense that they require further justification of why institutions behave in the asserted fashion and how markets are cleared.

The third scenario began with William H. Branson, who attributes departures from *IRP* to transactions costs which create a band within which deviations can occur. Frenkel and R. M. Levitch suggest that once transactions costs are accurately accounted for and removed, *IRP* remains robust. This robustness may be illusory, however. The data used in em-

pirical studies are typically the prices quoted in the interbank dealer market, where, in the short term and under normal conditions, risks of default on interbank borrowing and of suspensions of convertibility are usually absent. In fact, it is well known that bank foreign exchange traders normally use the *IRP* formula to design their quotes. But deviations occur also in this market during abnormal periods (viz., the pound in 1967 and the Deutsche mark in 1973), when default and/or convertibility risks might have been high.

## I. The Portfolio-Choice Model

We postulate the existence of two nations separated by currency borders. Investors of both countries have access to three types of securities: stocks, bonds, forward exchange contracts. The bonds of both countries as well as the forward contracts are subject to a risk of default; i.e., there is a nonzero probability that these obligations may not be fulfilled. We assume, however, that these risks of default are exogenous and independent of the investors' decisions; they may result, for instance, from the government of either country suspending convertibility and thereby preventing a number of individuals from honoring their promises.

Individuals maximize a two-period utility-of-consumption function which exhibits no complementarity over time. Each period utility is the sum of a negative definite quadratic form and a linear form:[2] $-c'Qc + q'c$ where $c$ is the consumption vector. One could show that after optimization with respect to the consumption menu, the derived utility is:

$$(1) \qquad -c_0^2 + R_0c_0 + \alpha[-\tilde{w}^2/\tilde{I} + \tilde{R}\tilde{w}/\tilde{I}]$$

[2] This utility function is justifiable only as an approximation covering an infinitely short consumption period.

where:

$c_0$ = period-0 nominal consumption expenditures, expressed in currency 1;
$\tilde{w}$ = period-1 nominal wealth also equal to period-1 nominal consumption;
$\alpha$ = coefficient of time preference;

and $R_0$, $\tilde{I}$, $\tilde{R}$ are appropriate price deflators.[3]

Consider now the individual's investment decision. His future wealth will be given by:

$$(2) \qquad \tilde{w} = z'\tilde{V} + \tilde{\epsilon}(F - \tilde{S})C$$

where:

$z$ = vector of fractional holdings of each stock and bond security;
$V$ = vector of future payoffs of securities, all translated into currency 1;
$C$ = forward contracts to convert currency 2 into currency 1;
$\tilde{S}$ = future spot rate of exchange;
$F$ = time-0 forward rate;
$\tilde{\epsilon}$ = the random fractional loss to the investor if the forward contract is defaulted on; $0 \leq \epsilon \leq 1$.

Taking into account the budget constraint:

$$(3) \qquad w_0 - c_0 = z'V_0,$$

where $V_0$ is the vector of time-0 market values of securities, one can optimize (1) after substitution of (2). The resulting optimality conditions are:

$$(4a) \qquad Gz + E[\tilde{\epsilon}(F - \tilde{S})\tilde{V}/\tilde{I}]C = E(\tilde{R}\tilde{V}/\tilde{I})/2 - (R_0 - 2w_0)V_0/2\alpha$$

$$(4b) \qquad E[\tilde{\epsilon}(F\text{-}\tilde{S})\tilde{V}'/\tilde{I}]z + E[\tilde{\epsilon}^2(F\text{-}\tilde{S})^2/\tilde{I}]C = E[\tilde{R}\tilde{\epsilon}(F\text{-}\tilde{S})/\tilde{I}]/2$$

[3] $\tilde{I} = (\tilde{p}_1'Q^{-1}\tilde{p}_1)/(p_o'Q^{-1}p_o)$, $\tilde{R} = \frac{1}{2}\tilde{p}_1'Q^{-1}q$, $R_o = \frac{1}{2}p_o'Q^{-1}q$ where $p_o$ and $\tilde{p}_1$ are the time-0 and time-1 vectors of prices expressed in currency 1.

where:

$$G = V_0 V_0'/\alpha + E(\tilde{V}\tilde{V}'/\tilde{I}).$$

The determinant of the linear system (4) is $|G|\Delta$ where:[4]

$$(5)\quad \Delta = E[\tilde{\epsilon}^2(F\text{-}\tilde{S})^2/\tilde{I}] - E[\tilde{\epsilon}(F\text{-}\tilde{S})\tilde{V}'/\tilde{I}]G^{-1}E[\tilde{\epsilon}(F\text{-}\tilde{S})\tilde{V}/\tilde{I}].$$

Assuming that no two sets of stock or bond securities are perfectly correlated ($|G|\neq 0$), two cases arise. If $\Delta=0$, which implies that forward contracts and some linear combination of stocks and bonds are perfect substitutes,[5] then $C$ is indeterminate. If, however, $\Delta>0$, then:

$$(6)\quad C = E[(\tilde{R} - 2\tilde{V}'z_0)\tilde{\epsilon}(F\text{-}\tilde{S})/\tilde{I}]/2\Delta$$

where $z_0$ is the value of $z$ obtainable from (4a) when $C=0$, and $(\tilde{R}-2V'z_0)/\tilde{I}$ can be interpreted as the investor's marginal utility at zero forward contracting.

## II. Analysis of the Demand for Forward Contracts

We now study the composition and the variations of the demand equation (6) under the assumption that there exists no value of $F$ for which $\Delta=0$. We shall refer to this as the case where there is no perfect arbitrage opportunity.

The demand (6) can be decomposed into the sum of two terms. The first one is:

$$(7)\quad C_s = E[\tilde{R}\tilde{\epsilon}(F\text{-}\tilde{S})/\tilde{I}]/2\Delta$$

and represents the demand for forward contracts which would exist if no alternative instruments (stocks or bonds) were available for investment ($z=0$); it is therefore essentially a demand which is motivated by the relative levels of the forward and future spot rates. In accordance with traditional forward-market theory, we call it the "speculative demand," although, in the language of financial theory, it does not constitute "speculation" (see Jack Hirshleifer) but simply an investment in currencies. The speculative demand is zero for:

$$(8)\quad F_s = E(\tilde{S}) + \frac{\operatorname{cov}(\tilde{S}, \tilde{R}\tilde{\epsilon}/\tilde{I})}{E(\tilde{R}\tilde{\epsilon}/\tilde{I})}$$

where it is increasing (Figure 1). The covariance of the future spot rate with future goods prices and the default risk moves the intercept of the speculative demand away from the expected spot rate, contrary to the *MT*s assumption.

The second term in (6):

$$(9)\quad C_h = -E[\tilde{\epsilon}(F\text{-}\tilde{S})\tilde{V}'/\tilde{I}]z_0/\Delta$$

is a component of demand connected with the individual's portfolio investment and could perhaps be called "hedging demand." Hedging here is tantamount to diversification which the investor undertakes to reduce his real risks. This label should, therefore, not be identified with the one used by Grubel, for instance. The purpose of this hedging demand is *not*, as it was in the traditional analysis, to prepare the ground for the riskless conversion of the bulk of the investor's foreign income into his home currency. Rather, by diversifying into forward contracts, the investor intends to reduce the variability of his future real income, wherever it may originate. We note also that the investment so hedged includes investment in bonds as well as stocks; we do not refer to a covered bond transaction per se as "arbitrage" but rather as a hedged investment in bonds.

We reserve the term arbitrage for a motive which appears in the denominator $\Delta$

[4] It is necessary that $\Delta\geq 0$ in order for the second order condition to be satisfied.

[5] One could prove that $\Delta = 0$ if and only if two conditions are fulfilled: (a) $\tilde{\epsilon}(F-\tilde{S})$ is equal to a linear combination of $\tilde{V}$ and (b) the same linear combination of $V_o$ is null. The latter condition holds for only one value of $F$, which we denote $F_p$. See Adler and Dumas.

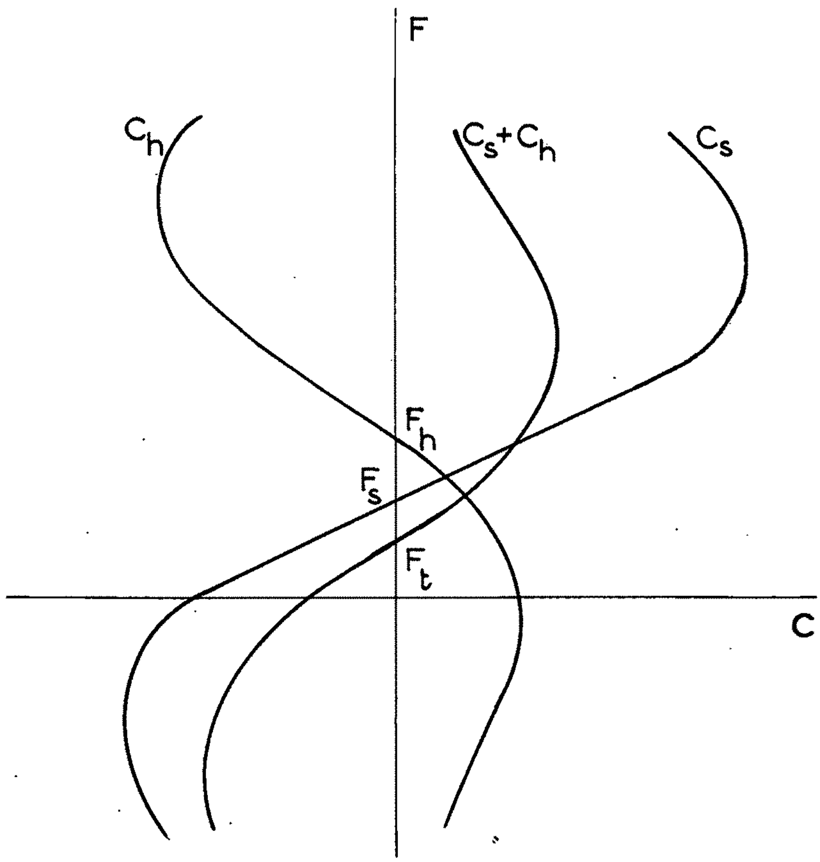

FIGURE 1. THE SPECULATIVE, HEDGING AND OVERALL DEMAND SCHEDULES WHEN THERE ARE NO PERFECT ARBITRAGE OPPORTUNITIES

of the demand. As the returns from forward contracts $\tilde{\epsilon}(F-\tilde{S})$ are progressively better approximated by a linear regression on the returns from stocks and bonds, $\Delta$ approaches zero for some value of $F$. In the neighborhood of that value, the investor takes advantage of the quasi arbitrage opportunity and the result is a magnification of his speculative and hedging demands.

Figure 1 makes two further points clear. The curvature of the $C_s$ curve seems to confirm traditional diagrammatic renditions of the speculation function. In the absence of perfect arbitrage opportunities the elasticity of the curve falls to zero at finite quantities of forward contracting. These curvature characteristics seem robust for well-behaved utility functions, other than the quadratic. But in those cases we have checked, it is impossible to decompose the total demand into the sum, $C_s$ and $C_h$, of two components. In all cases, however, the $C_s$ and $C_h$ functions cannot be observed separately.

We now consider briefly the case where there exist perfect arbitrage opportunities, i.e., where $\tilde{\epsilon}(F-\tilde{S})$ is equal to a linear combination of $V$, for some value $F_p$ of $F$. Then for $F=F_p$, if the same combination of $V_o$ is null, $\Delta(F_p)=0$ and $C$ becomes indeterminate. Furthermore $F_p$ is also a root of the numerator, so that for other values

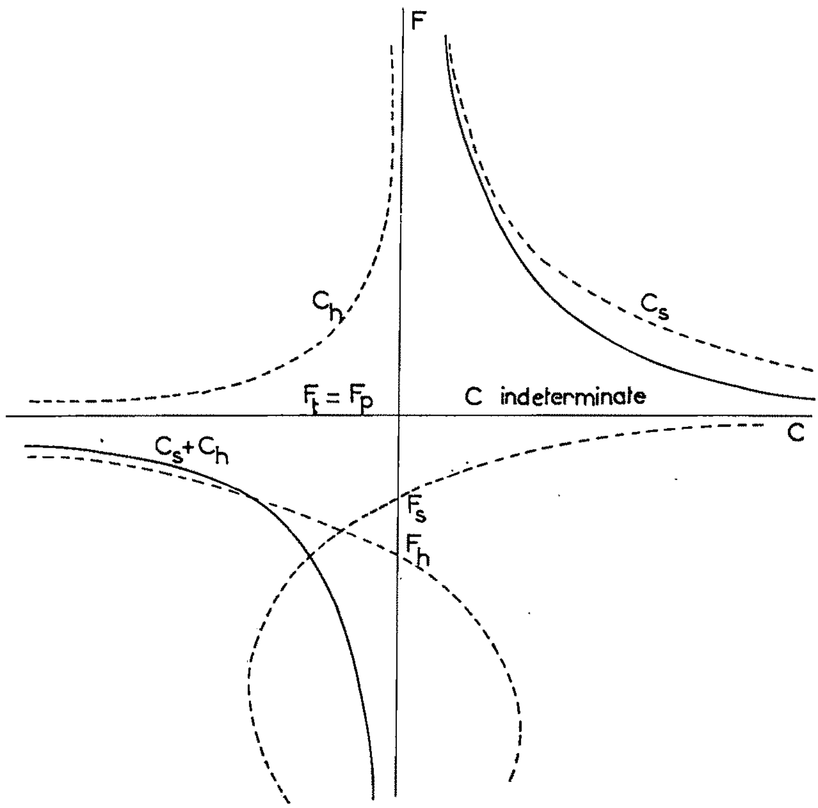

FIGURE 2. THE DEMAND SCHEDULE WHEN THERE EXIST PERFECT ARBITRAGE OPPORTUNITIES

of $F$, the demand reduces to a rectangular hyperbola (Figure 2).[6] The numerators and denominators of the speculative and hedging demands retain their original degrees, but infinite branches appear at $F=F_p$; this is an extreme illustration of the magnification effect of the arbitrage motive.

### III. The Equilibrium Forward Rate and the Predictions of the Modern Theory

As was mentioned in the introduction, the modern theory of forward exchange predicted that the equilibrium forward rate was always bracketed by the expected spot rate $E(\tilde{S})$ and the interest rate parity rate. To disprove this claim on the basis of the present model, we now consider the relationship between these three rates in the special case where the bonds are default free in both countries with interest rates denoted $r_1$ and $r_2$.

At equilibrium, the sum of all forward contracts is null: $\sum_k C_k = 0$, where $k$ subscripts represent the investors. Assuming that $\bar{I}$, $\bar{V}$, $\tilde{\epsilon}$ and $\tilde{S}$ are identical for all investors, we can apply this condition to (6) to get the equilibrium rate:

$$F = E(\tilde{S}) + \frac{\text{cov}\,(\tilde{S}, \tilde{M}\tilde{\epsilon})}{E(\tilde{M}\tilde{\epsilon})} \tag{12}$$

where $\tilde{M} = (\sum_k \tilde{R}_k - 2e'V)/\bar{I}$ is the inves-

[6] This hyperbola is somewhat of an oddity; it would not reflect rational behavior since, in the presence of a perfect arbitrage opportunity, the investor could instead reach infinite wealth by entering forward contracts in infinite amounts. The explanation is that, for large values of wealth and consumption, the quadratic approximation to the utility function (footnote 2) is no longer valid.

TABLE 1

| | | | cov $(\tilde{S}, \tilde{M})$ | |
|---|---|---|---|---|
| | | | $\leq 0$ | $\geq 0$ |
| cov $(\tilde{S}, \tilde{M}\tilde{\epsilon})$ | $\geq 0$ | $K \geq 0$ | $IRP \leq E(\tilde{S})$<br>$F \geq E(\tilde{S})$<br>$F \geq IRP$ | $IRP \geq E(\tilde{S})$<br>$F \geq E(\tilde{S})$<br>$F \geq IRP$ |
| | | $K \leq 0$ | Impossible | $IRP \geq E(\tilde{S})$<br>$F \geq E(\tilde{S})$<br>$F \leq IRP$ |
| | $\leq 0$ | $K \geq 0$ | $IRP \leq E(\tilde{S})$<br>$F \leq E(\tilde{S})$<br>$F \geq IRP$ | Impossible |
| | | $K \leq 0$ | $IRP \leq E(\tilde{S})$<br>$F \leq E(\tilde{S})$<br>$F \leq IRP$ | $IRP \geq E(\tilde{S})$<br>$F \leq E(\tilde{S})$<br>$F \leq IRP$ |

$$K = \frac{\text{cov}\,(\tilde{S}, \tilde{M}\tilde{\epsilon})}{E(\tilde{M}\tilde{\epsilon})} - \frac{\text{cov}\,(\tilde{S}, \tilde{M})}{E(\tilde{M})}$$

tors' aggregate marginal utility of wealth and $e = \sum_k z_{ok}$ is a vector containing for each security a one or a zero depending on whether this security's net supply is positive or null. In a similar fashion, one could derive the interest rate relationship from the optimality conditions (4):

$$\text{(13)} \qquad \frac{1 + r_1}{1 + r_2} = E(\tilde{S}) + \frac{\text{cov}\,(\tilde{S}, \tilde{M})}{E(\tilde{M})};$$

hence:

$$\text{(14)} \qquad F - \frac{1 + r_1}{1 + r_2} = \frac{\text{cov}\,(\tilde{S}, \tilde{M}\tilde{\epsilon})}{E(\tilde{M}\tilde{\epsilon})} - \frac{\text{cov}\,(\tilde{S}, \tilde{M})}{E(\tilde{M})}.$$

The default risk on forward contracts is, in this particular case, entirely responsible for the deviation from *IRP*. However, *contra* Aliber, if $\tilde{\epsilon}$ is independent of $\tilde{S}$ and $\tilde{M}$, the right-hand side of (14) is zero and *IRP* prevails even if $\tilde{\epsilon} < 1$. Of the six possible relations, outlined in Table 1, between $E(\tilde{S})$, $\tilde{F}$, $(1+r_1)/(1+r_2)$, only two, those emphasized by heavy outlines, correspond to the pattern predicted by the Modern Theory.

## IV. Conclusion

The main results of this paper have been summarized in the introduction. One policy implication, however, can be brought forth: under those conditions which make bonds and forward contracts perfect substitutes and which therefore also produce *IRP*, *it is impossible for the government successfully to affect the volume of short-term capital flows by intervening in the forward exchange market.* In this case, the forward exchange trading decisions are indeterminate for everyone and so, of course, is the equilibrium volume of forward contracting. The *MT* allows the speculative demand for foreign exchange, by intersecting the perfectly elastic arbitrage schedule, to determine the equilibrium volume of transactions and therefore implies that by "counter-speculation" the government can affect this volume along with the reverse arbitrage capital flows. But when forward

contracting is an arbitrary decision and forward contracts a redundant security, it is obviously impossible to specify or predict how much of them will be traded. Our theory bears this out.

APPLICATION OF OPTIMAL CONTROL TO PROBLEMS OF ECONOMIC STABILIZATION

# Control Methods for Macroeconomic Policy Analysis

*By* GREGORY C. CHOW*

## I. Why Optimal Stochastic Control?

The use of econometric models for the quantitative analysis of macroeconomic policy is now generally accepted. A great deal of research in the last several years has been devoted to the development and application of optimal stochastic control techniques in policy analysis. This development appears to be natural and necessary. Using an econometric model, one can make projections of the key economic variables in future periods given a set of proposed future values for the policy variables or instruments. One may then examine the nature of these projections in order to evaluate a policy proposal. This approach to policy analysis is deficient for two reasons.

First, the dynamic response of the economic variables to a particular course assigned to the policy variables is complicated and unpredictable. This makes the selection of policy by trial and error extremely inefficient. There is a need to specify a loss function of the key economic variables and to minimize its value with respect to the policy instruments. The specification of an objective or loss function and the derivation of a policy solution by optimization is an essential feature of optimal control. It is much more efficient than the method of trial and error. The objective function is also useful for the evaluation of other policy proposals than the optimum policies.

The second, and perhaps more important, reason is due to the uncertainty of economic projections. Given the proposed time paths for the policy variables, one cannot rely on an econometric model to make perfect predictions of the important economic variables. This uncertainty not only makes it difficult to evaluate a given policy path, but it makes the evaluation of such a path unrealistic and irrelevant.

The former difficulty can be resolved by stochastic simulations which incorporate the random elements in the econometric model in making projections; the means and variances of the future paths can then be calculated. Because of uncertainty in the economy, a policy maker often will not adhere to a fixed plan irrespective of future developments. Future decisions will be made on the basis of future observations of the economy. Hence, it is usually unrealistic and irrelevant to evaluate the consequences of a preassigned sequence of policy actions. A more realistic policy takes the form of a reaction function, or a feedback control equation; it is a rule to determine the future values of the policy variables according to future economic observations. By the technique of optimal stochastic control, the solution to a multiperiod planning problem under

* Economic Research Program, Princeton University. Financial support from the National Science Foundation is gratefully acknowledged. This paper was typed by Alice Furth.

uncertainty is given by a set of feedback control equations. The solution in feedback form is important from both the descriptive and the normative points of view.

We can therefore conclude that in policy analysis it is necessary to optimize, and optimization has to be performed in a stochastic setting to yield optimal feedback control equations. Deterministic control theory ignores uncertainty in the econometric model and yields a preassigned future path for the policy variables as a solution. This deterministic solution path, nevertheless, has one interesting characteristic. If the econometric model is linear with an additive random disturbance, if its parameters are known for certain, and if the objective is to minimize the expected value of a quadratic loss function for T periods, then according to a theorem due to Herbert A. Simon and Henri Thiel, the optimum solution for the first period is identical with that of the above deterministic path. This result is known as the first-period certainty equivalence principle. Imagine how this principle can be applied to evaluate the outcome of an optimal sequential plan for a stochastic control problem with twenty periods as the planning horizon. A twenty-period deterministic control problem is solved to obtain $x_1$, the optimum setting of the vector of policy variables for the first period. Given $x_1$, we generate $y_1$, the vector of endogenous variables in period 1, using the econometric model and a random drawing for the vector $u_1$ of random disturbances. Having generated $y_1$ stochastically, we have the initial condition to solve a nineteen-period deterministic control problem to obtain the optimal $x_2$ for the second period. We then generate $y_2$ from $x_2$ and a random drawing of the vector $u_2$ of random disturbances for the second period, using the econometric model. An eighteen-period deterministic control problem is then solved to obtain $x_3$, and so forth until $x_{20}$ and $y_{20}$ are obtained. All this will give one observation of a sequence of the $x$'s and the $y$'s for twenty periods. The process can be repeated $n$ times. Each observation provides a value for the loss function, and the expected loss can be estimated by averaging over the $n$ observations. This would be a laborious and costly procedure. By contrast, using the technique of stochastic control to be described in the next section, we derive a set of feedback control equations which determine the optimal values for the future policy variables in terms of the values of future economic observations. The minimum expected loss associated with the optimal policy can be calculated by a simple formula. Furthermore, the means, variances and covariances of the future paths of all economic variables can be obtained analytically without resort to stochastic simulations. They contain much useful information concerning the dynamic performance of the economy under the rules of optimal stochastic control.

## II. Techniques of Stochastic Control

Before presenting some important applications of stochastic control to the analysis of macroeconomic policy, I will survey briefly the available techniques. Of most importance is the derivation of the optimal feedback control equations and the associated expected welfare loss. Solutions are now available for linear as well as nonlinear econometric models, as described in Chow (1975, 1976a, 1976b). The techniques can also be classified according to the treatment of uncertainty. Beginning with the case of complete certainty where all model parameters are assumed to be known and all random disturbances are set equal to their mean value zero, one can first introduce random disturbances and secondly allow for uncer-

tainty in the model parameters. We will postpone till the end of this paper the treatment of a third kind of uncertainty, namely in the specification of the model itself. For the control of a linear model with a vector of random disturbances but known parameters, assuming a quadratic loss function, we can find the optimal solution as a set of linear feedback control equations. When uncertainty is introduced into the parameters of a linear model, and when either the parameters or the disturbances in a nonlinear model are treated as uncertain, the solutions available are only approximately optimal. Stochastic control theory is still useful for the calculation of the expected loss associated with the approximately optimal policies and the derivation of the important dynamic characteristics of the economy under control.

For expository purposes in this section, I will illustrate the solution to the optimal control of a linear system with unknown parameters using a quadratic loss function. The system is written as

$$(1) \quad y_t = A_t y_{t-1} + C_t x_t + b_t + u_t$$

where $y_t$ is a vector of endogenous variables at time t, $x_t$ is a vector of policy variables at time t, $b_t$ is a vector combining the effects of all exogenous variables not subject to control, the matrices $A_t$, $C_t$, and $b_t$ consist of unknown parameters whose probability distribution is assumed to be given, and $u_t$ is a vector of random disturbances having mean 0, covariance matrix $V$, and being serially uncorrelated. Endogenous variables and policy variables with higher order lags can be eliminated by defining new endogenous variables so as to retain the form (1) of a system of first order linear stochastic difference equations in which only the current control variables $x_t$ appear. We can include the policy variables in the vector $y_t$ so that $x_t$ need not be an argument of the loss function. After suitable transformations, the model (1) can also be used to deal with serially correlated random disturbances. These technical details are explained in Chow (1975). The loss function for a T period control problem is

$$(2) \quad W = \sum_{t=1}^{T} (y_t - a_t)' K_t (y_t - a_t)$$

where $a_t$ is a vector of targets for the variables $y_t$ and $K_t$ is a diagonal matrix giving the relative penalties for the squared derivations of various variables from their targets.

To ease the exposition without effecting the essential argument, let me assume that $a_t = 0$ and $b_t = 0$ for all t. The problem is to minimize the expected value of the loss function for T periods by choosing a strategy for $x_1, x_2, \ldots, x_T$. The control variables will be selected sequentially, the vector $x_t$ for each period being determined only after the up-to-date information is available. This information consists mainly of $y_{t-1}$ which includes the observations of all past endogenous variables and policy variables affecting the current endogenous variables at time t. Using the method of dynamic programming, we first solve the problem for the last period T by minimizing

$$\begin{aligned}(3) \quad V_T = E_{T-1}(y'_T K_T y_T) &= E_{T-1}(y'_T H_T y_T) \\ &= y'_{T-1}(E_{T-1} A'_T H_T A_T) y_{T-1} \\ &\quad + x'_T(E_{T-1} C'_T H_T C_T) x_T \\ &\quad + 2x'_T(E_{T-1} C'_T H_T A_T) y_{T-1} \\ &\quad + E_{T-1} u'_T H_T u_T\end{aligned}$$

where we have used (1) to substitute for $y_T$, taken mathematical expectation $E_{T-1}$ conditioned on the data available at the end of period T−1, assumed $a_t = 0$ and $b_t = 0$, and defined $K_T = H_T$ for future convenience. Minimizing (3) with respect to the vector $x_T$, one obtains the optimal feedback control equation for the last period,

$$(4)\quad \hat{x}_T = -(E_{T-1}C'_T H_T C_T)^{-1} \cdot (E_{T-1}C'_T H_T A_T) y_{T-1} = G_T y_{T-1}.$$

(Without the assumptions $a_t=0$ and $b_t=0$, the solution (4) would contain an intercept $g_T$.) The minimum expected loss for the last period associated with the optimum policy is obtained by substituting (4) for $x_T$ into (3):

$$(5)\quad \hat{V}_T = y'_{T-1}(EA'_T H_T A_T) y_{T-1} - y'_{T-1}(EA'_T H_T C_T)(EC'_T H_T C_T)^{-1} \cdot (EC'_T H_T A_T) y_{T-1} + Eu'_T H_T u_T.$$

To solve the problem for the last two periods, we apply the principle of optimality in dynamic programming to minimize with respect to $x_{T-1}$ the expression

$$(6)\quad V_{T-1} = E_{T-2}(y'_{T-1}K_{T-1}y_{T-1} + \hat{V}_T).$$

The rationale for (6) is that whatever $x_{T-1}$ is chosen, which will affect the outcome $y_{T-1}$, we shall choose the optimum policy $\hat{x}_T$ according to the feedback control equation (4) to yield the minimum expected loss $\hat{V}_T$. The optimal policy for both periods can thus be obtained by minimizing (6) with respect to $x_{T-1}$, given that $x_T$ will be optimally chosen. Substituting (5) into (6) and letting

$$(7)\quad H_{T-1} = K_{T-1} + (EA'_T H_T A_T) - (EA'_T H_T C_T)(EC'_T H_T C_T)^{-1} \cdot (EC'_T H_T A_T),$$

we rewrite (6) as

$$(8)\quad V_{T-1} = E_{T-2}(y'_{T-1}H_{T-1}y_{T-1}) + Eu'_T H_T u_T.$$

Note that, except for a constant, (8) has the same form as (3) with the subscript T−1 replacing T. Therefore, by the same argument, the optimum $\hat{x}_{T-1}$ will be given by equation (4) with T−1 replacing T; the minimum total expected loss $\hat{V}_{T-1}$ for periods T−1 *and* T will then be found as in (5). The process continues until $\hat{x}_1$ and $\hat{V}_1$ are obtained. $\hat{V}_1$ is the minimum total expected loss for all T periods. It can be computed by equation (5) with the subscript 1 replacing T, where $H_1$ is obtained by solving the difference equation (7) for $H_t$ backward in time. In these calculations, the approximation has been made that all expectations involving the unknown parameters $A_t$ and $C_t$ in the future are based only on data available at the beginning of period 1. Otherwise, the derivation will be more complicated because the expectations in equation (4) are functions of the data $y_{T-1}$, $y_{T-2}$, etc. We have just demonstrated how the optimal feedback control policies and the associated expected loss for all periods can be obtained analytically. The above derivations can be extended to deal with nonlinear econometric models with unknown parameters, as described in Chow (1976a).

## III. Applications to Macroeconomic Policy Analysis

Having elaborated on the two major concepts in optimal stochastic control, namely, the minimum expected loss and the feedback control equations, we will illustrate their applications to the analysis and formulation of macroeconomic policies.

Using the minimum expected loss, one can compare various policy proposals as described by different feedback control equations or reaction functions. The candidates for comparison include such control equations as the ones prescribing the policy variables to grow at constant percentage rates, reaction functions estimated from time series data as descriptive of the historical decision making process, and policies which rely exclusively on a subset of active instruments while keeping the re-

maining passive instruments to grow at some constant rates in order to study the relative effectiveness of fiscal and monetary policies. The minimization of expected loss can also be used to measure the trade-off possibilities for inflation and unemployment implicit in an econometric model. Without using the techniques of optimal control, one can experiment with different policies using an econometric model and observe the resulting rates of inflation and unemployment, hoping to trace out the trade-off possibilities. However, this approach is defective because the inflation-unemployment combinations generated by the experiments may not be the best possible. By varying systematically the parameters of the loss function in an optimal control formulation, one can trace out the best combinations of inflation and unemployment that can be achieved according to a given econometric model. Finally, the minimum expected loss can be used to measure the value of information and the costs of delays. The amount of information can be described by the variances of the estimated parameters and of observation errors; the variance-covariance structure, when incorporated into the analysis, will affect the minimum expected loss. Delays in information and in carrying out the decisions can also be modeled in the framework of stochastic control and the resulting minimum expected losses can be compared, Chow (1975, pp. 182ff, 202).

Secondly, the feedback control equations are extremely useful for policy analysis. When combined with the other econometric equations, they become a part of a stochastic model whose dynamic properties can be studied by analytical techniques. For the analysis of any policy, optimal or not, one would like to ascertain the means, variances and covariances of the important time series generated by an econometric model given the policy. Spectral properties of these time series can also be deduced analytically, as described in Chow (1975). Since automatic stabilizers can be specified by feedback equations, one can study the dynamic properties of an economy subject to different stabilization schemes. One can even optimize with respect to the parameters in the automatic stabilization schemes by the techniques of stochastic control for nonlinear systems in order to find a good scheme. Various dynamic policy multipliers, including the impact, delayed, interim, and long-run multipliers, can be calculated from a nonlinear econometric model after appropriate linearizations; they are by-products of the optimal control calculations for nonlinear models which I have proposed. The tools of stochastic control can also be used to compare econometric models, in terms of the optimal feedback control equations which they imply, of the degrees of stability under the optimal stabilization policies, and of the sensitivities of the control solution to changes in the parameters of the models or the loss functions. In short, the techniques of stochastic control can be used to deduce the policy implications of econometric models systematically and efficiently.

Let me conclude this paper by a proposal to deal with the third kind of uncertainty in econometric models, the uncertainty associated with the specification of the model itself. The decision maker, when faced with a serious choice between two or three competing models, is advised to calculate the optimal policies based on these models, and to examine how these and other proposed policies perform under the assumptions of the different models. A payoff matrix should be used, with different columns corresponding to the different models and different rows corresponding to the different policies to be examined, each element in the matrix being the expected loss asso-

ciated with a combination of model and policy. Such an analysis might uncover policies that are superior to the inactive policies for all models. This finding would be extremely important. If no such active policies could be uncovered which dominate the inactive policies for all the seriously competing models, much useful information would have been obtained on the degrees of differences in these econometric models, the needed areas of econometric research for macroeconomic decision making, and the empirical basis for current policy recommendations or decisions. A Bayesian would assign probabilities to the competing econometric models and choose that strategy which minimizes the expected value of the entry in the above payoff matrix. To any rational economic decision maker, Bayesian or not, the techniques of optimal stochastic control are important not because existing econometric models are nearly perfect but because how imperfect the models are, what imperfections matter for policy analysis, and what areas require most research can be ascertained efficiently only by the use of these techniques.

# Some Stabilization Problems of 1971-75, with an Application of Optimal Control Algorithms

*By* ALBERT ANDO AND CARL PALASH*

This paper attempts to analyze the relative contribution of various exogenous factors and of monetary and fiscal policies to the inflation and recession of 1973–75, using the MIT-PENN-SSRC (*MPS*) model and an optimal control algorithm applied to this model. Our conclusion is that while the rate of inflation in this period could not have been reduced much by aggregate monetary and fiscal policies, it was possible to have maintained a much lower rate of unemployment without worsening the rate of inflation by appropriate monetary and fiscal policies. We also suggest a possible reason why policy makers may have considered the very restrictive policies of 1974 appropriate at that time.

When the basic cause of inflation is excess final demand, a necessary ingredient of any policy to control inflation is some measure to reduce final demand. But, to the extent that the inflation is caused by factors other than excess demand, any policy measure to reduce final demand is unlikely to be effective in controlling inflation. In order to make this proposition more precise and quantitative, we need to identify the relative contribution of several factors to the inflation of 1974–75 period.

When the *MPS* model, which is used for our analysis here, or any other fairly large scale, economy-wide econometric model is simulated with residuals of all equations fed back into their respective equations, the model reproduces the historical path of all endogenous variables identically. In such a simulation, all exogenous shocks to the economy, such as the sudden increases of the price of oil, are incorporated either in values of exogenous variables or in values of residuals. Taking advantage of this feature, we can resimulate the model beginning in the middle of the 1960's with appropriate changes in monetary and fiscal policies so that the unemployment rate is always kept above 5 percent with the average of around 7 percent throughout the later 1960's and 1970's. Under such a policy, we enter the 1970's with the rate of inflation close to zero, and we can interpret the rate of inflation generated in such a simulation for 1974–75 period as that due to factors other than excess demand. In terms of the deflator of domestic, private, nonfarm product, the rate of inflation averages 8.5 percent in 1974, with the maximum of 10 percent reached in the second quarter. The actual, historical rate of inflation in terms of the same index is 12.8 percent for 1974. These figures suggest that at least two-thirds of the inflation in 1974

This is a summary of a longer paper on the same subject which is scheduled to appear in *Frontiers of Quantitative Economics,* Vol. III, edited by Michael Intriligator, North-Holland Publishing Co., Amsterdam 1976, where data and analytical results that support statements made here are presented. Ando's contribution to this paper has been partially supported by the National Science Foundation under grant GS-32383X. Palash's participation in the preparation of this paper does not imply that views expressed here reflect those of the Federal Reserve Bank of New York or its staff.

was due to factors other than excess final demands. Further detailed analysis reveals that, in addition to such factors as the sudden increase of the oil price, the rise in food prices, and the devaluation of the dollar, two major contributors to inflation were the loss of productivity per manhour and quite significant increases in the markup in final good prices over the minimized average cost.

Against this background, both exogenous shocks given to the *U.S.* economy and monetary and fiscal policy postures adopted by the federal government were unusually deflationary. Exogenous increases of raw materials prices have basically the same effect on the economy as imposition of additional excise taxes, and the order of magnitude was extraordinarily large. And because the decline in final demand and output was accompanied by increases in prices, the standard automatic stabilizers worked in a perverse manner, leading to the full employment surplus in the federal budget of some $20 to $30 billion in the fourth quarter of 1974. On the monetary side, the short-term money market rates of interest were raised to unprecedented levels during the spring and summer of 1974. Although the actual rate of inflation was very high, there is good reason to believe that the expected rate of change of prices was much less than the actual rate of inflation. Furthermore, there is every indication that the market-required risk premium in equity rose very substantially during this period. The net result was that the long term required rate of return appears to have risen rapidly in 1974. Thus, the severe recession of 1974–75 can be fully explained by exogenous shocks and monetary and fiscal policy actions of this period. Moreover, there is some indication that the severity and rapidity of the decline in final demand, the reasons for which were not fully comprehended by the government policy makers and businessmen alike, contributed substantially to the loss of productivity per manhour and to the increased markup, and hence to inflation.

Once these points are clarified, we can see why a much less restrictive set of monetary and fiscal policies in 1974 would probably have resulted in much less severe loss of output without noticeable worsening of inflation. Using the *MPS* model, we show that this conclusion is indeed highly plausible, and the rate of unemployment in 1974–75 period could have been contained at no more than 6.5 percent or so without any worsening of inflation.

The monetary and fiscal authorities in this period clearly did not explicitly aim at creating recession, but they concentrated their attention on inflation and attempted to reduce the rate of inflation by restricting final demands. Since the inflation was not primarily caused by excess final demand, this policy design resulted in a sharp reduction of demand without much moderation of inflation. This point is most clearly brought out by an application of optimal control techniques to the analysis of policies followed in this period.

In applying optimal control techniques to the problem at hand, the most delicate problem is the specification of the objective function to be maximized. The common approach is to use a function whose first and second derivatives with respect to target variables (with appropriate signs) are all negative. This procedure works more or less satisfactorily under normal conditons. However, when one or more target variables cannot be reduced below a certain level due to external factors, the maximization of such an objective function subject to an econometric model without explicit allowance for this constraint produces a set of policies that are "unreasonable." This is because, in these circumstances, the negative second

derivative of the objective function with respect to the constrained target variable makes the implicit weight given to this variable much greater than intended.

We have shown that the maximization of a seemingly reasonable objective function without explicit allowance for the minimum inflation rate due to external factors in 1973–75 period does indeed generate a set of policies very similar to the ones actually followed. When the implicit relative weights attached to inflation and unemployment in the objective function generating this result are calculated, the weight for inflation turns out to be so high that the weight given to unemployment is almost insignificant. This situation can be easily remedied once we allow for the inflation rate that is due to external factors in the objective function.

The problem of unintentionally assigning "unreasonable" weights to target variables as a result of incorrect analysis of economic conditions facing policy makers was handled explicitly in this paper using an optimal control framework. It is quite plausible that, in formulating monetary and fiscal policies in much less formal manner, policy makers can nevertheless be trapped into a similar situation, leading to an imposition of inappropriate set of policies on the economy. We suggest that this is what has happened in 1973–75 period.

# On the Use of Feedback Control in the Design of Aggregate Monetary Policy

*By* J. H. Kalchbrenner and P. A. Tinsley*

## I. A Feedback Strategy for Monetary Policy

Periodic feedback revision in policy plans to incorporate recent measurements of economic activity is perhaps the minimal strategy response to uncertainty. This paper illustrates an evolution of feedback revisions in monetary policy by an optimal control exercise with the MIT-PENN-SSRC (*MPS*) quarterly model over the turbulent eight-quarter interval beginning in mid-1973. The purpose of the exercise is to trace the impact of measured historical dislocations of the economy on the *ex ante* expectations of a feedback strategy, and contrast the result with two alternative strategies: an open-loop strategy without feedbacking, and the optimal "prescience" strategy based on perfect foresight.

The design of the feedback exercise is to revise *ex ante* monetary policy at six-month intervals: t=1973–III, 1974–I, 1974–III, and 1975–I. At the beginning of each recontract quarter, the hypothesized planners select an eight-quarter path for nonborrowed reserves that minimizes the expected loss for the next eight quarters conditioned on their current information set $E\{L_t|t-1\}$.

Policy loss for this rolling horizon procedure was represented by an eight-quarter sum of asymmetric components

$$(1)\quad L_t = \sum_{j=t}^{t+7} [2(U_j > 4.8)^2 + (G_j^p > 2.5)^2 + 5(|\Delta R_j| > 1.5)^2 + 10^{-4}(M_1 - M_1^*)_j^2],$$

where the first term penalizes unemployment exceeding an approximation of the "natural rate" of the *MPS* quarterly model (and zero otherwise); similarly, the second term is the square of the annual rate of change in the implicit deflator of private business output that exceeds 2.5; the third term inflicts a sizeable penalty on quarterly swings in the 90-day Treasury bill rate that exceed 150 basis points; and the last term imposes a mild penalty on deviations from the 5.1 percent growth path in $M_1$ that is approximately consistent with the long-term price objective in (1).

To avoid overstating the amount of information that was historically available at each recontract quarter, the hypothetical planners were provided with *ex ante* forecasts of 17 exogenous variables and selected "add factor" forecasts of the model residuals (i.e., the random disturbances of the structural equations) that were based on historical assumptions by the *FRB* model group in the quarter prior

* Adviser and Chief (Special Studies), Division of Research and Statistics, Federal Reserve Board. We are indebted to L. Hanson, A. Havenner, and especially J. Berry for superb programming. We are also grateful to J. Enzler for discussion of historical forecasting procedures. An introduction to control techniques by analogy to statistical estimation and a more detailed analysis of Federal Reserve Board (*FRB*) staff procedures from the perspective of control theory can be found in Kalchbrenner and Tinsley (1975). The views expressed herein are solely those of the authors and do not necessarily represent the views of the Board of Governors of the Federal Reserve System.

TABLE 1—EVOLUTION OF FEEDBACK FORECASTS AND THE IMPACT OF HISTORICAL DISTURBANCES

to the relevant recontract date. The selected exogenous variables include conditional forecasts of federal expenditures and tax rates in addition to projections of the price deflators of exports and imports. The set of implicit add factors was constructed by adjusting selected intercepts of the structural model until the forecasts of unemployment $U$ and inflation $G^p$ conditioned on both the *ex ante* exogenous variable projections and a given $M_1$ path coincided with the historical forecasts associated with that $M_1$ path. In all cases, the projections were adjusted for subsequent revisions in the data.

Although the aim of this exercise is to assess the value of a feedback strategy with a policy model in a realistic information con-

text, it is perhaps inevitable that the "optimal" feedback response will be compared with historical monetary policy. There are several differences in procedure that make a strict comparison invalid. First, the control instrument in the feedback exercise is nonborrowed reserves. Second, the information sets were based on historical files generated as staff background material and do not correspond to actual briefing material that is heavily modified by information from judgmental data banks. Third, the feedback exercise recontracts every six months whereas historical monetary policy is formally reassessed at monthly intervals. Fourth, the effective loss function and planning horizon of the planners is not known. Fifth, the implicit assertion that the exogenous variables and historical disturbances are independent of the monetary policy control settings is a debatable assumption. Finally, to preclude discussion of current policy, the *ex ante* feedback plans for quarters subsequent to 1975–II are not shown.

A portion of the results of the feedback exercise is listed in Table 1. The first four columns depict the evolution of *ex ante* expectations concerning the unemployment rate $U$ and the rate of growth in the price level $G^p$ and money $G^m$. The first column, for example, lists the forecasts that are conditioned on both the 73–III information set and the nonborrowed reserves path that minimized the eight-quarter loss function (1) initialized in 1973–III. The quarterly model was then simulated for two quarters along the "optimal" nonborrowed reserves path where the *ex ante* information set is replaced by the historical exogenous variables and stochastic disturbances. The results of this two-quarter simulation are listed in the *ex post* feedback column of Table 1. These simulation results are then the initial conditions for the next optimization and simulation cycle. This eight-quarter optimization and two-quarter simulation cycle is repeated for each of the three remaining recontract periods.

For rough comparison, the *ex post* portion of Table 1 also lists (a) a *pseudo-historical* simulation where nonborrowed reserves was set on its historical path, and (b) a *prescience* solution that is the result of minimizing a 14-quarter horizon where the historical exogenous variables and disturbances were known for the first eight quarters and the projections for the remaining six quarters were conditioned on the information set of 1975–I.

Table 1 indicates the difficulties in this period of obtaining accurate medium-run forecasts of the arguments of the policy loss function and the apparent insensitivity of the feedback strategy to measurement of large forecast errors. If we (somewhat imprudently) characterize the monetary policy intentions of the planners by the *ex ante* $M_1$ projection rates, there is a modest initial response to a sequence of

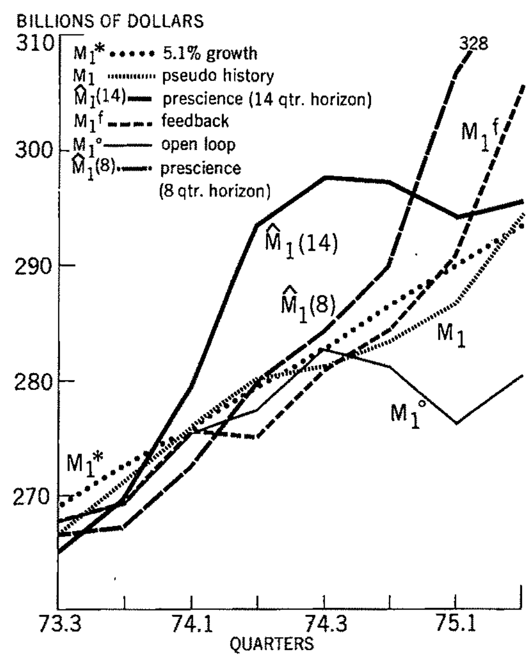

FIGURE 1: $M_1$ TRAJECTORIES FOR ALTERNATIVE STRATEGIES

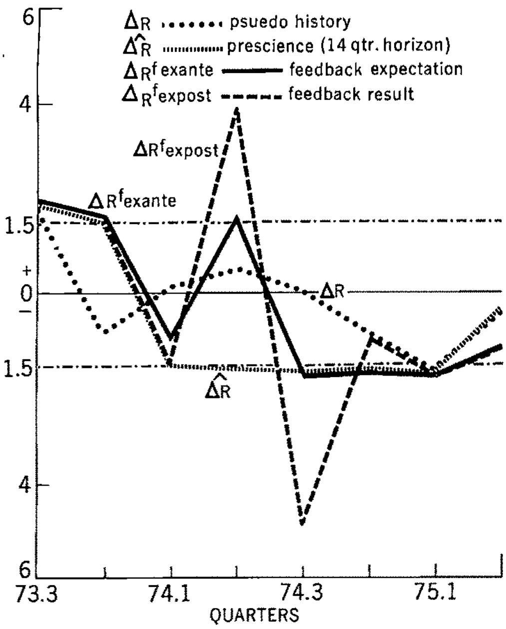

FIGURE 2: BILL RATE CHANGES PRODUCED BY ALTERNATIVE STRATEGIES

severe misses in the conditional forecasts of inflation. By the 74–III plan, it is evident that the rise in unemployment projected for the first half of 1975 is more severe than previously expected; however, *ex ante* planned expansion of $M_1$ in the fourth quarter is thwarted (compare *ex ante* and *ex post* $M_1$ growth in 74–IV). A pronounced departure in effective $M_1$ growth from the open loop plan (the 73–III column) is not accomplished until the first half of 1975.

Hindsight is suggestive but ultimately frustrating. As shown in Figure 1, the optimal prescience solution for $M_1$ (based on a 14-quarter horizon) is an interesting contrast to both the feedback $M_1^f$ and historical $M_1$ paths. The eight-quarter growth rate of the prescience solution is approximately equal to the growth of historical $M_1$ (and of the long-term desired path $M_1^*$, for that matter) but most of the expansion is dumped into the first half of 1974. The result of this growth rate pattern is a substantial easing of the unemployment rate in the last half of the period at the cost of a moderate rise in the rate of change of the implicit deflator.

The feedback strategy hits the accelerator hard about four quarters later than the prescience response. This exaggerated policy response is fairly typical of control solutions that assign all uncertainty to the stochastic disturbances of the final form equations. (See discussion in Kalchbrenner and Tinsley.) Whereas the amplitude of the feedback response would probably be moderated by allocating at least a portion of the uncertainty to the "slope" coefficients of the final form model, it is not obvious that more frequent filtering would substantially advance the timing of the feedback response.

The prescience solution based on an eight-quarter horizon $\hat{M}_1(8)$ is thrown in for contrast with $\hat{M}_1(14)$ to illustrate the impact of a short planning horizon. The relative oscillation of $\hat{M}_1(8)$ is an attempt to play off the differential policy response lags in inflation and unemployment against the short-horizon assumption that the world expires at the end of 1977–II.

To complete the record of state performance, the Treasury bill rate swings produced by alternative strategies are sketched in Figure 2. Note that interest rate smoothing was a binding constraint on the effective feedback response (e.g., the 74–III *ex ante* plan). The discrepancy between the *ex ante* expectations and *ex post* results of the feedback strategy for the bill rate and $M_1$ reflects the decision to stick to the preselected nonborrowed reserves path for six-month intervals; if deemed desirable, the *ex post* swings could be attenuated by more frequent feedbacking.

## II. A Brief Post-Mortem

Since, as a general rule, certainty equivalence strategies tend to be unusually sensitive to initial condition displacements, the cautious initial response of the feed-

back strategy to large perturbations indicates the difficulty in efficiently filtering current measurements.

1. *The crowd consolation.* As indicated in Table 2, our hypothetical policy makers were not alone in underestimating the severity of the dislocations of economic activity. Neither the sequence of extravagant inflation rates nor the subsequent jump in unemployment were anticipated with any reasonable lead time by model or judgmental forecasters. In the six quarters prior to 1975, historical monetary policy is not inconsistent with intermittent feedbacking on the effective information sets that were historically available.

2. *The phenomenological phumble.* As might be expected, an untuned model has considerable difficulty in processing stochastic information from unfamiliar sources. Information on the considerable boost in the price of imports and raw materials and dismantling of price controls literally had no place to go in traditional econometric models. (A partial list of structural modifications was suggested in the timely paper by James Pierce and Jared Enzler.) The procedure of simply adjusting structural equation intercepts is not likely to provide efficient filters of perturbations from unexpected sources.

3. *Add factor strategies.* Traditionally, add factor adjustments to model intercepts are intended as corrections to the conditional mean projections of future stochastic disturbances to reflect recent information from model or judgmental data banks. This mean correction procedure is consistent with a certainty equivalence strategy for quadratic loss functions but is inappropriate for asymmetric loss functions such as (1).

It can be shown that an approximation to optimal instrument settings for a simple asymmetric loss function can be obtained by the conventional deterministic solution after the intercepts of the underlying model are adjusted by "add factors" that are proportional to the standard deviations of the model disturbances. Normally,

TABLE 3—REDUCTION OF ONE PERIOD FORECAST ERRORS BY FILTERING CONTEMPORANEOUS INDICATOR ERRORS

| State Variable | Relative Forecast Error Range[a] | Variance Reduction (%) 14 Indicators | Variance Reduction (%) $M_1$ Components |

[b] Constant (1958) dollars.

this strategy adjustment is apt to be of small consequence, but in a period such as 1974 the posterior variance of selected disturbances should be set significantly higher than the estimated variances due to the wider dispersion of prior uncertainty.

4. *A case for monthly filtering.* Since relatively firm estimates of performance in a given quarter are not available until about the middle of the subsequent quarter, in practice there is considerable emphasis on diagnostic examinations of monthly and even weekly entrails to give the planners more elbowroom in the design of the feedback strategy. Indeed, one justification for the prominant role of "judgmental" forecasts in staff briefings is their consideration of weekly and monthly series outside the quarterly model data bank.

An outside indication of the return to massaging intermediate indicators is illustrated in Table 3. The procedure was to determine the potential reduction in the variance of the one-period forecast errors of six candidate state variables, say $e_y$, if one had been able to accurately measure the contemporaneous (quarterly) forecast errors in certain intermediate indicators, say $e_z$. (The significant problem of measurement error is ignored here but see William Conrad.) Since the quarterly model equations are coupled, the forecast error of even a single indicator is potentially a linear combination of all 69 stochastic disturbances in the *MPS* model.

A simple filter was used to "blow up" the measured forecast errors of the indicators $e_z$ into estimates of the disturbances of the structural equations $\hat{\epsilon}$, which were then weighted to form estimates of the forecast errors of the "unobserved" states $\hat{e}_y$.

$$(2) \qquad \hat{e}_y = G_{y\epsilon}\Sigma G'_{z\epsilon}\left[G_{z\epsilon}\Sigma G'_{z\epsilon}\right]^{-1}e_z, \qquad \Sigma = E\{\epsilon\epsilon'\},$$

where $G_{z\epsilon}$ and $G_{y\epsilon}$ are the reduced form multipliers of the disturbances for the indicator and state variables, respectivel.y The variance matrix $\Sigma$ was constructed from a sample of model disturbances for the nine years preceding the feedback interval.

Two sets of indicators were used. The first consisted of 14 variables that can be measured monthly ranging from personal income, manhours and the value of common stock prices to interest rates, components of $M_2$, commercial loans and free reserves. The alternative indicator set consisted only of currency and demand deposits. As indicated in Table 3, $M_1$ alone is not a particularly good indicator of unexpected movements in potential arguments of a policy loss function. It pays to "look at everything" in the context of a well-specified model structure. (See discussion of filtering and references in Kalchbrenner and Tinsley and John H. Kareken, Thomas Muench, and Neil Wallace).

Since variance reduction is only an indicator of average improvement, the bottom of Table 3 indicates how filtering on

the 14 indicator set might have improved the forecasts of price inflation over the feedback period.

We also examined feedback corrections based only on measurement of the forecast errors of the indicator sets. Preliminary results suggest (a) linear approximations of feedback correction rules (i.e., without iterative improvement) can be misleading in the context of a nonlinear model, (b) the effective importance of any given indicator depends on the specification of the loss function, and (c) for the loss function (1), the variance of feedback corrections was dominated by measurements of the forecast errors in free reserves, the bill rate, and the components of $M_2$.

### III. Future Directions

Control theory is neither an autonomic black box nor a miracle cure. Although the returns to filtering are promising, the limited performance of simple feedbacking with historical information sets is a sobering incentive to more creative exploitation of theoretical control techniques.

This paper reports on one aspect of a sequence of control projects in progress at the Federal Reserve. Projects at the Board include (a) the sensitivity of strategies to specification of the policy loss function, (b) modification of the quarterly model to accommodate "rational" expectations, (c) linking of quarterly, monthly and weekly models to efficiently filter current measurements and extract more frequent control settings, and (c) the construction and use of policy multiplier sequences as stochastic processes. (See discussion and references in Kalchbrenner and Tinsley.)

# DISCUSSION

HENRY C. WALLICH, Board of Governors of the Federal Reserve System: The use of optimal control techniques in planning for economic stabilization is approaching the policy stage. At the present time, as the papers before us show, the principal application of these techniques has been the examination of models and of past policies. Its use for effective policy advice still seems some distance away. But initial efforts to build an optimal control approach into Federal Reserve policymaking are underway. I believe that there is potential for progress at both the technical and the policy levels. It is important, therefore, for the producers and the potential users of this technique to become better acquainted. Model builders and policy makers must explore one another's needs and capabilities.

Policy makers, I believe, regard their role as somewhat more modest than that with which the terminology of the loss function sometimes endows them. The Federal Reserve, to be specific, is responsible for only one phase of the nation's economic policy—the handling of monetary policy. The overall objectives, moreover, are given by the Employment Act. Most of the economic policies that influence the rate of growth, employment, and the degree of price stability, are handled elsewhere in the government. Particularly when several objectives are involved, which obviously cannot all be attained with one instrument, it seems somewhat presumptuous to state one's preferences in the form of "targets."

The monetary policy official naturally has ideas also about desirable fiscal policy, and about many other policies that influence economic development. Only in the very short run can he make fairly firm assumptions as to what these policies will be. For the longer run, a not unreasonable attitude for him may be to think of monetary policy as helping to create the environment in which other public policies, as well as decisions made in the private sector, will become effective. Any given monetary policy may be consistent with alternative combinations of growth, unemployment, and inflation. The monetary policymaker will adjust his action to what he sees happening in these other spheres. But he should not overestimate his ability to influence the outcome.

The time horizon over which target values are to be set likewise presents difficult problems. One may believe that a lower rate of economic expansion in the immediate future will lead to more sustainable growth and lower ultimate unemployment and inflation than would a more aggressive policy. But unless such preferences are built into a loss function, and a long time horizon is allowed for, rather extreme policy proposals may follow from optimal control techniques applied to econometric models with long lag structures, as some of the papers at this meeting indicate.

The policy maker may also be troubled by an appearance of misplaced concreteness. He may be accustomed to thinking in directional terms—up or down—or in terms of rates of change—faster or slower. He may want to reserve judgment as to precise targets for unemployment and inflation until the economy is a little closer to what he might consider optimal. And if in addition he were asked whether he has a quadratic loss function, i.e., whether he is indifferent to an equal degree of over- and undershooting of his targets, he might be tempted to think the whole thing a spherical nuisance, i.e., a nuisance from every angle.

Monetary policy in the United States, moreover, is made by a group, the Federal Open Market Committee. The loss functions of all its members are unlikely to be identical. Perhaps one could think of a consensus loss function, or at least of one that would be Pareto optimal as between two disagreeing groups. But as a practical matter, it is probably easier for such a group to arrive at agreement on something on which they are compelled to take immediate action such as bank reserves, or the money supply, or the Federal funds rate, than about desirable conditions in the economy over which they have no immediate control. This leads me to my next topic, the role of intermediate targets.

*Intermediate Targets.* In an optimal control framework, it is argued, there is no need for

intermediate targets. It is the ultimate goals that go into the loss function. The pursuit of these ultimate targets by means of intermediate targets such as money supply or interest rates, it is argued, is in theory suboptimal. Their function is to serve as information variables from which insights into developments in the real sector can be gathered. The central bank should look at them as it should look at other readily observable data—everything should be looked at as a source of information about real developments that are not directly or not frequently observable.

This line of argument is in conflict with some of the main developments in monetary policy making in the United States during the last 10 or 15 years. There was a time when the Federal Reserve indeed did "look at everything." It was not a technique lending itself to much precision, and the development of intermediate targets was generally regarded as a step forward.

The advantages of intermediate targets have often been described as those of better observability and better control. I regard particularly the latter as significant. Moving directly from money market conditions or bank reserves, which the central bank controls, to the ultimate targets of growth, employment and price stability conveys very little of a sense of the quantitative impact of monetary policy action. At best, one can have a sense of the direction of policy, and even there, as we have learned, mistakes are possible if the central bank does not distinguish between endogenous and exogenous movements in its policy variables. This uncertainty is enhanced by long lags of policy action. By focusing on the money supply or on interest rates, a better intuitive sense of the thrust of policy is likely to be achieved. The sense of having some protection against the extreme kind of error that might manifest itself by extreme values of these variables, can be helpful.

Policy makers may be reluctant to surrender this means of obtaining some direct feel for the economic meaning of their actions and to replace it by a system that tells them to move some variable like unborrowed reserves, or the Federal funds rate, perhaps drastically, in order to achieve some particular results in the real sector. It might come close to flying with an automatic pilot. Manual control, I believe, would instill greater confidence.

Concern over possibly extreme values of policy variables is likely to be another obstacle to the greater use of optimal control that will have to be dealt with. The experience of the postwar period seems to show that extreme settings of policy variables, even for relatively short periods, can be destabilizing. Frequent variation in instrument settings likewise may add to instability. Given the lags and the uncertainties, moderate instrument settings and a degree of steadiness seems preferable most of the time, quite aside from possible side effects of wide policy gyrations on the functioning of financial markets. Policy makers who do have such preferences for moderation and steadiness can, of course, put them into their loss function, as the paper by Kalchbrenner and Tinsley does. But that is only partial protection, unless the penalties assigned to wide deviations in the paths of instrument variables are very high and hence perhaps unreasonable. Moreover, one may remain suspicious about the properties of a feedback process that needs to be disciplined in this artificial way.

*Models.* The policy evaluation—or advice—derived from an optimal control system presumably is no better than the model through which the feedback flows. Policy makers are likely to be interested in several aspects.

First, while models have reached a certain degree of proficiency in short-run predictions under ordinary circumstances, and in that sense agree with each other, there nevertheless seem to be important differences. Policy multipliers seem to vary importantly among models. Ever within particular models, these multipliers seem to be sensitive to small changes in the specification of particular equations, or to the choice among alternative equations of seemingly equal theoretical and empirical plausibility. Chow's paper suggests a minimax strategy, choosing among the models on the basis of which minimizes the worst case. That procedure would provide some insurance, but otherwise seems to adopt

a rather pessimistic slant. Alternative procedures might be to examine models for robustness of their policy advice under varying assumptions, or perhaps to look for a policy that is robust with respect to switches among models. Clearly one of the precautions policy makers would want to apply is to use a variety of models. But when there are significant differences, it is not easy to work up much confidence.

Second, there is likely to be concern about the possibility of bias in particular models or specifications of loss functions. Ando and Palash point out that in a quadratic loss function, if the target values for unemployment and inflation are set low, such as at zero, the unemployment variable will obtain an unintendedly high weight. My own concern is that on the contrary an inflation bias may enter the process, via the structure and the typical use made of most models. They seem to underestimate inflation because of a questionable process of forming price expectations, which relies on distributed lags of past experience instead of on rational expectations based on observed government policy. The paper by Kalchbrenner and Tinsley makes reference to the severe underestimation of inflation.

Additionally, an inflation bias may appear if model simulations are kept too short, since price effects typically lag volume effects. Long model simulations into the future are not popular, owing to the difficulty of estimating exogenous variables and perhaps also because of the longer run instability of some models. Nevertheless, by limiting a simulation or forecast to only a few quarters ahead, the long-run price effects may be cut off. These effects then will carry less weight in the optimal control simulation while volume effects, which occur with less of a lag, dominate.

Third, still another question about the performance of present-day models relates to their ability to deal with severe exogenous shocks such as the devaluation of the dollar, or the rise in oil prices. Such effects, as Kalchbrenner and Tinsley put it, simply "had no place to go in traditional econometric models." Now that the high rates of unemployment and inflation that resulted have become part of the data, users of the models' output are likely to be concerned about possible distortions from these outliers.

*Uncertainty.* Policy makers may be concerned about the kind of advice they are likely to get when the outlook appears more uncertain than usual. At such times, anyone with a firm opinion is likely to carry disproportionate weight, but in the case of advice from a model that is part of the risk to be guarded against. The natural tendency of policymakers, under such conditions, will be in the direction of greater conservatism, i.e., to do "less" than they otherwise would. The meaning of "less" may not be the same for everyone, although technically it would seem to imply that policy action should then be so designed as not to add to the variance of the loss. In practice, it may just mean to keep doing whatever was being done before.

Among technicians, views do not seem to be unified concerning the implication of varying uncertainty. A well-known theorem by William Brainard states that, under specified conditions, uncertainty reduces the scale of action. Kalchbrenner and Tinsley, in an earlier paper, seem to be of the same opinion. I have heard others quoted to the effect that uncertainty probably but not necessarily implies greater conservatism. In any event, the users of optimal control probably would like to know whether they run the risk, under particularly ticklish conditions, of being confronted with extreme advice from this source as they often are from other sources as well.

*The Outcome of the Policy Simulations.* Ando and Palash and Kalchbrenner and Tinsley have very properly indicated to what extent their findings point to alternative *ex ante* policies that in the light of contemporaneous information could have been adopted to produce better results. *Ex post* simulations, employing information that policymakers did not have at the time, may provide valuable lessons for the future but do not constitute a valid criticism of past policies. If I understand the two pairs of authors correctly, they both claim that, with the benefit of hindsight, policy could have been significantly improved. Kalchbrenner and Tinsley also seem to find that, on an *ex ante* basis, optimal control would not have done better. Feedbacking, in

other words, is not enough to produce better policies, according to their findings. I might add that in a set of papers by Hyman-Shapiro and Hirsch that will be discussed this afternoon, evaluating recent policies with the aid of eight alternative models in an optimal control framework, the conclusion is reached that even with the benefit of hindsight the inflation and recession of the last few years could not have been avoided, although policy could have been improved upon.

GARY FROMM, National Bureau of Economic Research: The papers presented at this and related sessions on optimal control are among the most important being given at the 1975 annual meetings. While none of them is pathbreaking, each contributes to a growing literature in a relatively new field in economics, one that should expand in significance as knowledge and techniques develop over a span of years. At this stage it is easy to find flaws in the methodology and its application for the design of optimal economic policies. But, especially on the eve of the 1976 Bicentennial and Adam Smith's *Wealth of Nations*, it should be recognized that perfection in theory or practice is not to be attained at the outset but only after substantial development and experience.

To some economists, especially policy makers, the thought of using formal models and control theory for the design of optimal stabilization and growth policies seems, on its face, as nonsensical. Yet these same skeptics speak approvingly of automatic stabilizers and formula flexibility, which are highly related to types of strategies that would result from applying control theory methodologies. It should be recognized that at one limit, control theory produces simple strategies like Milton Freidman's prescription of constant money supply growth. But, even if simple rules only are desired, it seems likely that somewhat less rigid control mechanisms could yield improved economic performance. For instance, a slightly less restrictive economic strategy would permit seasonally adjusted money growth rates to vary systematically within prescribed bands inversely to a leading indicator index.

However, even with application of more complex optimal control strategies, complete stability and growth objectives are likely not to be achievable because of lack of knowledge of the structure of an evolving economic system, imperfect and missing data, modeling deficiencies of misspecifications, incompleteness, and aggregation, and stochastic shocks. But, I am certain that the results reported at this session and those of comparable papers are valid—use of control theory techniques can reduce output fluctuations and inflation while raising the realization of economic potential.

With that introduction let me now turn to the present papers. Rather than picking on details of each, I will concentrate my remarks on issues common to all. One of the key aspects is the choice of an objective function. Often, as is the case in several papers here, a quadratic loss function is chosen such that deviations from targets are penalized at nonlinear rates. Such a loss function may, perhaps, correspond to actual preferences. However, analysts frequently choose targets arbitrarily and it is not realized that nonoptimal solutions may be derived as a consequence. This can arise for two reasons. First, with a multiple argument objective function, if all targets are not achievable, points within the possibility frontier are as likely to be selected as solutions as points on the frontier. Second, unless the targets are on the frontier at the bliss point, target achievement does not lead to maximization of social utility (or, the converse, minimization of disutility) nor to optimum policy. That is, a target loss function is appropriate only if targets are at the bliss point. Determination of the latter requires knowledge of both the structural constraints of the system (the frontier) and the positive utility function. But, if the positive utility function is known (or assumed), then it no longer is necessary to ascertain the bliss point in advance, and direct solution for optimal policy can be undertaken without specifying any targets or goals.

Clearly, the economics profession must do considerably more work on the determination of social utility functions before strong reliance can be placed on optimal control policy pre-

scriptions. Again, despite the fears of some skeptics, this is not as hopeless as it seems at first blush. Both direct survey and indirect revealed preference methods already have shown some promise in ascertaining social trade-offs or preferences for output, inflation, income transfers, and related variables. It should be remembered, too, that even if social preference functions are not explicitly identified, they are implicit in economic policy choices made by the President and the Congress. The key question is can we do better by consideration of explicit trade-off functions than by leaving them hidden and implicit. The answer, I believe is clear. As in other areas of decision analysis, formalization of implicit assumptions and structural characteristics (the trade-off functions and constraints) should lead to more informed and intelligent choices which are more consistent with welfare maximization than those which would occur without such explicit identification.

In specifying or estimating these welfare or tradeoff functions, analysts should beware of strong simplifying assumptions such as ignoring time dimensions and preferences, complementarities in preferences among arguments, trade-offs in amounts and variations in arguments, and, in general, the impact of uncertainty and stochastic influences. Too often, for the sake of expediency in the ease or cost of computations, extremely simplified functions have been assumed. There is need to perform sensitivity analyses with different forms, arguments, and parameters of such functions because policies and their ranking can change dramatically as these are altered. Fromm and Taubman found, for instance, that choices between policies shifted as the elasticity of substitution in a *CES* utility function was varied within plausible limits.

The same violence of simplications has been true with regard to structural constraints. If the world truly were linear and recurcive, optimal control solutions could easily be calculated. But most models of the economy reveal significant nonlinearities and, in selected blocks, strong simultaneity. My own experience with the Brookings and *FED-MIT* models has shown that linearizing such systems, even on a piecewise basis, drastically alters structural characteristics and multipliers on policy instruments. Therefore, extreme caution is advised in interpreting optimal control results that depend heavily on linear approximations.

The handling of uncertainty is another problem area. Again, based on simulations with the Brookings model and employing a utility function that incorporates risk preferences, it would appear that strong simplifications, such as certainty equivalence, are dangerous and lead to nonoptimal policy prescriptions. One clear need in this area is to define some terminology. For instance, we need definitions that differentiate between stochastic terms in estimation and model solution within sample periods, beyond sample periods, and for residuals of *ex ante* and *ex post* predictions with and without introduction of prior information such as constant and parameter adjustments or add factors.

In the short time allotted, it has been possible only to touch on a few general issues and not grapple with details and some of the admittedly strange results of applying control techniques in the Ando and Palash and Kalchbrenner and Tinsley papers. But these authors and Gregory Chow, are to be congratulated for fine efforts which should lay a basis for much future work in this important field.

POLITICAL ECONOMY: SOME USES OF THE EXIT-VOICE APPROACH

# Individual Mobility and Union Voice in the Labor Market

*By* R. B. Freeman*

Standard economic analysis of the impact of trade unions on the labor market is straightforward: unions are monopolistic organizations that raise wages and create inefficiency in resource allocation. Industrial relations experts tell a more complex story, stressing the diverse effect of unions on work rules, managerial decision making, and "virtually every aspect" of the activity of enterprises. To what extent do the non-wage effects of collective bargaining make the monopoly model incomplete or misleading? Do unions perform economically significant functions beyond altering wage rates?

This paper examines the non-wage effects of trade unions in the context of the "exit-voice" model of the social system developed by Albert O. Hirschman (1970). Unions are treated as the institution of collective voice in the job market; voluntary quits as the expression of exit. Comparisons are made between the free market quit and union voice mechanisms for transmitting worker desires for conditions of employment, compensation packages, and rules of the work place to employers; some empirical implications of the analysis are drawn and preliminary empirical findings described.

* Dept. of Economics, Harvard University. I have benefited from the comments of Albert Hirschman, James Medoff, John Dunlop, Zvi Griliches, and Martin Segal.

## I. Employment Relations and Conditions of Work

What makes the exit-voice framework a potentially fruitful way of looking at trade unions are "the peculiarities of the employment contract . . . which distinguish it from other kinds of contracts." (Herbert Simon, p. 183) In a world of uncertainty, imperfect information, and transactions costs, employment involves an authority relation in which workers sell "labor power" to enterprises for extended periods of time. As Ronald Coase puts it, "the contract is one whereby the factor (labor) for a certain remuneration . . . agrees to obey the directions of an entrepreneur *with certain limits*" (pp. 336–37). Because of on-the-job skills specific to enterprises (a learning curve phenomenon) and the cost of mobility and turnover, there are gains to be had from regular employment, a continuing relation between firms and much of their work force, in which allocative and remunerative decisions are not directly determined by the price mechanism.[1] Because workers care about nonpecuniary conditions of employment and rules of the work place, and because different conditions, rules, and methods of organization have different costs, the labor contract tends to be com-

[1] Because I focus on the situation with regular work relations, the analysis is not directly applicable to the case of craftsmen who change jobs regularly.

plex and multidimensional, involving numerous issues beyond wages, including the "social relations of production." (John R. Hicks, pp. 317–18) Because workers have some control over their own activities and can affect the productivity of others, particularly in "team" settings where monitoring of individuals is expensive, their attitudes or morale are potentially important inputs into the production process.

The complex, multidimensional and continuing nature of the employment relation creates a substantial information problem in the job market (Oliver Williamson, Michael Wachter, and S. Harris). Within firms, prices convey only crude information about preferences and costs. In the external market, workers and employers must appraise diverse conditions, rules, and compensation packages across enterprises. Over time technological changes continually alter the structure of the work place and jobs while changes in real income lead workers to demand new conditions of employment and methods of compensation. Firms or organizations have continual need for information from workers not only as Hirschman stresses because of decline or decay but because of changes in opportunities and efficient modes of behavior.

From the perspective of the exit-voice framework information about conditions and preferences can be provided by: free market "exit," consisting of quits and related behavior and/or by "voice" consisting of the collective bargaining system by which workers elect union leaders to represent them in bargaining. Each mechanism has certain strengths and weaknesses, which must enter any welfare economics calculation. Each is, from the perspective of positive economics, likely to produce different market outcomes in the various aspects of the labor contract.

## II. Quits as an Information System

Worker control of their own effort in work places creates several forms of "exit-behavior": quitting, rejecting a job offer; absenteeism, the partial withdrawal of labor time; reduction of work effort in the form of malingering and slack or in extreme cases "quiet sabotage." Strikes, which involve temporary collective exit, are best viewed as a tool of voice since they involve expression of demands by union or union-like group organizations.

Employers can learn about worker preferences and the causes of discontent from individual quits either inferentially by linking different levels of exit to different or changing characteristics of the employment relation in what amounts to hedonic price type calculations or through direct questioning, "exit interviews," of those who quit or make related decisions.

The amount of information provided by either channel is, unfortunately, likely to be small relative to the costs of processing the data. Inferring reasons for discontent from "abnormally" high quits requires specification of underlying multidimensional characteristics of work places; a reasonably large sample; and sufficient variation in conditions or in changes in conditions to permit the assignment of causality. Inferences about the preferences of workers who quit may, because of "selectivity bias," yield incorrect information about average evaluations or the evaluations of future potential quitters. The wider the variation in tastes among workers due to differences in preferences and position in the work place (especially seniority) and the greater the different modes of expressing exit (the young quit, while older employees choose less drastic actions), the more difficult will the inferential process be. If all persons had the same tastes, introspection by managers or foremen would yield answers at no cost.

Exit interviews run into a different difficulty—that of motivating the worker who leaves to detail work place problems. There is no gain to quitters from providing management with desired information about dissatisfaction, and there are possible losses via bad references—retaliation for conveying bad news. As a result, the leading personnel management text reports that "it is extremely difficult to get reliable information by means of exit interviews" (C. Meyers and P. Pigors, p. 222). The information content in other forms of exit behavior will be even smaller. A worker guilty of absenteeism for reasons of discontent with work relations will hide the reasons for fear of being fired, while malingering or quiet sabotage are by their nature covert activities.

Finally, whatever information the quit mechanism provides about current conditions of work, it provides much less about changes in conditions and, more importantly, about the trade-offs workers are willing to make in wages or other conditions for desired improvements; especially when the changes involve more than marginal adjustments in the work place. Innovations in the labor contract can be appraised only by potentially costly trial and error experimentation: changing conditions or compensation and observing outcomes.

Despite the high noise to signal ratio in labor market quits, the mechanism has desirable properties. Quit behavior depends solely on individual free market "marginal decisions" and does not require collective organizations like unions. Such behavior has well-known efficiency properties. Over time, some employers will extract the signal from the noise in quits or by trial and error find the "optimal" labor contract and come to dominate production or be imitated by competitors.

Certain features of the quit mechanism suggest, however, that there may be some divergence from optimum for extended periods of time. Since workers who leave an enterprise do not benefit from the improvement in conditions that may result, the extent of quitting to convey information may be suboptimal. That is when quits are effective in altering work conditions, the irreversibility of the decision provides too little incentive for workers to leave. Even if the level of *quitting* were optimal, however, the possibility that quitters differ in their evaluation of conditions from other workers (notably older or specifically trained persons who are unlikely to quit and whose position in the firm gives them a different set of interests) makes reliance on quits potentially misleading. Other forms of exit behavior must also be evaluated. In recessions or declining markets, moreover, quits will be ineffective as a mode of workers expressing preferences and obtaining desired changes.

Hirschman's analysis suggests other malfunctioning. Consider the situation in which all employers offer the same work conditions and where workers quit particular enterprises in the hope of attaining better conditions but in fact cannot do so. Each firm has a constant pool of applicants for jobs and a constant quit rate; no information is conveyed about what to change and there are no advantages in profitability. More generally, the same result would occur if the firms had different but similarly undesirable work conditions. Workers disliking bad condition $A$ in firm $A$ would move to firm $B$ where they would find bad condition $B$ and so forth. In this musical chairs equilibrium, quits are ineffective and excessive, at least until "random mutations" by enterprises produce a better wage-benefits-conditions package, so that quits differ substantially among employers. As a result there will be a long

period of adjustment to equilibrium.

From the perspective of workers, the information flow is especially likely to be faulty with respect to aspects of jobs, ranging from treatment by supervisors and coworkers to actual (as opposed to nominal) work responsibilities to evaluations of hazard (W. Kip Viscusi), which cannot be calculated without actually accepting employment. Under the quit system, each worker, would, say, learn about the bad qualities of a job only after a trial period of work and quit. If all workers knew about the job, no one would apply (without larger compensating differentials), but the information each gains is lost.

The question is not, however, whether individual mobility *ultimately* provides enough information to attain something akin to the optimal labor contract in the long run but rather how it does relative to the alternative institutional mechanism of voice, to whose operation I turn next.

## III. Collective Voice by Trade Unionism

The institution of voice in the labor market is trade unionism and collective bargaining. There are several reasons why collective rather than individual activity is necessary for voice to be effective within firms. First, the authority relation makes it difficult for individuals to express discontent due to the danger of being fired—it is clearly easier to retaliate against a single worker than the entire work force. Even with unionization, however, some protection of voice is needed, particularly for activists, as is recognized in the Wagner Act, which makes it an unfair labor practice to fire or otherwise discriminate against persons for trade union activity. Second, the communal nature of work conditions and rules which apply to all workers in the establishment creates a public goods problem of preference relation. Individuals cannot bargain over plant-wide conditions nor trade wages for fringes when there are sizeable set up costs. They will not have the incentive to reveal their preferences when the activity of others may produce the public goods at no cost to them. Elicitation of preferences and determination of acceptable bargaining packages are one of the major tasks of trade unions and critical components in the operation of successful collective bargaining systems. Third, because of the regularity of employment, there is a need to "police" or monitor contracts and thus for a collective agency specializing in information about the contract and in representation of workers. The ubiquity of grievance systems (found in 96 percent of contracts) or grievance and arbitration (93 percent) reflects the importance of contract interpretation in the operation of collective voice (U.S. Department of Labor).

The major advantages of unionization are that it provides: a direct channel of communication between workers and managenment; an alternative mode of expressing discontent than quitting, with consequent reductions in turnover costs and increases in specific training and work conditions; and social relations of production which can mitigate the problems associated with the authority relation in firms.

Union voice proffers very different information about workers' preferences than individual mobility—specific facts about areas of discontent and actual tradeoff possibilities (albeit masked by negotiating strategies). It creates an institutional mechanism for innovation in labor contracts and what may be termed a "new market" for labor contracts.[2] It focuses managerial attention and effort on labor

[2] Recent theoretical work on the existence of contingent claims markets and constrained transactions is thus relevant, surprising as this may be to the theorists, to analysis of the trade union institution (Jerry Green and Eytan Sheshinski).

issues on a regular basis, alerting firms to problems fairly continually rather than by sudden sharp outbursts of discontent. In large enterprises, union voice provides central management with information about local conditions and operations that is likely to differ greatly from that obtained from the organizational hierarchy.

By providing a mode of expressing discontent beyond exiting, direct information about worker desires and certain preferred work conditions that cannot be readily offered by nonunion establishments, union voice can be expected to reduce quit rates, absenteeism and related exit behavior. In the exit-voice model, there is *ceteris paribus,* a reasonably well-defined and economically significant trade-off between the two mechanisms. The reduction in quits will reduce labor turnover and training costs and increase firm-specific investments in human capital and possibly have efficiency gains.[3]

One desirable nonpecuniary condition of work, an industrial jurisprudence system with formal grievance, arbitration and related protection against managerial authority in establishments, may be "produced" only by unionization or some related mechanism. The essence of industrial jurisprudence is the dilution of the power of the foremen and other supervisors, which would presumably be difficult to attain in nonunion establishments where management has the "last word." Desire for such rules and procedures implies that union voice enters as a direct argument in utility functions (suggesting that in the absence of monopoly wage gains, workers would take lower pay for collective bargaining) and by affecting morale and the social relations in the firm, possibly in the production function as well.

On the negative side, the major disadvantage of union voice is that, as the standard monopoly model stresses, it creates monopoly power in the job market and wages above and employment below competitive levels. There are other costs to unionization as well: government, management, and workers invest considerable resources in bargaining which might have been spent on direct production; the productivity of the work force may be reduced by "featherbedding" (one possible exercise of monopoly power which would not show up in wages per se). Some work rules, like closed shops, may be "inequitable" to some workers; and more generally as a "political organization" unions may not reflect the desires of all members in a reasonable or "fair" manner.

Accepting the costs of collective bargaining, the normative question is whether these costs exceed the benefits due to reduction in exit behavior, improved flow of information, and provision of protection against managerial authority. There is, in our analysis, a trade-off: by providing information and a mechanism for potentially complex bargaining among workers and between workers and management that is more efficient than quits, collective bargaining is likely to yield a better "mix" among wages, work conditions, rules of the work place and a reduction in turnover costs and increased firm specific human capital, at the expense of higher price of labor.

## IV. Union Voice and Market Outcomes

The fact that unions are "political" organizations whose activities depend on the preferences of workers as a group has important implications regarding the impact of collective bargaining.[4] Whereas quits reflect the desires of marginal work-

[3] Of course the reduction in quits could be too great with bad consequences for overall labor mobility.

[4] While recognizing the political and organizational nature of unions, in this essay I neglect the effect of these factors on behavior, treating unions solely as an institution that conveys the desires of members. This omission will be rectified in future work.

ers, voice reflects the demands of some average of workers. If as a first approximation the median voter model is applied to union behavior, policy will be set by the median member (who is the marginal voter) with the consequence that greater weight will be placed on the preferences of relatively immobile workers (such as older workers and the specifically trained) than under the quit mechanism.[5] Trade unionism transforms the supply side of the job market by *making median (or some other average) rather than marginal preferences the "determinant" of the labor contract.* In the job market, individuals for whom there is a great gap between (pecuniary and nonpecuniary) wages in an establishment and opportunity wages are especially likely to exercise voice when work conditions change in an undesirable way. This contrasts with Hirschman's product market case in which those with higher consumer surplus are most likely to exit when quality of goods deteriorate.

The switch from a marginal to median (or other average) supply calculus might be expected to create inefficiencies since optimality criteria invariably require marginal first order conditions. Because of the union's role in facilitating information flows and coordinating worker preferences in bargaining, however, the situation is more complex. Bargaining among workers (which would not exist in the absence of unions) and potential worker demands for public or lumpy goods at the work place *could* offset inefficiency losses. Consider, for example, a situation in which management can choose one of two modes of organizing work, which, exclusive of their impact on workers, have equal profitability. Method A greatly reduces the well-being of immobile senior workers, while method B has no effect on them but displeases the mobile young slightly. In a market where information is conveyed by quits, the behavior of the young would lead management to choose method A, despite the loss of consumer "surplus" to older personnel. In a market with collective bargaining, the union might arbitrage the differences in preferences, so that the firm will pick B, with a negotiated redistribution giving the young some compensatory benefit and the old a less onerous loss than under A. This scenario can be expanded, to take account of different frequencies of quitting under A and B with similar results. The greater the difference between the losses under the two modes, the greater is the possibility that a superior bargain could be struck through the voice mechanism. I do not claim that the union will, in fact, arbitrage worker preferences correctly for the behavior of the union will depend on its internal organization, organizational goals, and political power of the various groups which are neglected here. The possibility is, however, there.

A second situation in which average preferences may yield better outcomes occurs when desirable work conditions or fringe benefits involve substantial fixed costs. Marginal evaluation could, as is well-known, lead enterprises to reject provision of employment conditions which would pass a benefit-cost test.

Advantages or disadvantages of union voice aside, by providing a distinct market mechanism for imparting information, aggregating preferences, altering authority relations, and changing marginal to average evaluations, collective bargaining will yield outcomes that differ from those in competitive markets. I conclude by sketching briefly some of the empirical implications of the model and the evidence regarding them.

[5] The median voter model is used as the simplest voting model. With many dimensions to contracts and groups within unions, it is obvious that a more complex game-theoretic model is needed to explain actual events.

As noted earlier, unionization is expected to reduce quits and raise investments in firm specific training. Studies of interindustrial variation in quits have generally found a negative relation (John Pencavel, John M. Burton and J. Parker, Vladimir Stoikov and Robert Raimon), as does my preliminary analysis of the relation between unionization and quits using disaggregate data files, which provide a superior test, through the route of the linkage remains to be determined. At least one potential proxy for "specific training," years of tenure with an employer, is also positively affected by unionization (Freeman, forthcoming, a).

Reversing lines of causality, the exit-voice model suggests that when quitting is nonviable, workers may be more prone to unionization. This is roughly consistent with Alan Blinder's evidence that older workers and those with family responsibility are more likely to be union members; with *U.S.* trade union history, in which unionism has grown rapidly following major recessions or depressions; and with union activities in coal, lumber, and similar locales from which exit is costly. Other factors are obviously also important, however.

Trade unionism can be expected to increase the fringe benefits share of total compensation, both for information considerations (Richard Lester, p. 494) and preference aggregation reasons. Analysis of data from individual establishments finds a significant positive relation (Freeman, forthcoming, b).

As a relatively permanent market institution, preserving information about work conditions that might otherwise be lost through individual quits, trade unions can also be expected to *increase* differentials for bad working conditions relative to the competitive market outcome, a result supported by Viscusi's analysis of compensating differentials for dangerous work.

Through the various nonwage effects outlined here, unions might be expected to alter the overall production process and worker productivity. James Medoff and C. Brown find, in fact, positive trade union productivity effects in cross-industry, cross state regressions, holding capital-labor and worker quality fixed.

Finally the model suggests that by directing attention to work place problems and encouraging expressions of discontent and by keeping dissatisfied workers from quitting, unions may *increase* job dissatisfaction, other factors (wages, conditions) held fixed. My preliminary investigation of job satisfaction in large data tapes finds such a relation.

If the unionization-satisfaction result stands up to more detailed analysis, it has significant implications for understanding the entire voice mechanism. It suggests that voice, of necessity, produces "dissatisfaction" by making individuals especially sensitive to and willing to criticize conditions. To be effective, voice cannot be silent, even when it may produce "the goods."

# The Economics of Internal Organization: Exit and Voice in Relation to Markets and Hierarchies

*By* OLIVER E. WILLIAMSON*

The economics of internal organization is concerned with two closely related issues. As contrasted with received micro theory, which is preoccupied with the operation of markets (whence the firm exists mainly as an analytical convenience), the economics of internal organization emphasizes that market organization and hierarchical (internal) organization are alternative—sometimes substitute but also complementary—means of executing transactions. The object is to assign transactions to markets and hierarchies so as to achieve a most preferred (usually least cost) result, where this is judged principally in terms of transaction costs. Whereas conventional micro theory is relatively unconcerned with assessing the merits of executing transactions by one mode rather than another (partly because prevailing modes are commonly held to be optimal), the economics of internal organization regards the assignment of transactions to markets and hierarchies as intrinsically interesting.

The second issue of importance to the study of the economics of internal organization concerns organization form. Just as market structure matters in assessing the efficacy of price mediated transactions in the market place, so internal structure matters in assessing the properties of administrative organization. The hierarchical decomposition of tasks and the types of internal control processes that are employed are both germane to an assessment of internal organization.

This paper sets out some of the leading attributes of Albert Hirschman's *Exit, Voice and Loyalty* (*EVL*) (1970) and my *Markets and Hierarchies* (*MH*) (1975). As will be evident, both sometimes complement received micro theory where conventional theory is silent or ambivalent. In other respects, however, *EVL* and *MH* offer substitute ways of interpreting or dealing with issues that fall within the range of received micro theory—or straightforward applications thereof.[1] *EVL* and *MH* also bear complementary and substitute relations to each other.[2]

## I. Leading Attributes

Both *EVL* and *MH* approach the phenomena of interest in a "rational spirit." Rationality is construed somewhat more broadly, however, than is characteristic in

* Research on this paper was supported by a grant from the National Science Foundation (NSF SOC 72-05550 A02). Helpful comments by Albert Hirschman on an earlier version of the paper are gratefully acknowledged.

[1] Although stilted, received micro theory will be taken to be the approach to the study of economics set out in any of the better intermediate micro theory textbooks.

[2] There is a presumption that the reader is already familiar with *EVL* and *MH*, either as a result of having read the books or one or more papers that relate thereto. A series of papers that develop *EVL*, including a survey by Hirschman, were published in *Social Science Information* during 1974. Also see R. R. Nelson and M. Krashinskey (1973). Papers dealing with *MH* include Oliver Williamson (1974a); Williamson, Michael Wachter and J. Harris (1975); and Williamson (1976).

economics: although net benefit considerations govern, extra-economic and systems considerations, both of which stretch the net benefit calculus beyond its normal range, also appear.

### *A. Analytical Novelty*

Given that a good or service is to be provided, *EVL* is concerned with the quality characteristics of the resulting product—with special attention to the question of whether potential spillover benefits are conferred on the less informed part of the population by the more informed subset. *EVL* proposes that the standard economic model, in which "exit" is the principal mechanism by which adaptations are accomplished, be augmented to make allowance for the mechanism of politics; namely, "voice." Exit adaptations can and usually are taken by parties acting independently. For voice to be effective, however, generally requires collective action.[3]

Rather than focus on goods or services as such, *MH* is concerned with the manner in which the implied set of transactions needed to accomplish any given productive outcome are organized. Contractual efficiency requires that transactions be organized in such a way as to economize on the bounded rationality attributes of human decision makers and to design interfaces between successive stages of production that promote harmony and attenuate opportunism. Both market and internal contracting modes are examined. Market modes include complex contingent claims contracting, incomplete long-term contracts, and recurrent spot contracts. Internal modes include peer group organization, simple hierarchies, and compound hierarchies of various kinds. As contrasted with the standard economic model of received micro theory, in which the firm is regarded as a production function to which a profit maximization objective has been assigned, the firm in *MH* terms is a device for economizing on transaction costs. For such economizing purposes, the details of internal organization (in factoring problems hierarchically and in internal control respects) matter.

### *B. Paradigm Problems*

The Nigerian railway case may be regarded as the paradigmatic example in *EVL*. Hirschman puts it as follows:

> The presence of a ready alternative to rail transport makes it less, rather than more, likely that the weaknesses of the railways will be fought rather than indulged. . . . This may be the reason public enterprise, not only in Nigeria but in many other countries, has strangely been at its weakest in sectors such as transportation and education where it is subjected to competition. [p. 44]

The suggested remedy involves blocking or inhibiting exit, thereby to mobilize voice and achieve a collectively superior outcome. Variations on the argument appear in conjunction with the treatment of public schools in the United States and of oligopoly.

The paradigmatic example in *MH* is the insurance problem. As is well-known, insurance suffers from disabilities of two kinds: adverse selection and moral hazard. It is less widely appreciated, however, that both are attributable to the same set of causes. Thus adverse selection difficulties appear because of (1) the impossibility or high cost of making *ex ante* discriminating judgments between applicants whose objective risks differ, which is a manifestation of bounded rationality, and because (2) poor risks cannot be relied upon to disclose their risk characteristics accurately, which is a reflection of oppor-

[3] *EVL* also points out that the study of politics (voice) can benefit by paying greater attention to the use of exit—as an alternative to or used in conjunction with voice. This aspect of the argument is neglected in this paper.

tunism. Similarly, moral hazard problems appear because of (1) the high cost of assessing *ex post* insurance claims in circumstances where risks and decisions are confounded (bounded rationality) and because (2) reports by insureds of negligent behavior cannot be taken at face value (opportunism). Conventional insurance is less complete for these reasons than it otherwise would be and nonmarket or market-assisted insurance alternatives are correspondingly more important.

By simple reinterpretation of parameters, in which productivity attributes of workers are substituted for risk attributes of insureds, the employment relation can be shown to be of the same form as the insurance problem; problems akin to both adverse selection and moral hazard arise and for identical reasons. The vertical integration problem, in turn, is a variant on the employment relation; and strong parallels exist or can be established in studying conglomerate organization as well. Thus labor markets, intermediate product markets, and capital markets can each be interpreted in a consistent framework. Hierarchical modes of organization supplant market modes in each instance in the degree to which they serve to economize on bounded rationality and attenuate the exercise of opportunism.

### *C. Antecedent Literature*

The antecedent tradition on which *EVL* relies is a mixture of politics and economics, the former of which is rather diffuse. Within economics, *EVL* relies in part on the literature that has been concerned with organizational slack (Richard M. Cyert and James G. March; Harvey Leibenstein) and partly on the market failure literature, of which Thomas Schelling's subsequent work on the "ecology of micromotives" is an example. This last is especially germane, in that the suboptimization outcomes which sometimes result when micromotives operate in an unrestrained way is the major concern of *EVL*.

The antecedent literatures on which *MH* mainly relies are (1) the transaction cost literature of the 1930's (John R. Commons; Ronald Coase), (2) the more recent market failure (Kenneth Arrow 1969) and contingent claims contracting literatures (Arrow 1974, Ch. 2), (3) aspects of organization theory (Herbert A. Simon, I. Goffman) and (4) the importance to the study of economics of factor nonhomogeneity (Friedrich A. Hayek, Peter B. Doeringer and Michael J. Piore). An attempt is made to identify a core set of factors which, directly or indirectly, underlie the transactional frictions with which each of these literatures is separately concerned. An "organizational failures framework" is then proposed, which framework is applied to the study of transactions across markets and within firms in a variety of contexts. The pairing of bounded rationality with uncertainty/complexity on the one hand and of opportunism with small numbers bargaining conditions on the other are key features of the framework.

### *D. Extraeconomic Dimensions*

Both *EVL* and *MH* introduce extraeconomic factors that do not ordinarily appear in conventional analysis. This does not imply that efficiency considerations are suppressed; rather a broad definition of efficiency is favored in which it is acknowledged that extraeconomic factors matter and by noting that alternative modes of organization affect these differently.[4]

A central concern of EVL is that market (exit) alternatives can *"atrophy the development of the art of voice"* (p. 43,

[4] In neither case, however, are the extraeconomic factors that are introduced well-integrated into the analysis.

emphasis in original), with debilitating system consequences. This challenges the usual economic presumption that more degrees of freedom are always to be preferred to fewer. The Hirschman view is shared by R. M. Titmuss, who argues that an all-donor system of collecting blood has superior properties to a mixed voluntary-commercial effort (Titmuss). The circumstances under which such arguments can be expected to hold, however, have yet to be delimited. The relevant public policy subset to which *EVL* applies is thus not well defined.

*EVL* also introduces the notion of loyalty and is concerned with its consequences. When is this functional, in that it facilitates recovery from adversity, and what are its limits? Finally, although *EVL* originally interpreted the exercise of voice as a costly undertaking, Hirschman now acknowledges that—for some individuals, for some purposes, over some range—voicing itself is valued. Evidently dissent has cathartic effects and/or the prospect of influencing outcomes is affirmatively regarded. "Public interest" activities for which the voicer can expect to receive acclaim attract voicing energies.

*MH* introduces the notion of atmosphere and argues that supplying a satisfying exchange relation is part of the economic problem, broadly construed. Reference to atmosphere is intended to make allowance for attitudinal interactions, and the systems consequences that are associated therewith. Market exchange tends predominantly to encourage calculative relations of a carefully metered sort and works well when there are few unsettled obligations that carry over from one transaction to the next. To process all transactions as though they were of this kind, however, is unwarranted. In particular to mediate transactions which are linked by attitudinal nonseparabilities as though they were independent (hence can be settled in a transaction-specific, *quid pro quo* fashion) can lead to inferior contracting modes in which anonymity is overstressed and system losses are incurred. Contracting for the services of human assets is the leading instance where the influence of current metering on future performance needs to be assessed with care. Considerations of internal due process arise in this connection. Collective organization, in both peer group and employment relation respects, arises partly for this reason.

## II. Some Similarities

### *A. New World Views*

The authors of *EVL* and *MH* plainly believe that they are onto a new way of organizing a wide set of social science phenomena. Hirschman puts it as follows: "I had come upon a manner of analyzing certain economic processes which promised to illuminate a wide range of social, political, and indeed moral phenomena" (p. vii). Among the applications which he notes are "issues as diverse as competition and the two-party system, divorce and the American character, black power and the failure of 'unhappy' top officials to resign over Vietnam" (p. vii). Likewise Williamson observes that "I was advised by a number of scholars to whom I distributed an earlier version of the manuscript that a distinctive worldview was being offered and that this ought to be emphasized" (p. xii), and goes on in his concluding chapter to contrast the proposed approach with a series of alternative paradigms—including, in addition to received micro theory, the structure-conduct-performance paradigm and the property rights approach.

That the *EVL* and *MH* approaches generalize is evident from subsequent work that has been done in each. The two other papers given in this session demonstrate that *EVL* helps to illuminate aspects of

both labor and urban economics. For an application of *MH* to the study of regulation see Williamson (1976).

### *B. Voice*

Both *EVL* and *MH* feature the use of market alternatives to autonomous contracting in which voice is prominent. But voice can take a variety of forms, and the forms characteristic of *EVL* and *MH* are rather different. Thus voice, as it is used in *EVL*, is mainly a protest activity in which consumers are appealing to suppliers for better quality products. Voice here takes place across a market. In *MH*, by contrast, voice takes place among the members of an internal organization and occurs in a continuing rather than in a sporadic way. Adaptations of a sequential-decision making kind, rather than of a prespecified contractual kind, are thereby facilitated.

Internal organization can be regarded, for some purposes, as an effort to attenuate costly and repeated bargaining between autonomous parties by joining the two parties in a common ownership unit, thereby to achieve a more nearly joint profit maximizing outcome. The resulting internal dialogue is apt to be rather different than that which occurs between a supplier of a good or service who is confronted by an articulate group of dissident customers who seek a change in policy which favors their objectives. Only if the dissidents were to integrate backward or take over the supplier would the parallels between *EVL* and *MH* be reasonably complete. This is not, however, in the spirit of *EVL*.

### *C. Understatement of Market Powers*

Both *EVL* and *MH* are of special relevance in circumstances where markets either do not or prospectively will not work well. The emphasis, accordingly, is on market frictions and on devising non-market or market assisted adaptations thereto. This is altogether useful, but the remarkable properties of markets for bringing large numbers of buyers and sellers into adjustment are somewhat neglected in the process. An undervaluation of the powers of markets may be an unintended byproduct of both.

## III. Some Differences

The differences that are treated here are often not very great. Sometimes they serve to complete or elaborate remarks already made in the sections above.

### *A. Markets*

#### 1. *Oligopoly*[5]

*EVL* takes the position that firms in oligopolistic industries are able and often do offer their customers shoddy merchandise without either losing trade or suffering the complaints of voice. Disgruntled, but silent and nonknowledgeable, customers move from one oligopolist to another under the "perpetual illusion" that things will get better only to discover, to their dismay, that they do not. The apparent exit choices that oligopoly affords are accordingly characterized as wasteful and diversionary. Full monopoly is said to be better since, absent the illusion of exit, voice would be mobilized and superior results would obtain.

There are two problems with the argument. For one thing, consolidated (monopoly) ownership gives no assurance that the diversionary range of choice to which Hirschman objects will be altered. If the monopolist offers multiple brands—which in the automobile industry to which Hirschman refers (pp. 27–28) is to be expected—voice-blunting consequences will presumably continue. Except, therefore, as product differentiation is impossible (as

[5] The discussion in this subsection follows Williamson (1974a, 1974b).

in homogeneous product industries), is prohibited, or users are somehow locked into whatever brand they are initially assigned, the voicing response on which Hirschman relies may fail to materialize. Additionally, Hirschman appears to undervalue the benefits of oligopolistic competition. *MH* offers a rather different view, where the problem of oligopolistic collusion is posed in contracting terms. The difficulty of reaching and enforcing a joint profit maximizing result by a group of oligopolists, which involves interfirm contracting of an implicit kind, is contrasted with the ease of achieving such an outcome by a dominant firm (monopolist).

Dominant firms enjoy collusive advantages over oligopolists in three significant respects. For one thing, the dominant firm does not have to write a complex interfirm "contract" in which future contingencies are identified and appropriate adaptations thereto are devised. Rather, the dominant firm can employ an adaptive, sequential (intrafirm) decision-making procedure, which economizes greatly on bounded rationality demands, without exposing itself to the risks of contractual incompleteness which confront autonomous parties to a horizontal interfirm agreement. Second, adaptation within a firm (in contrast to that between firms) is promoted by the more complete development of efficient, albeit often informal, communication codes and an associated trust relationship between the parties. Third, as between semiautonomous operating divisions in a dominant firm and fully autonomous oligopolists, the incentives to cheat are less and the machinery for penalizing defectors is more efficacious in the dominant firm. *MH* accordingly concludes that the net benefits of transforming oligopolies to monoplies, thereby to activate voice, are doubtful. Indeed, the opposite policy recommendation is reached: subject to the condition that a sacrifice of scale economies is not implied, dissolution of dominant firms into rivalrous oligopoly warrants serious attention.

### 2. *Capital Markets*

*EVL* pays scant attention to competition in the capital market. To the extent that it does, such competition is characterized as effete. *MH*, by contrast, regards competition in the capital market as integral and points up the symbiotic relations that have developed between internal organization (which, if of the appropriate kind, can usefully be regarded as a miniature capital market) and the capital market itself. Conglomerate organization is interpreted in these terms.

The argument here is that, where competition in the product market is weak or lacking, capital market competition for managerial control over corporate assets has an important role to play. The hierarchial transformation of firms from traditional, functionally organized entities to divisionalized structures permits an *internal* resource allocation competition to be set up which facilitates the assignment of capital to high yield purposes. Although the divisionalized firm's investment opportunities are limited, its *ex ante* knowledge with respect to each is very deep and its *ex post* ability to monitor investments is great. Both adverse selection and moral hazard problems associated with conventional capital market operations are thereby attenuated.

### 3. *Command Economies*

Command economy issues of two types should be distinguished. One entails the polity; the other concerns the organization of firms. *EVL* explicitly addresses the former but not the latter. The *MH* treatment of firms in an enterprise system has a bearing on the organization of firms in a command economy, but the issues are not expressly developed.

*EVL* notes with respect to the polity in command economies that "With exit-competition playing a much smaller role in the Soviet economy than in the market economies of the West, it was found necessary to give voice a more prominent role" (p. 34). It offers no corresponding advice, however, for the organization of firms.

Although *MH* is concerned throughout with the organization of an enterprise system, the organization form issues which are addressed in this context apply more generally. As compared with conventional industrial organization, where internal organization is neglected and concern over market organization predominates, *MH* argues that internal organization profoundly matters. To shift a transaction out of the market and into the firm without simultaneously examining the way in which such a transaction will be subject to internal incentives and controls is at best hazardous and can be foolhardy.

The limits of hierarchies in both vertical integration and firm size respects are relevant in this connection. Both capitalist and socialist firms experience expenditure distortions as the incremental transaction is shifted out of the market and into the firm. Unsurprisingly, the extent to which these develop is a function of organization form.

### B. *Public Policy*

Quality issues are of major concern throughout *EVL*. These appear in connection with the Nigerian railway problem and in the discussions of oligopoly and connoisseur goods.[6] And the connoisseur goods discussion leads into general system concerns that the possible failure of voice to be mobilized in requisite degree will result in deterioration with respect to "a number of essential services largely defining what has come to be called the 'quality of life' " (p. 53).

The strategy of exit-blocking so as to induce voice, thereby to impose connoisseur preferences on the remainder of the population, can be addressed in two parts. First, in what circumstances, if any, can it be justified in simple efficiency terms? Second, where these conditions do not obtain, what *prima facie* indicators ought to be satisfied before exit-blocking is seriously entertained? This latter is the more difficult issue and is not addressed here. I nevertheless think it instructive that exit-blocking need not turn, always or entirely, on complex value judgments of a nonefficiency kind.

Thus assume that the only significant differences between two consumer groups is that one has greater time, inclination, or capacity to evaluate alternatives in a discriminating way. Imposing the choice of the more discriminating group on the other can then be regarded, I submit, as an efficient outcome in conventional specialization of labor terms. (That it does not obtain "naturally"—i.e., without public policy assistance—is presumably explained by frictions in the system.) In circumstances, however, where the groups arguably differ in preference and other respects, exit-blocking is a political decision with deeper ramifications. The possibility of supplying immobile or disadvantaged sectors of the population with wherewithal, so they could exercise exit, rather than constrain already mobile segments ought also be considered as a remedial measure.

*MH* raises quality considerations mainly in conjunction with the discussion of atmosphere and then in only a limited way. To the extent that alternative contracting modes differ in atmospheric respects and these affect the quality of life on the job, neglect of these will result in suboptimization. Put differently attitudinal nonsepara-

[6] Quality considerations also come up in discussions of how the quality of government is affected by loyalty.

bilities are neglected only at the risk of transactional inefficiency.

The public policy thrust of *MH* is mainly with respect to antitrust enforcement. A revision of antitrust thinking is urged in which transaction cost considerations are expressly taken into account. More discriminating policies with respect to vertical integration, conglomerate organization, dominant firm industries, and oligopolies are proposed.

Also, *MH* conjectures that problems of devising market alternatives to regulation for natural monopoly industries are apt to be more severe than the advocates of franchise bidding (Harold Demsetz 1968; R. A. Posner 1972) have indicated. Subsequent application of the contracting approach to the franchise bidding issue supports the conjecture (Williamson 1976).

## IV. Concluding Remarks

As indicated at the outset, the paper's emphasis on the economics of internal organization biases the discussion in favor of the *MH* approach. Despite this bias, it is apparent that *EVL* has many interesting insights to contribute to the study of economic organization. In many respects, *EVL* and *MH* are complements to each other as well as complements to received micro theory.

Of special significance in this respect is the fact that *EVL* is mainly concerned with community objectives of a quality of life kind while *MH* is more narrowly concerned with transactional efficiency. Inasmuch as both are vital in the design of any high performance system, addressing complex economic problems in both the more aggregate language of exit and voice as well as in the more microanalytic contracting language of markets and hierarchies is apt often to be fruitful.

A comparative institutional approach to the study of economic phenomena is employed by both. The alternative to markets that is emphasized in *EVL* is voice. Shifting transactions out of the market into the firm (in labor, intermediate product, and capital market respects) is studied in *MH*.

The object of *EVL* is to mitigate the dysfunctional consequences that are associated with the unrestrained exercise of micromotives. Blocking or inhibiting exit, thereby to *mobilize voice* and achieve a *collectively superior* outcome is the recurring theme.

The object of *MH* is to evaluate organizing modes in terms of transactional efficiency, where this is judged comparatively. Institutions are assessed with respect to their properties for *economizing on bounded rationality and attenuating opportunism. Ceteris paribus*, those market and internal structures that realize transactional economies in these respects will display superior survival qualities.

# Consolidation or Diversity: Choices in the Structure of Urban Governance

By Dennis R. Young*

In very large measure, issues of structure in metropolitan area governance can be characterized by a basic organization choice: consolidation or diversity. Along several dimensions, a basic policy variable is whether public decisions are to be made by a few large organizations or units of government, or many small ones. Two key dimensions are *spatial* and *vertical* organization.

*Spatial organization* refers to the drawing of political boundary lines over urban space, dividing population groups into separate political constituencies. The issue for urban governance is how such boundaries should be drawn—specifically, whether they should encompass large or small areas, and small, homogenous or large, diverse population groups. *Vertical organization* refers to the possible separation of the "collective demand articulation" from the "supply" aspects of public service provision. Governments often have the options of contracting to, or subsidizing, private or other public suppliers rather than producing services "in house." To what extent should the supply and demand aspects of government be separated, and supply arrangements diversified?

A number of contributors to the field of political economy have provided insights into the resolution of these organizational questions. Albert O. Hirschman's (1970) theory of "exit and voice" is especially germane, as "consolidation" usually implies an organizational structure more dependent on the nonmarket forces of "voice," while diversification often implies increased reliance on market-like forces of "exit."

* Associate Professor, W. Averell Harriman College for Urban & Policy Sciences, State University of New York at Stony Brook.

## I. Spatial Organization

Two key principles underly much of the existing economic theory applying to delineation of political boundary lines over urban space. The first principle, advanced in a classic paper by Charles Tiebout (1956) is that urban areas can be organized into a heterogeneous, polycentric system of many small communities whose individual populations have relatively homogeneous tastes for public goods. Such a mode of organization is said to allow citizens to locate in communities whose public service packages and tax burdens conform most closely to their individual preferences. In Tiebout's model, an equilibrium is developed via citizen mobility, under which local public goods are allocated in an approximately optimal fashion, analogous to the functioning of the marketplace for private goods.

Tiebout's theory assumes the absence of interjurisdictional externalities. Such external effects between communities not only upset the optimal allocation of resources of the Tiebout model, but of course represent a key problem of urban governance. Political economists have offered two approaches to the resolution

of intercommunity externality problems. Those in the Tiebout tradition of favoring polycentric governance have stressed the use of intergovernmental agreements to ameliorate interjurisdictional externalities. This simply means that adjacent communities whose activities impose benefits or costs on one another can bargain in order to reach a level of externality production that would be socially optimal. This solution seems desirable except for the possibility that external effects may be widespread and may involve many different jurisdictions. Under such circumstances, the possibility of a bargain becomes remote, as the decision-making costs of reaching agreement among affected communities becomes very large.

The second mode offered by political economists for the solution of interjurisdictional externality problems is internalization via the adjustment of political boundary lines so that external effects are fully encompassed by single political jurisdictions. This is Mancur Olson's (1969) principle of "fiscal equivalence," under which a given political constituency would face both the full costs and the full benefits of a particular public service or action. Olson notes the delicacy of drawing boundaries via this principle. In particular, boundary lines encompassing too small an area will fail to fully internalize external effects. On the other hand, boundaries drawn too widely risk the danger of "internality." In this case, relatively few people in a confined part of a jurisdiction are affected by a particular externality or (proposed) public good, but since the whole jurisdiction is required to support a collective action, a satisfactory resolution may not take place. Thus, there is the danger of substituting "political externalities" for interjurisdictional externalities, by moving from boundaries that are too narrow to boundaries that are too wide.

The alternative of a federal structure of government presents, at least in theory, an attractive compromise to the Tiebout polycentric system on the one hand, and complete consolidation on the other hand. Metropolitan federalism offers the possibility of retaining the political identity of communities at the local level while allowing a higher level of government to ameliorate intercommunity external effects. But the compromise is certainly not without its own problems. Clearly an all-encompassing layer of government at the metropolitan level will face problems similar to "internality." That is, controlling coalitions of local communities may impose political externalities on other localities in the metropolitan area.

Hirschman's theory of "exit and voice" adds a few new wrinkles to the foregoing traditional political economy arguments. For example, Hirschman (1974) observes that reliance on the exit option is far too heavily emphasized by the Tiebout theory. In the first place, even where mobility is high, people move for a mixture of motives, not necessarily dominated by public goods considerations. Second, the level of mobility, even among high income groups is restrained. Hirschman describes the phenomenon of "exit fatigue" that quickly sets in with respect to moving one's residence. However, limitations on exit do not necessarily contradict the efficacy of a system of many small, homogeneous, self-governing communities. In particular, the mechanism of voice itself may be more effective when applied in the context of smaller, homogeneous rather than large heterogeneous communities. This, in fact, seems more important than the exit option, in explaining the empirical findings of researchers such as Elinor Ostrom and Gordon Whitaker (1973), Robert Bish (1971), and Brian Stipak (1974), that small, homogeneous communities seem to be more successful in achieving desired

levels and quality of services if they are politically self-contained than if they are part of a larger jurisdiction.

There are several reasons for the possibly increased effectiveness of voice in the context of smaller, more homogeneous communities. First, is the phenomenon of internality. Political externalities can be imposed on non-self-governing communities contained within large political jurisdictions, but not on self-governing communities. In addition, there is the likelihood that citizens will participate (use voice) more in smaller jurisdictions where they have a higher probability of impact and can see what effects they are having. Such an hypothesis is consistent with Olson's (1971) theory of collective action, which Roland McKean (1974) uses to explain the failure of citizens to participate in the political process. It also seems consistent with Hirschman's (1974) observation that exercise of voice can be sometimes viewed as a pleasurable or fulfilling experience. In particular, we would surmise that such fulfillment would be enhanced by the greater expected impact of voice in smaller jurisdictions.

Other aspects of the exit-voice framework, however, seem to contradict the efficacy of a system of many small jurisdictions, especially where mobility *differs* substantially among population groups. In particular, a polycentric system implies the presence of choice in selecting one's jurisdiction of residence, and the *potential* use of exit as an ultimate, if not immediate, response to deterioration of the services in one's present community. But, as Hirschman notes, exit will first be used by mobile, high income consumers who are more sensitive to quality than cost. These citizens will move to more expensive (suburban) jurisdictions leaving behind (and often effectively locking in) people who are less mobile, less quality-conscious, and less willing or able to utilize voice to repair the quality deterioration that has taken place. For these and other reasons, communities become segregated into those with high quality, high cost and low quality, low cost programs.

Exit-voice theory suggests that it may be preferable to eliminate the exit option in such a system, i.e., to lock quality-conscious consumers into the same jurisdictions as their less quality-conscious compatriots. This could be effected by replacing the polycentric arrangement with a consolidated metropolitan government. Under such a consolidation, quality-conscious consumers, having nowhere to exit, would presumably use voice more effectively in checking general deteriorations in service.

But consolidation is no panacea. The key considerations appear to be income and political control. As long as some people are poor, they will be more price than quality conscious. As long as middle income groups are numerous and powerful, they will maintain political control and skew the allocation of public resources toward their own ends, irrespective of the governing arrangement. Middle and upper income groups operating within a polycentric governmental structure, create suburban tax havens through zoning, to eliminate the transfer of resources to the support of low income communities. Alternatively, under a consolidated structure, middle and upper income groups utilize the political process to effect the same ends within a jurisdiction. It is simply testimony to the relative inefficiency of the latter or the subtlety of the former in inhibiting resource transfers, that suburban jurisdictions have opposed consolidation.

We can speculate that effective resolution of urban governmental spatial structure may require multiple independent communities controlled by different population groups. Alterations of the price-

quality trade-offs would have to be accomplished by structural reform in the form of income redistributive arrangements (e.g., revenue sharing) at the metropolitan level. In this manner, the effect of local control would be to strengthen voice of each (relatively homogeneous) citizenry, while the effect of income redistribution would be to redress the price-quality trade-off of lower income communities.

The issue of intercommunity externalities is placed within the context of exit-voice theory by noting that by definition, there is but limited exit possible from widespread external effects. In such a circumstance, a voice-oriented institutional framework seems required. In the urban environment, this suggests areawide units of government overarching local communities, for services such as transportation, air and water quality, waste disposal, and energy distribution. But in view of the aforementioned difficulties in using voice in large heterogeneous governmental jurisdictions, how can this level of government be successfully structured? The fundamental problems persist: minorities will be neglected by virtue of their submergence in a majority sea, while participation will be inhibited by the sheer size of the jurisdiction. These effects may be minimized but not eliminated by keeping the size of areawide jurisdictions to smallest units consistent with substantially internalizing relevant externalities.

Given the existence of public functions involving extensive areawide effects, there seems no easy way to circumvent these problems in the implementation of voice. Areawide levels of government are necessary, and necessarily imperfect.

## II. Vertical Organization

There are various options for governmental units to ensure that public services are supplied to their jurisdictions: governments can produce services themselves, contract with other producers, or allow citizens to use the marketplace under arrangements for possible subsidy and regulation. Robert Warren (1964), Bish (1971) and others point out that the foregoing "supply response" aspect of public goods provision is conceptually distinct from the "demand articulation" function of government, and should be organized by different criteria. Thus, it is argued that governmental units need not be large enough to fully exploit scale economies, or to produce every variety of differentiated product, for they can always contract with efficiently sized or specialized (private or other public) suppliers.

Furthermore, it is argued that governmental units should focus solely on demand articulation. Political economists of the polycentric school reason that a system featuring local communities organized as "consumer cooperatives," purchasing from multiple suppliers competing for contracts with these cooperatives, is efficient both in a production sense—controlling the cost and quality of services, and an allocation sense—matching service outputs to local preferences. But this conclusion, which is heavily dependent on the effectiveness of exit (by communities) in the markets for public services, would seem to vary with the nature of particular public services. For example, Oliver Williamson (1973) notes that "contractual incompleteness"—the inability or costliness of exactly specifying the desired nature of a service or the expected behavior of a contractor under all possible contingencies—can mar the desirability of contracting relative to "in-house" supply. In simplest terms, contracts appear to work best in areas where all important aspects of the output are quantifiable, where the technology is known and costs are predictable, and where a degree of competition can be assured.

A basic option alternative to formal

contracting or in-house supply, is to sanction private supply under some type of franchise or regulatory scheme which may involve rate setting, public subsidy, or the enforcement of various operating rules and guidelines. There is, of course, a wide spectrum of practices in this category ranging from regulation of monopolistic utilities, through administration of voucher programs to finance consumer use of competitively provided services. Arguments for privately supplied, publicly regulated services stress the motivational benefits to suppliers of self-financing and (in some cases) competition, as well as the ability of individual consumers to select the specific quantities desired at a given price.

The exit-voice framework provides an interesting perspective on these questions of consolidated or diversified, public or private supply. In particular:

Government in-house supply depends for its discipline directly on citizen voice expressed through the local political process. This voice is inevitably inexact and "noisy" as it must be integrated through channels of complaint and voting.

Government contracting combines exit and voice. Voice is directed by citizens, through the political process, to governmental overseers. Those overseers exercise both exit and voice in attempting to discipline contractors. A presumed advantage of contracting, as already noted, is that it strengthens citizens' voice by converting local government into a kind of consumer cooperative whose interests are aligned with the citizens, rather than a supplier whose interests may be at odds with those of the citizenry.

Government regulation of private monopoly provides for very weak forms of both exit and voice. Exit is hampered by the paucity of alternatives and the essentialness of services. Voice is muffled by the usual insulation of regulators from the political process, and the unequal strengths with which supplier and consumer interests are heard by regulators. On the other hand, regulation carries within its framework of definition the potential for the exit and voice strengths of the contracting arrangement. In particular, voice can be strengthened by bringing regulatory commissions into the general governance structure. Exit can be strengthened by eliminating the permanence of franchises and introducing precise performance criteria upon which rate or subsidy increases, and franchise renewals, would be granted.

Use of competitive private supply takes greatest advantage of control via exit. Here the consumer wields direct power via his choice to patronize one producer or another. Interestingly, competitive supply can also exhibit the most direct manifestation of consumer voice. For under this arrangement, consumers are more likely to articulate their concerns directly to suppliers before exercising exit. Furthermore, it is under this arrangement that suppliers are most likely to listen to these same consumers (precisely because of the threat of exit).

Beyond these general observations, particular characteristics of services influence the efficacy of exit and voice, and the desirability of one or the other of the foregoing supply arrangements. For example:

—economies of scale may preclude or discourage the provision of choice among several suppliers; hence, exit via competitive supply arrangements may be unrealistic for such services as telephone, electricity, rail transport, water supply, and sewers.

—the difficulty of precisely specifying the desired nature of service output or supplier behavior in all contingencies can make exit a sterile means of control. "Information rich" voice (dialogue between consumers and producers) is needed to reach a satisfactory resolution, and avoid

the risks of strategic behavior under misguided contract specifications. Thus, in-house supply may be preferred to contracting, and monopoly, or costly exit, may be preferred to competitive arrangements for this reason. An example here is elementary schooling whose output is sufficiently complex and ephemeral so that contracts cannot be completely specified and parental exit does not neatly convey the reasons for dissatisfaction.

—some services pose natural exit barriers, i.e., high personal costs for changing one's source of supply, which reduce the efficacy of competitive arrangements by taking the edge off the threat of exit. Examples include day care centers and nursing homes where changes are disruptive of the lives of clientele; or housing where exit involves the high dollar costs of moving.

—for services which Hirschman describes as "connoisseur goods," exit may be limited to those who can afford more expensive private alternatives. Such is the case with education, health care, and housing. In this circumstance, the danger is that "quality-conscious" consumers will exit, leaving behind those consumers who cannot exercise exit nor effectively use voice. Hirschman's analysis suggests that barriers to exit (or abolition of alternatives) would help prevent quality deterioration by keeping the most effective wielders of voice locked in. On the surface, this hypothesis appears to argue for monopolistic arrangements which (hopefully) channel voice effectively. Alternatively, it may well be that correcting income balances through subsidy can do much to void the problems of connoisseur goods. A combination of corrective subsidy plus consumer information might ease the segregation of quality and nonquality-conscious consumers and reduce the correlation of this bifurcation with income and minority groups (just as local revenue sharing might do the same for communities as a whole).

—some services have no viable consumer groups that can competently exercise exit (and perhaps voice also). Services provided to children, the ill or infirm, or criminal offenders, clearly preclude exit as a viable option at the consumer level. Hence, the options are seemingly reduced to in-house government supply or contracting. But these arrangements are also hindered in these circumstances by the absence of a strong advocacy group to whom government would be responsive. A possible circumvention of this problem, suggested by this author (1974), is the use of "proxy consumers" to make exit choices and exercise voice on behalf of individual consumers. For children in school, or elderly persons in nursing homes, members of the immediate family often serve this purpose. But even in such areas as criminal corrections or foster care, judges, probation officers, social workers and lawyers potentially fit this role.

Given the foregoing variety of service characteristics which affect the efficacy of exit and voice, we should expect that different services can be best organized vertically in different ways. For example, if exit is hampered by exit costs, vague service character, or absence of a viable consumer, then contracts might be avoided in favor of in-house control, and consumer's choice must be supplemented by voice-responsive governmental supervision of some kind. Or if exit is effective relative to voice, i.e., where service character is well defined, consumers are viable, and exit costs low, then competitive or contract arrangements could be emphasized.

In contrast to the discussion of spatial organization of urban government, the economist's bias towards exit as the principle means of regulation, appears to serve him better in the domain of vertical organization of public services. While there

is a considerable variety of practices in the United States at the present time, it seems safe to propose that voice-dependent modes of supply organization are emphasized too heavily for local public services. Recent experiences in education, sanitation, even fire protection, indicate possibly greater useful exploitation of exit, through contracting and competition, to replace stagnant forms of bureaucratic and regulated monopoly supply. (See E. S. Savas, 1974.)

### III. Conclusion

Consideration of the various problems in each organization dimension of urban governance reveals no uniform preference for voice-based (consolidated) or exit-based (diversified) modes. In the extremes, complete spatial and vertical integration would bring out in full bloom the circumstances under which voice is dysfunctional, while full diversification along these dimensions would do the same for exit. The choices in between are numerous, varied, interdependent, and dependent upon the character of individual services, and clientele populations. A review of this discussion reveals various circumstances where exit seems to work best and where exit fails, and where voice seems to work best and where voice fails.

Economists are fond of the term "market failure" which is taken to mean the failure of market arrangements to bring about an optimal allocation of goods and services. Using Hirschman's terminology we can take the liberty of characterizing market failure more broadly, as the circumstances in which the use of exit, or exit-based organizational arrangements, fail to maintain organizational performance. Such a definition would extend the classical one to include not only the conventional conundrums of externalities and economies of scale, but also the various other factors discussed here such as exit costs and complexity of output. Given the characterization of market failure as failure of the exit mechanism, it is but a short step to defining a complementary concept—"nonmarket failure." Nonmarket failure would be the circumstances in which the use of voice, or voice-based organizational arrangements, fail to maintain organizational performance.

The twin concepts of market failure and nonmarket failure bring to mind two immediate ideas seemingly worthy of further development. First, just as we can envision ideal market conditions under exit based arrangements (e.g., perfect competition, with all its concommitant assumptions), we can also attempt to visualize ideal circumstances for voice-based arrangements—perhaps where self-governing communities or organizations are composed of small homogeneous units. Given these "ideals," one approach to organizational reform might be to attempt to approximate these ideals in practice.

A second outgrowth of the duel concepts of market failure and nonmarket failure is not so sanguine, however. A review of the various circumstances under which exit fails and voice fails reveals that voice does not necessarily succeed where exit fails. For example, overcoming the exit failure due to areawide externalities in urban areas requires a large, heterogeneous voice-based metropolitan government structure which is also subject to voice failure. Thus, for a given circumstance, market failure and nonmarket failure are *simultaneously* possible!

It is likely therefore that there is a core of public services and other economic activities for which no perfectly satisfactory organizational solutions may be available. While this appears to be a very pessimistic conclusion, it may have its redeeming virtues. For it may serve to warn reformers of various persuasions, both econ-

omists and political scientists, that "the grass is not necessarily greener on the other side." Some areas of economic activity at least, appear to be necessarily organized in an imperfect way.

# DISCUSSION

ALBERT O. HIRSCHMAN, Institute for Advanced Study: In the venerable folklore of traditional economics political action in the economic sphere has typically been considered as noxious interference with the totally beneficent market mechanism The equally venerable opposing point of view castigates the Invisible Hand as the Blind Forces of the Market—note the clever replacement of Adam Smith's metaphor by one that uses a closely related image—and instead advocates planning by a political authority that, in turn, is assumed to be totally beneficent. A principal intent of my work on exit and voice, considerably bolstered by all three papers presented at this session, was to show that there is a wide range of economic processes for the efficient unfolding of which both individual, economic action (via exit) and participatory, political action (via voice) have important constructive roles to play. The novelty of the theory for the economist—apt to infuriate or to disconcert both market and planning enthusiasts—consists in its stress on voice not as a substitute for the market nor as a restraint on it in a few well defined situations, but as another generally available mechanism that, like the market, has its strengths and weaknesses, its successes and failures. There is also a stress on the possibility of unstable equilibria between exit and voice as one drives out the other and on the lack of once-and-for-all solutions through optimal mixes of exit and voice. In other words, the new approach does not satisfy our craving for equilibrium, harmony and final repose. If it has met, nevertheless, with the beginning of a response from economists, this is probably because of the new or renewed emphasis on such phenomena as ignorance and the cost of information, transaction costs, bounded rationality, X-efficiency, and even altruism. The possibility of "market failure" is today no longer limited—as was taught not long ago by received doctrine—to the presence of externalities, and I welcome Dennis Young's proposal to redefine this concept broadly in terms of situations where exit doesn't do a good job of stirring up management and of restoring efficiency. In this perspective the availability of another mechanism—voice—should not be viewed as a threatening rival, but as a welcome resource whose potential contribution to a containment of our multiple troubles deserves to be closely studied. For example, while looking at the provision of medical services precisely in this manner, Carl Stevens has recently proposed to complement consumer sovereignty—that is, exit—by *consumer participation* and to limit professional producer sovereignty by *lay management constraints*. These terms are useful modulations of the perhaps excessively compact "voice."

My comments, including some further thoughts will be in four parts.

1. In all three papers, when voice scores over exit this is primarily because it is information-rich whereas exit conveys little beyond the fact of restlessness or restiveness on the part of the consumer, customer, employee or whoever else one has an economic relation with. Take Freeman's paper on labor and the employment relationship: here dissatisfaction arises from a mixture of motives that includes unhappiness about a whole array of working conditions no less than the desire for higher wages and benefits. Unions are more efficient in communicating information about this complex mixture of complaints than the personnel turnover rate. To make this point even stronger I would add that the *content of discontent* is apt to change over time: exit always takes the same form no matter what the complaint; but voice can articulate newly arising demands—often, to be sure, with a considerable lag as the union leadership takes its own time to understand and adopt the new "outlandish" grievances of its members.

According to Williamson, markets are not working properly whenever the parties are involved in a relationship which it is difficult to specify fully in writing because of uncertainty and complexity or which lends itself peculiarly to the display of bargaining behavior. In these cases the substitution of hierarchy for market relationships between the parties is indicated. In my language hierarchy can be considered as a special variety of insti-

tutionalized voice and here is therefore another case where voice wins out over exit because of the fullness and frankness of information which it carries.

Finally, Dennis Young uses the same criterion in favoring a large admixture of voice for the organization of certain public services. He mentions primarily situations in which exit is costly and disruptive to the consumers of the services, as in the case of day-care centers or nursing homes. In my view, these are also frequently situations in which the producers themselves are still groping for satisfactory ways of doing a job which they have taken on because there was a demand for it. In such increasingly important cases of *producer ignorance*, information-rich voice on the part of consumers or of Young's "proxy consumers" is far more helpful than the blankness of exit.

2. That voice conveys more information than exit is one facet of the polarity which is highly important for economic applications, and which I had neglected in my book. Another is the fact that voice, to the extent that it is political action or action in the public interest, is liable to escape from the fetters of the benefit-cost calculus and can therefore suddenly gain an unexpected edge over silent, self-regarding exit.

Young notes quite correctly one dilemma in the design of local government: the larger the territorial unit encompassed by municipal government, or by a subdivision of that government such as a school district, the less feasible will it be for the individual citizen to practice exit and the more important is it therefore for voice to function actively and intelligently; yet voice is presumably more apt to become mobilized when the area to which it extends is none too large. Decentralization of public schools and of public services has been advocated precisely for the purpose of facilitating and activating citizen participation.

It may be questioned, however, whether the propensity to voice is likely to increase *indefinitely* as the territorial unit within which voice is raised shrinks in size. Voice can become an end in itself, and its exercise can become confused with the attainment of its objective. As soon as that happens its *cost* (in time spent, for example) can measure instead the *satisfaction* or *benefit* received from its exercise or "consumption." For this mutation of cost into benefit to occur it is necessary that the exercise of voice be felt as something beyond the many activities that are primarily self-regarding. Though originally prompted by personal concerns, voice becomes an enjoyable, exhilarating experience when it is also action in the public interest, sometimes just because it is felt as a release from the unremitting pursuit of purely self-regarding activity. But voice stands to lose this public interest dimension if the area within and on behalf of which it is raised shrinks unduly: it then becomes essentially self-regarding like exit and at that point its cost will once again be rigidly computed. Here is perhaps a simple explanation of the consistently higher voter turnout in national as compared to local elections. In local elections, the public interest dimension is less obvious and the cost of voting tends to be computed and related to its conceivable benefits; national elections, on the other hand, partake of the character of public celebrations and even of the traditional "feast of fools": the lowly citizen is transformed into the sovereign—though only for one day as Rousseau lamented—and he enjoys himself thoroughly in the process.

3. What has just been said explains much about the economist's preference for exit: voice is a far more complex, less predictable mechanism. In my book I stressed the similarities between the ways in which exit and voice operate. I overlooked or failed to stress sufficiently certain characteristic differences. He who voices remains within the organization, maintains a relationship with it. Hence the organization and its management can do things to him and in particular can treat him, because he voices, differently from the way in which it treats the other members.

It can treat him *worse*, punish him for daring to voice. There may be *retaliation* and *reprisals* against someone who criticizes an organization, but remains within its reach. For that reason, it has been argued by Birch that the availability of a fast getaway (exit) is a precondition for a good volume of voice. I agree but would also point out that a number

of social mechanisms have been evolved to make voice retaliation-proof even in the absence of exit. Examples are the secret vote, the Ombudsman institution which make it possible for individuals in a bureaucratic organization to complain outside of hierarchial channels, and trade union bargaining as described by Freeman.

Another hazard that exists for voice far more than for exit is the exact opposite of retaliation: instead of being penalized, he who voices is singled out for *special favors*. By giving the complainant preferential treatment the delinquent organization seeks to still his voice and to buy him off: in this manner, it may once again avoid having to improve the *general* quality of its performance. This managerial strategy is present when firms extend "goldplated service" to their more important customers; it is also often practiced by administrative agencies rationing out goods and services to applicants according to nonmarket criteria.

This strategy of countering voice is employed not only for the purpose of appeasing important individual customers; it can be particularly useful to management in dealing with voice that takes collective form, as in the case of trade unions, consumer organizations and the like. Special treatment and favors extended to the leaders of such organizations could have results that range all the way from a slight reduction in militancy to outright corruption. This is one of the major risks to which the effectiveness of collective organized voice is exposed.

4. It was a general underlying assumption of my book that both forms of activism, voice and exit, would, if successful, achieve a benefit (a positive externality) for the nonactivists. This assumption would hold whenever a firm turns out a product (or the government a policy) the tastes for which are so constrained that any improvement in quality or performance undertaken by management in response to exit and voice is sensed as a positive event by everyone, activists as well as nonactivists. What happens when this constraint is relaxed? Suppose that different consumer-members have different ideas about what sort of improvements are needed and further that the ideas and tastes of the activists differ systematically from those of the nonactivists. To the extent that it is successful, the voice of the activists will then cause the quality of the product or policy to vary in such a fashion that benefits are bestowed primarily or exclusively on them. The reason is simple: voice is information-rich and is able to give precise instructions to management. Note that those who voice will here receive special benefits without any conscious buying-off activity on the part of the organization.

This constellation has implications that differ considerably from my previous model. I had argued that, when exit is available and loyalty weak, deterioration would make for rapid desertion of the potentially most influential carriers of voice and would thereby cause further deterioration of organizations that are so constituted as to respond more to voice than to exit. I still hold that this model corresponds to one set of important situations in the real world. But to the extent that the just noted conditions prevail, the outlines of another set with almost opposite characteristics appear. It can happen that an institution originally or nominally set up to service a wide group comes to cater predominantly to the wishes and tastes of an articulate minority or oligarchy within that group. If exit is available at all under these circumstances, it could then become the weapon that will typically be wielded by the "silent majority." In this perspective, the articulate few would develop a preference for voice whereas the comparative advantage of the underarticulate mass would lie in exit; exit might in fact be the only means of defense of the voiceless not so much against deterioration as against voice-induced quality changes that are not in their own interest. (I am indebted to Pierre Bourdieu and David Riesman for raising this point.)

Actually examples of this reversal of roles of exit and voice are not easy to find. While it is commonplace for voice to function as an instrument of the privileged and for the privileged, exit has not often been used to provide an avenue of self-defense for the voiceless. An important case in which exit did approximate this function was during the

nineteenth and early twentieth centuries in connection with mass emigration from Europe to the New World. But, on the whole, exit has not been readily available to the voiceless masses—they have had to assert themselves the hard way through passive resistance, revolts, and other attempts at voice. It has not often been the case that the advantage of the privileged with respect to voice is offset by a similar advantage the underprivileged might have with respect to exit. To the contrary, because of a number of technological and institutional innovations, the privileged have in recent times compounded their traditional superiority in voice with a remarkable prowess in exit—witness the flight to the suburbs, capital flight, the multinational corporation and the brain drain. In emphasizing the disruptive consequences of such exits and in looking to more voice for a remedy, I may well not have given enough attention to the possibility that by using voice instead of exit the articulate might just feather their own nest. I still believe, nevertheless, that, once in a while, they will do a bit better than that, if only because they cannot help it, that is, because the constraints I originally assumed do in fact apply.

RICHARD R. NELSON, Yale University: *Exit, Voice and Loyalty* is a book that has excited many people. One reason is that there are a lot of good ideas in the book. Let me propose that the ideas are at at least three different levels. At the most general level, *Exit, Voice and Loyalty* is a complaint about the narrowness of much economic thinking regarding ways to control economic activity and a proposal that we broaden and enrich our thinking. There is a suggestion that economists can learn something by reading in other disciplines, particularly political science. At another level, *Exit, Voice and Loyalty* is a proposal for dividing up the ways in which control can be exercised into two broad categories—exit and voice. Once one recognizes diversity, one is tempted to provide some useful categories of control. Exit-and-voice is a particular categorization. At still another level there are a number of analytic propositions about the relationship of exit and voice to various variables, and the interaction between the two. For example, it is proposed that the use of exit erodes the power of voice, that in many cases the exit of demanders of high quality leads to an organization that provides shoddy quality and hence that exit imposes a negative externality on those who remain, etc.

Clearly, different people have found different aspects about the book compelling. I am among the people who have found *Exit, Voice and Loyalty* an exciting book. However, regarding the book as general complaint and proposal for richer thinking, I was persuaded of these points before. I think *Exit, Voice and Loyalty* should be regarded as one of a number of books that have been making the same general point. But its unique contribution certainly does not lie there. At the middle level of ideas, I have found the exit, voice dichotomization important and useful. Earlier, I thought that it had a very wide range of useful applicability. More recently, I have become convinced that the range of useful application is limited. For example, when I think about questions like the extent to which collective demand machinery should be substituted for private demand machinery, I have not found that the exit-voice language has helped very much. In some cases it has provided synonyms for words and concepts found elsewhere in the literature, like demand aggregation, collective choice machinery, etc., but seems to have no real advantages over other terms. And in some cases the exit, voice language seems to be simply more cumbersome than more traditional language. But for certain arenas of my interest, like my work on the organization of day care, the exit-voice language was extremely helpful, and some of Hirschman's particular propositions quite apt. It is in arenas like this that I think *Exit, Voice and Loyalty* has made a unique contribution.

I make these remarks neither to extol nor to diminish the book. Rather, my intent is to focus attention on where I think the real contribution of the book lies.

The Williamson paper develops some themes roughly similar to those I have presented above. He too is concerned that the world view aspects of *Exit, Voice and Loyalty* may be less widely fruitful than some of the

enthusiasts seem to claim. I find that I have difficulty discussing the Williamson paper without getting drawn into a detailed discussion of the *Markets and Hierarchies* proposal along the same lines that I have sketched above regarding *Exit, Voice and Loyalty:* the book as a sweeping complaint and proposal for broader thinking, as a particular set of categories set forth as a useful general purpose organizer, and a number of particular analytic propositions that go beyond the categories aspect of the book. But I must avoid getting drawn in that direction. I only shall stress my agreement with Williamson's concluding comment—that *Markets and Hierarchies* and *Exit, Voice and Loyalty* may be complementary rather than competitive. I think that is true, and because each is most productive in different limited arenas. For my purposes it is more useful to focus on the Freeman and Young papers as examples of what two scholars have made out of *Exit, Voice and Loyalty.*

Reading Freeman's paper reinforces my impressions that the exit-voice language is useful in a number of cases, but also in many instances that the use of language is forced and other terms are better. Freeman focuses on the problem of an employer of getting information regarding the trade-offs, from the point of view of the workers, among various dimensions of the job offer. He points out, sensibly, that it might be far better to talk about these matters with worker representatives than to try to find out about them merely by looking at success or failure in hiring and holding workers. Voice here has a particular meaning, and rings right in that use, although the notion that voice is a richer communication channel than exit was not one of the central themes in Hirschman's book. Freeman stresses that union negotiations which he says are the main voice mechanism, are particularly important in deciding upon certain atmospheric or public aspects of the work condition. In a sense, the union is a mechanism whereby workers can decide on how much of various public goods (which must be paid for by lower money wages) they want. Here after the first quick point is made and Freeman gets down to discussing mechanism, I think the use of the voice language is a bit strained, and more standard terms and concepts, drawn from the literature on public goods decision making, seem more appropriate. Indeed Freeman falls back upon these. Freeman says *Exit, Voice and Loyalty* has been useful to him in enabling him to think back to an earlier, more institutional literature. But I wonder if it is the specifics of *Exit, Voice and Loyalty* that are helpful here, or whether what Freeman really is welcoming is the general climate that is conducive now to institutional exploration. Hirschman's book helped to build that climate, but so did a lot of others.

Young's paper shows the same mix of fruitful and cumbersome uses of concepts from *Exit, Voice and Loyalty.* The most fruitful use is where Young focuses on situations where exit is costly (moving) and there are opportunities to influence governmental action by greater involvement. The voice concept is a good one for connoting aggressive action from within. However, when Young begins to discuss the range of considerations bearing on whether or not one should try to establish governmental machinery to try to aggregate demands for certain kinds of goods, or to take into account diffuse externalities, I am not sure that he gains much by use of the term "voice." The problem is well-described by the more traditional language of the anatomy of market failure. The issues of the appropriate organization of governmental machinery are complex, discussed in many places in the literature, and it does not help very much to have the issue posed in terms of "voice." One problem of mechanisms that aggregate diverse interests is that the voice is babble.

In other words, jointly with me, and independently, Young has made more fruitful use of the exit-voice language. It seems to me that Hirschman's concepts, and many of his specific analytic propositions, are right on the mark regarding classes of product or service with the following attributes. Experience, rather than shopping, is where the key information comes from. The services or goods can be and often should be specially tailored to the demander by the supplier. It takes time and experience for the supplier to learn about the demander's

tastes or problems. The provider has some interest in retaining his customers. The day care study that Dennis Young and I did exploits Hirschman's ideas. I think they are applicable and underused in the study of professional services more generally, for example, in the content of the patient-doctor relationship. Of course there are many other uses in which the exit-voice language is useful. Many of these are discussed in Hirschman's book. Some new arenas where exit and voice concepts can be used fruitfully are contained in the Young and Freeman papers.

I can sum up my feelings this way. The ideas in *Exit, Voice and Loyalty* are important and useful. However, the scope and generality of the big ideas sometimes have been overstated. I believe that the power of the categories, when applied to a limited but important arena, is very considerable. And some of the detailed analytic propositions in the book are very useful in certain special cases. It is a book, very useful in a circumscribed arena, like Chamberlin's work on monopolistic competition, rather than a widely embracing world view. That is reason enough for praise.

# NEW DEVELOPMENTS IN THE THEORY OF MONOPOLISTIC COMPETITION

# A Survey of Advertising and Market Structure

By GERARD R. BUTTERS*

The economics of advertising is marked by the same emotional commitment to conflicting schools of thought that is usually associated with monetary theory and the economics of speculation. To all appearances, the choice of both the axioms used and data to be interpreted has been made in order to justify preexisting conclusions rather than to make an unbiased test between alternative theories. How else is one to explain the vehemence and fixity of many economists' views in the face of gradually accumulating, but still sparse, evidence?

The controversies endure in large part because advertising still remains outside the core of accepted theory. Neither the standard Marshallian partial equilibrium analysis nor the Arrow-Debreu general equilibrium analysis even admits the existence of advertising. Two major explanations of advertising are widely held: one considers advertising as a set of psychological ploys which induce consumers to buy products or brands that they otherwise would not buy; the other treats advertising as a provision of information which allows consumers to make more discriminating choices within the framework of a fixed set of preferences. The source of difficulty is that although these theories have opposing welfare implications, it is exceedingly difficult to devise tests which distinguish between them empirically. In the absence of a sound, agreed upon theoretical base, the field began its development by asking broad and imprecise welfare questions, such as "Is advertising good or bad?" and "Does advertising reduce competition?" by developing *ad hoc* arguments on all sides, and by amassing inconclusive empirical evidence to support alternative contentions. The result is that we have accumulated a rich fund of insights, but we are saddled with imprecise terminology and ill-posed questions which stand in the way of clear analysis. For recent surveys of the literature, the reader is referred to the books by James Ferguson and Richard Schmalensee. In the space allotted here, I can only point out one example of the imprecision of the current debate and make a few suggestions as to how research might proceed.

## I. Advertising and Profitability

A case in point is the ongoing controversy over the relationship between advertising, concentration, and profitability. A number of recent studies, most prominently those done by William Comanor and Thomas Wilson (1967, 1974), have found a significantly positive coefficient for advertising in regressions of industry rates of return on industry rates of adver-

* Assistant Professor of Economics, Princeton University. I would like to thank Michael Rothschild, Larry White, and Gregory Chow for helpful discussions.

tising expenditure (usually in the form of advertising divided by sales) and other variables. This result has been held to support the proposition that advertising raises profits through some mechanism such as by creating brand loyalty or by increasing the minimum efficient firm size. Three sets of objections have been raised frequently to this line of reasoning. The first set dismisses the positive coefficient as a statistical artifact, usually on the grounds that the accounting convention according to which advertising is considered as a current expense rather than as an investment biases the coefficient upwards. The second set asserts that the positive coefficient could equally well be due to a causal effect from profits to advertising or from concentration to both advertising and profits. The third set of objections denies the existence of substantial economies of size in advertising and the existence of absolute cost disadvantages to new entrants on account of advertising induced brand loyalties, thus striking at the theoretical justifications for the advertising-profits relationship. The jury is still out on all aspects of this debate.

A second school of thought holds that not only does advertising fail to create monopoly power, but also that it is a bulwark of competition. A recent summary of this view has been presented by Yale Brozen. He argues that advertising provides useful information about firms (their existence, size, location, etc.) and their products (their existence, prices, qualities, etc.) and therefore *reduces* entry costs and makes demand curves *more* elastic than in the absence of advertising. We are meant to conclude, it appears, that because advertising enables the condition of perfect information to be more closely approximated, the standard welfare theorems regarding perfect competition apply and we can rely on the free market to provide an optimal quantity of all goods, including advertising.[1] There are two major flaws associated with this reasoning: (1) it simply assumes that advertising acts solely to inform rather than to persuade, and (2) it does not take into account the multitude of externalities that are involved in both the production and dissemination of information.

A more fundamental objection to either the view that advertising creates profits or that it enhances competition is that the level of advertising expenditures should be considered to be an endogenous variable, jointly determined along with prices, quantities of production, and rates of return. The term "cause" in a dynamic economic system may reasonably be assigned to the equations of the system, the values of exogenous variables, or even the initial values of endogenous variables. It is not reasonable to say that current values of one endogenous variable, the level of advertising, are the cause of current values of another endogenous variable, say profits.

Putting this argument in a different way, to ask whether advertising is a cause of profits in a particular industry is to ask how profit rates would change, or would have changed, in response to a change in the advertising-sales ratio. This response would differ depending on whether the source of the change in advertising was (1) a change in the tax laws regarding advertising, (2) the imposition of a quota on firms' advertising, (3) the prohibition of advertising, (4) firms' errors in determining their advertising expenditures, (5) a change in technology affecting the advertising media, or (6) some other source. Certainly, then, any question along the lines of "Does advertising cause profits?" or "Does advertising

[1] A more fair and balanced appraisal of Brozen's position would also discuss the empirical evidence he adduces to support his defense of advertising.

enhance competition?" is ill-posed without further elaboration. In reviewing the literature, one must first check that writers' positions are, or can be, posed in an unambiguous manner.

Writers who believe that advertising is in part responsible for concentration and profitability usually have one of two barriers-to-entry models in mind. One is the economies of scale argument, that the average cost of inducing a sale through advertising expenditure, presumably holding product type and price constant, falls with increasing advertising expenditure, thus leading to absolute size barriers to entry. As a matter of semantics, it is as misleading in this case to say that "advertising causes profits" as it is to say, in an industry with substantial technical economies, that "production causes profits."

In many respects economies of size in sales promotion are the same as economies of large scale production and require similar treatment.[2] However, there are two significant ways in which advertising is different: one is that many persons have the suspicion that advertising is inherently wasteful and that therefore advertising scale economies are only private, rather than public gains; the other is that advertising costs interact with demand conditions in a way that production costs do not—one can reduce advertising costs substantially simply by lowering price. To discuss these differences, however, it is necessary to construct a theory which explains advertising in an equilibrium context involving both supply and demand conditions.

The second barrier to entry model holds that existing firms' current or past advertising somehow creates "brand loyalty" which raises the cost of new firms' entry above the costs of entry that were originally borne by the existing firms. In this case higher advertising leads to greater entry cost differentials and to greater profits for existing firms. Why, then, do not firms in all industries make optimal use of advertising, leading to a situation in which all industries have identical, or only randomly varying, levels of advertising and profits?

The usual answer is to regard advertising as a proxy for an underlying, perhaps unobservable, exogenous variable, "product differentiability." According to Comanor and Wilson (1974, p. 130), this is defined as "the product and market characteristics that permit heavy advertising expenditures to differentiate effectively the products of a firm from its rivals." They continue, "Although these product and market characteristics are not easily measured, they are typically characterized by heavy advertising expenditures." The imprecision and circularity of this definition, in addition to the lack of any operational distinction between "heavy advertising" and "product differentiability," are plain to see. On the basis of this definition, we can conclude at best that the regression results show that it is some other "product or market characteristic" which determines both advertising and profits. However, Michael Porter's recent work buttresses Comanor and Wilson's position considerably at this point by providing a concrete description of some of these market and product characteristics. (See his paper, which follows this one.)

Returning now to the alternative school of thought, a study of the price of eyeglasses by Lee Benham deserves special attention because it provides a clear interpretation of the statement that advertising enhances competition. Benham's proposition is that the *prohibition* of advertising causes prices to *rise* by preventing firms from generating enough sales to

[2] Note how neatly this sidesteps the issue of what the required treatment is!

operate at an efficient scale. He tests this proposition by comparing the prices charged for eyeglasses in different states in 1963. He finds that in those states which totally banned the advertising of eyeglasses, the average price was approximately twice as high as in those states in which no restrictions were imposed.

To conclude this section, I would like to point out that the differences between the two schools of thought are not as irreconcilable as they might first appear. There is no contradiction in believing both that advertising is crucial in facilitating firms' entry into new markets and that these entry costs might be steep enough to discourage entry. It is not inconsistent to hold that indivisibilities associated with advertising on nationwide television create market power in certain industries, but that a government policy to severely curtail advertising in these industries would cause prices to become even higher.

## II. Advertising as Information and the Equilibrium Problem

A major reason why the controversy over advertising and profits is so enduring is that there is no agreement on the more basic issue of how advertising affects sales. We can be sure that firms' advertising does increase their sales, because thousands of businesses with millions of marketing research dollars to spend could not all be wrong. Yet we have only vague and conflicting notions as to why this is true. If consumers respond positively to advertising, then what is to prevent firms from advertising inferior, inexpensive to produce goods and making large profits? If firms tend to advertise goods with poor quality, then why would consumers continue to respond to advertising? To deal with such questions one cannot separate the demand and supply sides of a market as neatly as in standard partial equilibrium analysis. The quantity demanded by consumers varies not only according to the price, quality, and advertising expenditure of firms, but also according to the nature of firms' advertising strategies, which in turn depend upon consumers' demand functions. The problems of developing an appropriate equilibrium concept to handle this interdependence of consumers' and sellers' behavioral strategies is very closely related to the problems raised by Michael Rothschild in his survey of the search literature.

An ideal theoretical structure to resolve these problems would take as given four sets of parameters, representing

(1) consumer preferences conditional on consumer information and perhaps also the amount of persuasion to which the consumer is subjected,
(2) the technology of production available to the potential producers,
(3) the technology of information transfer between consumers and producers, and perhaps also the technology of persuasion, and
(4) the regulatory framework of the industry;

from these parameters and the past history of the industry, the theory would predict such variables as concentration, prices, product quality or variety, quantities produced, profit rates, and sales promotion expenditures, including advertising. Specific models within this framework would make simplifying assumptions designed to focus attention on key trade-offs, such as the consumers' choice between searching or relying on advertising and the producers' choice between achieving sales promotion via lowered prices, improved qualities, or increased advertising.

Progress toward developing such models has recently been made in several ways. Porter (1974), by exploiting often ignored aspects of demand and information transfer, namely the distinction between convenience and shopping goods and the role

of the retailer in influencing consumers' brand choices, has greatly improved the explanatory power of the usual advertising-profitability regressions. Phillip Nelson (1970) has shown that various industry characteristics may be explained by making a distinction between "search goods," whose qualities may be determined by inspection, and "experience goods," whose qualities can only be determined after purchase. The further category of a "credence good," defined by Michael Darby and Edi Karni as one whose characteristics cannot be determined reliably even after inspection, might also be exploited to explain advertising behavior.

In a more recent paper, Nelson (1974) proposes an ingenious explanation of why national consumers respond positively to advertising of experience goods, despite the fact that such advertising often contains very little direct information. The explanation is centered around the assumption that sellers differ according to their efficiency in meeting consumers' desires. Those sellers who can produce a given product more cheaply, or who can produce a better quality product at the same cost, will seek to expand their sales to earn the maximum possible returns. They will promote their products both by offering a better buy than competitors and by advertising more heavily. As a result, the most heavily advertised brands will also tend to be the best buys, and consumers will be rational in buying products solely because they are heavily advertised. A thesis proposal by Thore Johnson at Carnegie-Mellon verifies that this argument is indeed consistent by framing it in a rigorous mathematical model.

As a final example, I will outline a model of my own which focuses upon the role of advertising in informing consumers about the existence of individual producers and the prices of their products. The following assumptions are made:

(1) All consumers are alike in that they have a perfectly inelastic demand for exactly one unit of the product.

(2a) In order to buy the good, each consumer must learn the "address" of at least one seller. Each seller may advertise this information, along with the price of his product, free of charge to consumers, but at a cost to himself of $b$ units per consumer informed. However, advertising messages cannot be directed to particular consumers; the distribution of ads is assumed to be completely random.

(2b) Consumers may also receive price and address information by direct search at a cost of $c$ units per search.

(3) The product sold is homogeneous and all of a large number of potential sellers have the same constant returns to scale production function.

(4) The government ensures that firms fulfill their advertised promises to deliver the product at their advertised price.

In this market sellers' policies may be summarized by their advertising strategies; namely, their choice of how many ads to send out at which price (or prices). Consumers' strategies may be characterized by the rule according to which they decide to terminate search and purchase at the lowest price then known to them. An equilibrium is defined as a set of sellers' and consumers' strategies such that no seller can increase his expected profits and no consumer can reduce his expected costs (the purchase price plus the costs of search), taking all other agents' strategies as given.

From these assumptions one can determine uniquely the equilibrium number of ads sent out at each price and the number of sales at each price. One can perform comparative statics exercises that show,

for example, that an increase in the cost of advertising, $b$, reduces the equilibrium number of ads sent and increases both the mean and the variance of the sales price distribution. Furthermore, one can determine whether or not the market is efficient in the sense that in equilibrium the process by which consumers and sellers are brought together is conducted at the lowest possible cost. The answer is no; in all cases the amount of advertising is excessive relative to the amount of search. After a slight modification of the assumptions is made, one can ask what would happen if advertising were taxed or searching were subsidized. It turns out that if we ignore the cost of governmental intervention, a low tax on advertising (or subsidy of search) increases efficiency, but a large one totally destroys the market.

This model illustrates the wide range of questions that can be posed clearly and answered within the context of a precise mathematical model. The real trick, of course, is to formulate similar models which parallel the "real world" closely enough that we are interested in the answers. My own model is deficient in this respect, especially in that it ignores product heterogeneity; but I hope to have demonstrated at least that the search for more rigorous and precise models of advertising behavior is a desirable complement to the traditional activities of running exploratory regressions and developing verbal analyses to interpret them.

# Interbrand Choice, Media Mix and Market Performance

*By* MICHAEL E. PORTER*

We have seen considerable attention paid in recent years to building information into microeconomic theory. George J. Stigler's pioneering model of the buyer's optimal investment in information held promise for conceptual and empirical investigation of the effect of information costs on market outcomes. However, developments since Stigler have largely focused on the normative properties of equilibrium in markets where information is costly. While this is important work, I will argue here that information costs can explain differences among product markets in the observed behavior of buyers and sellers and their allocative consequences, and that these market outcomes have important implications for policy. This paper will outline a framework for modeling the cross-product variation in the observed pattern and level of product information flow. One implication of differing information equilibria across product markets is that the mix of advertising media utilized by sellers will vary from industry to industry. I will argue that this variation has important implications for market performance, and will test that hypothesis empirically here.

## I. Information and Interbrand Choice

A central result of costly information is that buyers choosing among the available brands of a product (*interbrand choice*) must invest in information gathering. Interbrand choice in product markets and the associated equilibrium of information are developed in detail in a forthcoming book (Porter 1976) and can only be sketched here. Buyers facing the choice among brands have numerous sources of information available: their own experience with the competing brands, advice from friends, salesmen, technical literature such as *Consumer Reports*, advertising messages in the various media, etc. Buyers gather information to the extent that they expect it to increase their utility, net of its cost, by directing them to the brand of a product whose attributes best meet their needs. I assume a given array of brands. (The seller can influence the buyer's information gathering process by innovation which alters this array. See Porter 1976.) The cost of information is measured in utility terms, and includes not only the time and dollar outlays to secure it but also the subjective gain or loss from the act of consuming it (compare watching a television commercial and reading a technical publication). Subject to the existence of systematic differences in the expected variance of quality among brands across products, the buyer will be willing to spend more on information gathering for a product which represents an important part of his income, or for which the perceived benefits of an informed choice are otherwise high.

Across products, the overall utility the buyer derives from the product, the set of product attributes he values and his utility ranking across these product attributes will, in general, vary. Information sources inform the buyer about attributes (price, style, reliability, etc.) rather than

* Graduate School of Business Administration, Harvard University.

about whether the product is good or bad overall. Because each information source informs the buyer about a different set of product attributes, he will divide his outlay on information differently for each product depending on how he values each set of attributes. In addition, each information source involves different utility costs and each source provides the buyer with information of differing perceived reliability and usefulness which causes him to apply different weights to it in his decision. For example, information from past experience is costless but may or may not be perceived as reliable by the buyer. Information from retailers' salesmen is more costly to gather than, say, advertising that comes embedded in entertainment or news. But a salesman's presentation is considerably more versatile in addressing the particular buyer's information needs than a standardized advertising message, as well as more expert and less biased toward the manufacturer since the manufacturer rarely controls the retailer directly. From these considerations the buyer simultaneously determines his total outlay on information and the portfolio of information sources he consults, both of which vary in general from product to product (as well as from buyer to buyer). The amount of advertising, for example, varies from product to product not only because of varying efficiency for supplying messages to buyers (Lester Telser 1964, P. K. Else 1966) but also because buyers' demands vary depending on advertising's perceived cost/benefit ratio relative to other information sources.[1]

The manufacturer of a product must decide his optimal outlay on the sources of buyer information that he controls or influences. He sets advertising levels on the various media directly. He influences the information the retailer provides about his product indirectly through his provision for the gross margin the retailer receives, through sales efforts directed at the retailer using his manufacturer's sales force, and through other services he provides the retailer such as cooperative advertising, financing, etc. The manufacturer's expenditure on each advertising medium and on influencing the retailer will depend in part on the buyer's information calculus, or how responsive the buyer is to messages from the various sources. It will also depend on the cost of placing messages before potential buyers via each information channel (the technology of converting dollars to messages placed before potential buyers of the product). If the product is sold to a small proportion of households, for example, it may be less efficient to utilize media that reach all households than more specialized media that cost more per message but are subject to less leakage.

From the responsiveness of buyers to each information source (the net revenue to the seller as a function of the number of messages received from that source) and the dollar cost of placing (or influencing) messages before the buyer from each source, the manufacturer calculates his optimal portfolio of sales promotion expenditures. The seller's optimal portfolio is affected by the presence of existing and potential competitors. The set of sales promotion portfolios chosen by competing sellers results from a market equilibration in which competing advertisers tend to drive up the cost and depress the effectiveness of any one rival's messages. Thus the observed levels of outlays on information transfer in a market will depend on three equilibrating processes: the buyer's information equilibrium, the individual seller's equilibrium and the market equilibrium reflecting the interactions of seller outlays

[1] Phillip Nelson's (1970, 1974) approach, though important in its focus on the buyer's information problem, also suffers from a lack of completeness. See Porter (1976).

on each other. Previous research has by and large focused on one of those at a time.

Such a process will, in general, cause the portfolio of information channels utilized by sellers to vary among products. It will also lead to market power at the retail stage, as was shown in an earlier article (Porter 1974). For some products the information supplied by retailers is more influential in determining brand choice than the information supplied directly by the seller (typically expensive, infrequently purchased products). The retailer's influence on the buyer's choice thus should yield him the ability to extract concessions from manufacturers, and this bargaining power is evident among the statistical determinants of the profits of consumer goods manufacturers. The interbrand choice process should also affect the process by which product innovations are diffused, because buyer's varying propensities to gather information influence the channel by which new or improved products can be promoted.

More broadly, information costs and the resulting interbrand choice process impel sellers to perform two complementary functions: producing (including innovation) their product and informing buyers about it. Imperfections in the market for "informing" may distort outcomes in the market for "producing." The firm most efficient at manufacturing or innovating may not be the most efficient in informing sellers about its product. In addition, we cannot map from the observed product and technology space to buyers' utility space because buyers will differ, in general, in their degree of informedness. This latter observation complicates the empirical analysis of product variety.

The process of interbrand choice leads to market power among sellers to the extent that sellers' information lacks perfect substitutes (because sellers can supply it more cheaply than alternative sources) and that select sellers have superior access to the channels of information than their existing or potential rivals due to imperfections in its supply. Some have argued that advertising and other information provided by sellers improves buyers' choices and hence improves market performance rather than detracts from it. Where providing information yields market power to sellers, the welfare benefits of better informed choice must be weighed against the welfare costs of the market power.

## II. Advertising Media Mix and Market Performance

Included in the array of possible information sources available to buyers are the various types of advertising media: network television, spot television, magazines, newspapers, etc. Since these media have differing utility costs to the buyer, provide information about differing attributes, and differ across products in their cost efficiency of placing messages before potential buyers, a consequence of interbrand choice and market information equilibrium should be that the media mix (or vector of seller outlays on each advertising medium) will vary from product to product. Such variation in practice is apparent to even the most casual observer of consumer goods industries. Furthermore, the variation in media mix is in large part exogenous from the seller's viewpoint, depending on characteristics of the product, buyer population and the technology of the media which are beyond the seller's control.

Is advertising fungible, or does the mix of advertising media occurring in a market have implications for market performance? One often sees the argument that printed advertising (e.g., magazines and especially newspapers) is more "informative" and hence of greater social benefit. Indeed,

printed advertisements often contain prices and other relatively objective information, which is contrasted by some to "persuasive" television advertisements. While this issue is an interesting one, it resists scientific analysis. The effect of media mix on allocative performance can be analyzed objectively, however.

A number of empirical investigations of the structural sources of market power have verified the importance of the level of advertising outlays in an industry in determining the average profitability of firms in it.[2] Does the mix of media adopted by sellers, as well as level of advertising outlays they choose, influence market power? There are strong reasons to suspect that it does. Advertising's effect on market power is due not to its effect on the buyer per se but to imperfections in its supply which give some firms systematic advantages in advertising over their existing and potential competitors. These imperfections operate primarily via the mechanism of entry barrier. Advertising leads to entry barriers because its provision is subject to economies of scale, creates absolute cost advantages for going firms and enhances the capital required for entry into an industry. This theoretical link, amended somewhat from the Comanor and Wilson view, is described in Porter (1976).

But the relationship between advertising and entry barriers will vary by advertising medium. The economies of scale in advertising depend on the threshold level of advertising required of entrants to achieve parity with going firms. Consider an entrant facing a market with going firms spending $X$ percent of sales on advertising. Under the best of circumstances, the entrant must spend $X$ percent of his sales on advertising to achieve a comparable level of product acceptance. (Of course a firm may choose to spend less but such strategy will be associated with lower levels of profitability [Porter 1976].) Apart from scale economies, the entrant may suffer an absolute-cost disadvantage in that the capital cost of establishing a given market share through advertising is greater for the $n + 1$th seller than for the $n$th.

What is less often recognized, however, is that entrant's disadvantage varies markedly depending on the media used by going firms, because the size of the "effective" threshold is different for different media.[3] Suppose that the going firms compete nationally but advertise solely in local newspapers. The entrant need offer his competing product only in one or more local markets, spending on advertising only enough to achieve parity there with its national competitors. Suppose, instead, that the going firms utilize network television or magazines reaching a national audience. Here the entrant, if he is to achieve parity in advertising, must promote his product to a much larger market and spend as much on advertising as the going firms regardless of his sales volume. National magazines, and to a greater extent network television are highly indivisible media with respect to geographic market boundaries and market size, and this indivisibility increases the effective threshold level of advertising on them the entrant must vault.

The divisibility of each medium by market size also depends in part on the structure of advertising rates used in the medium as well as the variety of competitors in each media type. While media rate structures are complex, we can sketch

[2] See William Comanor and Thomas Wilson (1974) and Porter (1976). Porter (1976, Ch. 6), discusses the standard criticisms of this result.

[3] These arguments also apply to the advantages of leading firms over their smaller rivals in the industry. For an extension of the concept of entry barriers to competition *within industries*, see Porter (1976, Ch. 4), and Richard E. Caves and Porter (1975).

some suggestive implications here.[4] The seller wishing to utilize network television must beam his message over a large percentage of the network's stations, which are comparable in number for the three major networks. Network rates are also roughly comparable across networks. However, spot television rates vary markedly across TV stations as stations' audience sizes vary. Thus a potential entrant can introduce his product and initially direct his advertising outlays to small cities with lower rates, moving to the larger cities as his scale increases; this option is not available in network advertising.

Magazines vary markedly in advertising rates, also depending on circulation and on the specialization of the readership (e.g., *Time* versus *Progressive Grocer*), the more specialized and larger circulation the higher the rates. For many of the large circulation national magazines, however, zoned or regional editions allow firms to utilize the media but direct the advertisements to a less than national market at a modest cost disadvantage relative to national advertisers. Newspaper rates also vary with circulation and specialization. In addition, in any given city there are typically a number of different papers with differing levels of these indices. Like magazines, the large circulation metropolitan papers usually have zoned editions which allow the advertiser to purchase an advertisement which will be seen by only a portion of the readership of the paper. These factors reduce the effective threshold. Magazines, though typically national, can in some cases be divisible by region by the advertiser. Newspapers are local, and are divisible even below the local metropolitan area in many cases. Thus the potential entrant faces smaller drawbacks with magazines than with network television, and less still with newspaper advertising.

In addition to a medium's divisibility by market size, the effective threshold depends on the absolute cost of a single message on each medium and the economies due to increased effectiveness of repeated messages. Absolute outlays vary by medium: sponsoring a half-hour program on network television in prime time requires an outlay on the order of $50,000 per showing; a full page color advertisement in *Business Week* costs approximately $14,000; a 30-second prime time spot television in Los Angeles costs approximately $4,000; and a full page advertisement in the *Chicago Tribune* costs approximately $8,000.[5] However, it is possible to purchase newspaper and magazine advertisements in varying increments down to the small fraction of a page at linearly decreasing rates. The minimum purchase of television advertising is the 10-second announcement, which is typically 50 percent of the cost of the standard 30-second commercial. Thus while sponsors can purchase network television advertising by the individual commercial through sharing programs, the smallest individual outlay is in the thousands of dollars as opposed to the tens or hundreds for the other media. These figures themselves do not suggest high absolute costs, but if a minimum message bombardment must occur (as suggested by Comanor and Wilson), they loom more significant. The argument that repetition must occur for effectiveness of messages would seem most significant for electronic media where the message is not available for repeating readings. This would tend to reinforce the greater minimum absolute outlays that television requires.

Finally, there has been intensive controversy over whether quantity discounts

[4] All rate structure information discussed below is derived from Standard Rate and Data Service, Inc., publications.

[5] The absolute outlays for spot television, magazines and newspapers vary by publication or station.

amplify any economies of scale in the repetition of messages. (See Comanor and Wilson 1974, pp. 53–61 and James M. Ferguson 1974, p. 78.) While the presence of quantity discounts is unclear in network television, published rate schedules do suggest volume discounts in spot television and for advertising in many magazines and newspapers. Neglected in the discussion of the quantity discounts issue, however, is the presence of great economies of scale in national over local TV advertising. There appears to be a distinct cost advantage to advertising via the network versus utilizing spot advertising. Network rates range from approximately 10 to 70 percent of the sum of the individual station rates, with the discount varying by time of day and season. This means that a potential entrant cannot effectively utilize spot advertising in a limited area to counter network advertising by going firms.

Taken together, this evidence suggests that network television advertising and to a lesser extent advertising in large circulation national magazines should have the most significant impact on market power. Local newspaper advertising carries the least impact. And other media probably fall somewhere in between. In addition, the significance of magazine advertising for market power should depend on the type of magazine utilized, since the effective threshold outlays on these vary with the geographic scope and specialization of the magazine.

## III. Empirical Tests

To test for the influence of the media mix on market power, I compiled data on advertising expenditures by media in 39 of the 42 consumer goods industries used in an earlier analysis of structure-performance relations (Porter 1974).[6] The core variables used in the study are: profit after tax as a percent of stockholder's equity, eight-firm concentration ratio, minimum efficient scale as a percent of industry sales, industry growth, a dummy variable for local or regional industries, absolute capital requirements for production at minimum efficient scale, advertising as a percent of sales ($A/S$), advertising per firm for the leading firms ($A/F$) and an advertising interaction variable ($INTER$) equal to the product of $A/S$ and $A/F$. In addition, the distinction between convenience and nonconvenience goods described in Porter (1974) was utilized here. To these were added data on relative outlays on national television, spot television, magazines, national newspaper supplements and local newspapers of leading firms in each industry in the sample. Although data for some media were not available, the ones included represent a substantial majority of estimated total media outlays.[7] To that extent they accurately measure the proportional expenditures on the principal media.

The average percent of total advertising outlays of the leading firms spent on each advertising medium were computed for each industry. $A/S$ for the industry was multiplied by the percent of total advertising accounted for by outlays on each advertising medium to approximate the ratio of the advertising outlays on each medium to sales:

$NET/S$ = network television advertising/sales

$SPOT/S$ = spot television advertising/sales

$MAG/S$ = magazine advertising/sales

$LOCNEWS/S$ = local newspaper advertising/sales

[6] The sources, construction and limitations of the media data are described in a technical appendix available separately from the author.

[7] See *Advertising Age*, May 17, 1971 for an estimated breakdown of total media outlays. Radio represented only an estimated 6 percent of outlays in 1968, and network radio only .4 percent. Other omissions are discussed in the appendix.

TABLE 1—MULTIPLE REGRESSION EQUATIONS EXPLAINING PROFIT RATES INCLUDING THE MIX OF ADVERTISING EXPENDITURES BY MEDIA

| | Intercept | Eight-Firm Concentration Ratio | Minimum Efficient Scale | Growth | Regional Dummy | Absolute Capital Requirements | A/S | INTER | NET/S | NATL/S | INTER 1 | INTER 2 | $R^2$ | Corrected $R^2$ |

*Note:* figures in parentheses are t values. The significance of the regression coefficients is tested using a one-tail t test and the significance of the coefficients of multiple determination is tested using the $F$ test.

[a] Indicates coefficient is significant at the 90 percent level.
[b] Indicates coefficient is significant at the 95 percent level.
[c] Indicates coefficient is significant at the 99 percent level.

From these ratios the following additional variables were constructed:

| | |
|---|---|
| *NATL/S* | = national advertising/sales, the sum of *NET/S* and *MAG/S* |
| *TV/S* | = the sum of *NET/S* and *SPOT/S* |
| *INTER 1* | = an interaction variable equal to the product of *A/S* and *NET/S* |
| *INTER 2* | = an interaction variable equal to the product of *A/F* and *NET/S* |

### IV. Results

Table 1 presents multiple regression equations incorporating the media-mix variables.[8] The results, subject to the usual deficiencies in the data, are striking. For the full sample of 39 consumer-goods industries, replacing *A/S* with *NET/S* increases the size and significance of the coefficient of advertising and the corrected $R^2$ of the equation, although advertising outlays on network television represented no more than 70 percent of total advertising. *INTER 1* produces a similar improvement, though not as striking. *NATL/S* yields results slightly inferior to *A/S*. Introducing the ratios for other media singly, additively, or in interaction form yielded insignificant (and sometimes negative) coefficients.

Consistent results are obtained when we partition the consumer-goods industries into convenience and nonconvenience goods—a distinction previously found central to understanding the influence of advertising on profitability. For convenience goods *NET/S* is more significant than *A/S* and improves $R^2$, while *NATL/S* performs even better. *INTER 1* similarly improves results over the results with *A/S*. Advertising intensities for other media alone and in combination yielded no significant variables, although the coefficient of *LOCNEWS/S* was consistently negative. The inclusion of the growth-concentration interaction described in Porter (1974) did not affect the results.

In nonconvenience goods, the respecified advertising interaction variable *INTER 2* (*A/F* * *NET/S*) produced major improvements in significance level and in corrected $R^2$. Again, other specifications of the media data were unsuccessful, though respecifying the advertising interaction variable using *NATL/S* was nearly as significant as the original advertising interaction variable (*INTER*).

Taken as a group, these results suggest that the elevation of market power due to advertising is primarily due to the size of advertising outlays on network television and magazines, especially the former. There is apparently little interaction between total outlays the firms make on advertising of all kinds and the share of advertising allocated to individual media. Other forms of advertising appear to have little significance for long-run market power, though they may well be central to maintaining market shares.[9] The requirement of matching competitor outlays on these media puts entrants at no serious disadvantage which would yield going firms market power.

### V. Conclusions

Our results, though tentative, reaffirm the importance of interbrand choice and of the technology of the various information channels utilized by sellers for under-

[8] The results for the other variables besides advertising are substantially similar to those described in Porter (1974).

[9] As one might expect, the correlation between *A/S* and *NET/S* is high (approximately .9 in convenience goods, .8 in nonconvenience goods). *MAG/S* was somewhat less correlated with *A/S* (.7 and .5 in convenience and nonconvenience goods, respectively) and *LOCNEWS/S* virtually uncorrelated with *A/S*. The fact that *NET/S*, and *NATL/S* improved the sta-

standing industry performance. Although some information is surely provided most efficiently by the seller, the marginal contribution of advertising to market power must be weighed against these benefits. Second, the equilibrium in the information markets that determines sellers' proportional outlays on the various advertising media is central to industry performance, because our results suggest that the media have asymmetrical implications for market power.[10]

We have much to learn about how information equilibria vary among product markets, and what influence is wielded by the technology of the various media for providing information to buyers. Such knowledge will not only illuminate the bases for market power but also amplify our understanding of intermarket variations in: levels of advertising by media, the structure of distribution channels and how they are located, the role of independent information sources such as *Consumer's Reports,* and the differences in such traits across countries and over time.

Such analysis is also central to policy-making. Our preliminary results suggest that social limits in advertising may be relevant to network television and to a lesser extent magazines, but not clearly to other media. The process of interbrand choice also has implications for improving the degree to which buyers make informed choices. Providing more information to consumers is not likely to improve the quality of choice without change in the parameters that determine the amount and type of information that the buyer consumes. Finally, the analysis of "consumer protection" should be related to a comprehensive model of consumers' investment in information.

tistical results allows us to reject the hypothesis that $A/S$ is the relevant variable, and that these new variables performed well statistically because of this collinearity.

[10] The occurrence of asymmetrical effects of the media on profitability argues against the view that advertising's effect on market power is due to the mismeasurement of profits in accounting data. (For a statement of this position, see Ferguson (1974). If mismeasurement was the cause of the result, it is difficult to see why outlays on different media would have asymmetrical impacts in measured profitability.

# Product Differentiation and Welfare

By MICHAEL SPENCE*

One of the functions of the market system is to select the commodities that are produced and sold. This process is variously referred to as product differentiation, product selection, and monopolistic competition. Product differentiation involves a set of real economic choices because there are increasing returns or declining average costs in the development, production, marketing and distribution activities of firms. The full range of possible products is neither feasible nor desirable in the presence of increasing returns to scale.[1] Product differentiation is also an important component of imperfectly competitive strategic interaction, both static and dynamic. Some would argue it is, in many industries, the most important part of the dynamics of competition.

My main purpose here is to discuss some of what has recently been learned about the welfare aspects of product differentiation and monopolistic competition in a market system. In order to do this, it is necessary to measure welfare, and I shall adopt the strategy of measuring welfare with the multiproduct net surplus, the difference between the benefits to consumers, gross of revenues paid, minus the costs of production.[2] A product's marginal contribution to surplus is the additional gross surplus it adds, minus the cost of producing it. That in turn is the area under the inverse demand function minus the costs of production. The total surplus, of course, is not the sum of these marginal surpluses; typically the total net surplus will be greater for products which are substitutes.

Everyone who is sensitive to the intricacies of market structure is aware that product differentiation has interesting information aspects, and that there is a collection of activities associated with marketing that bear on the demand for and sales of a product. I do not deal with these here, though they are important. But so are the limits of the price system in selecting products and product characteristics. These are the subject of this paper.

If firms are not perfect price discriminators, then the revenues of a firm selling a differentiated product are not equal to that product's contribution to gross surplus. Similarly profits are not equal to its net contribution to surplus. Revenues and profits are less than the gross and net contributions to surplus respectively. But profitability is the criterion by which products are selected or rejected in a market system. In the light of the divergence between benefits and profits, it seems reasonable to suppose that the criterion of profitability may not always lead to de-

* I am grateful to Richard Caves, Richard Nelson, and Oliver Williamson for their comments. Support for this research from the National Science Foundation and the John Innon Guggenheim Foundation is gratefully acknowledged.

[1] One can think of products being points in a continuous spectrum of attributes. The market selects a finite subset of points in the continuum, these being the products actually produced. For recent contributions to this subject, the reader can refer to Robert L. Bishop, Edward Chamberlin, Kelvin Lancaster, Bruce Owen and Spence (1975), and Spence (1975).

[2] For a discussion of the accuracy of this measure, see Robert D. Willig (1973).

sirable results. Indeed, that is the case.

This paper divides into three sections. In the first, I have attempted to summarize the forces that generate welfare problems in product selection, and the nature of the problems generated. There are several of these forces, and some of them work against each other. It is nevertheless useful to identify them and to understand the direction in which they push market outcomes. The second section deals with the magnitudes of welfare losses. In the past, some of the costs of imperfect competition have been measured by the cost of the nonmarginal cost pricing of the existing set of products. Using some numerical examples, I have tried to show that a significant fraction of the cost of imperfect competition may be due to the currently unmeasured cost of having too many, too few, or the wrong products. This analysis is far from decisive empirically, since it is based on numerical examples. It is however suggestive, that over a range of assumptions about the structure of demand and costs, product selection failures may be significant components of welfare costs.

In the third section, I have tried to outline, somewhat briefly, how the empirical study of product differentiation in an industry might proceed. The problem here is that the welfare analysis requires the estimation of the demands for products that currently do not exist. This line will be pursued more fully in subsequent papers.

The reader may find it useful to read this paper with the concrete case of television programming in mind. Pretend that pay television on the cable makes per program charges feasible.

## I. Welfare Problems in Product Selection

There are several market forces operating in the selection of products.

### *A. Profits and Net Surplus*

In the absence of price discrimination, the profits of the seller of a product will fall short of the net surplus generated by the product. Therefore, a product can have a positive potential net surplus and at the same time, be incapable of generating positive earnings. The exception to this principle is the case of constant or diminishing returns to scale in production. The fact that profits do not capture all of the net surplus is a conservative force, tending to eliminate products that should be made available. I hasten to add that this is one of several forces. It does not warrant the conclusion that there are too few products, or too little variety.

The tendency to lose desirable products is greater, the more substantial are the increasing returns or fixed costs.

### *B. Falling Average Costs*

In a monopolistically competitive market, without entry barriers beyond those imposed by the usual profitability requirement, prices are set above marginal costs, and entry occurs until profits are driven to zero, or equivalently until prices are equal to average costs. These statements technically apply to products that are symmetrically different in the way that it has become customary to assume in the theory. Since price is at average cost and above marginal cost, marginal cost is below average cost and average costs are declining at that point. It does not follow from this fact that there are too many products. It is true that there are more products than there would be if nonnegative profits were required and price were equal to marginal cost. It is also true that prices equal marginal costs in the first best optimum. But it is not true that the first best or second best outcome is achieved when profits go to zero. Profits can be above or below zero when the

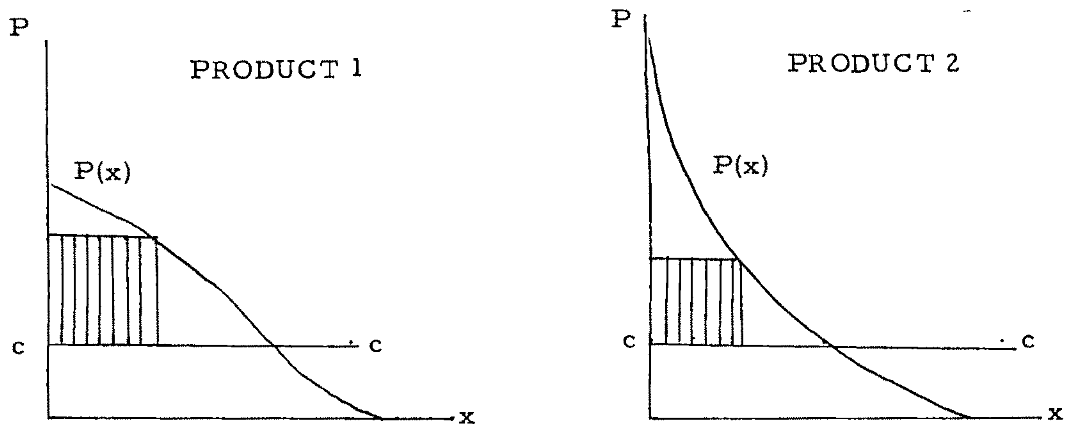

FIGURE 1.

marginal contribution of a product to the surplus falls to zero.[3]

This point is most easily seen for the case in which average costs decline indefinitely. In that case, if price equals marginal costs, profits are always negative. But it is not true in general that the optimal number of products is zero.

### *C. Revenues, Gross Surplus, and Biases Against Products*

Products are not equally subject to the conservative force discussed under (1) above. There are biases in product selection. Although revenues, in the absence of price discrimination, do not capture all of the gross surplus generated by a product, the fraction of the gross surplus that is or can be captured varies from product to product. The ratio of revenues to gross surplus depends upon the properties of the demand functions. Rather than analyze this in the abstract, let me illustrate the point with the case of constant elasticity demands. For the time being, I suppress explicit consideration of interproduct interactions. Let the price elasticity of demand for a product be $\eta$. It is easy to establish that at any price, the ratio of revenues to gross surplus (the latter being the area under the inverse demand function) is

$$\beta = 1 - 1/\eta. \tag{1}$$

Therefore, as $\eta$ rises, the fraction $\beta$ rises. The fraction of gross benefits that appear as revenues to the selling firm is larger, the higher the price elasticity of demand.

Since products vary in elasticities, it is quite possible for a product with a low price elasticity to have a higher net surplus and lower profits than a product with a high price elasticity of demand. This has two implications. The tendency to lose valuable products, discussed earlier, is stronger for low elasticity products. And second, the process of selection of products in a differentiated product industry will be biased against the lower elasticity candidates.[4]

The nature of the bias is illustrated in Figure 1. The first product has a lower

[3] The content of the so-called excess capacity theorem is therefore limited to the statement that at the equilibrium, average costs are still falling.

[4] This conclusion appears to run counter to the intuition developed in countless students of microeconomics, that low elasticities are nice for sellers because they permit higher markups. I don't wish to try to overturn this truth, but rather to point out nevertheless, that the surplus is harder to capture with the price system for low elasticity products. Let me put this more positively. I would expect the incentive for sellers to try to price discriminate would be higher for lower elasticity products.

surplus and higher profits than the second. The profits of both products in Figure 1 are positive. However, if there were a fixed component of costs, then the first product could be profitable and survive, while the second would not, even though the second one contributes more to the surplus. If the two products are substitutes, and if the market mechanism selects the more profitable, then again the first product will be taken.

If one does this analysis more rigorously, it turns out that it is *not* exactly the elasticity that matters, but rather what fraction of net potential surplus for a product is capturable by the selling firm. This depends upon both the structure of demand and of costs. But the qualitative nature of the bias is clear. If the potential consumers of a product have a highly variegated set of willingnesses to pay for it, so that there is a small group with a high willingness to pay, and then rapidly declining reservation prices after that, then the selling firm will have difficulty capturing the surplus, and the product will have difficulty being supplied under the market system. With some caution, one might refer to such products as special interest ones. They tend to be supplied by clubs or other institutional devices that do not use the pure price system.

### *D. Interactions Among Products*

Thus far, I have discussed forces that affect a single product. Let me turn now to interactions among products that are imperfect substitutes. Apart from biases in selection, interactions on the demand side determine whether there are too many or too few products, too much or too little variety. In what follows, I shall assume that products are substitutes, that they have fixed and variable costs, the latter being linear or convex, and that market equilibria are Nash equilibria in quantities. From a social point of view, the fixed component of cost can be regarded as an entry fee for having an additional product.

Perhaps the best way of approaching product interactions is to describe the circumstances that lead to too many products. They are two. The first is high own price elasticities, for these cause firms to contract output further away from the level at which price equals marginal cost. And that leaves "room" for further entry, room which would be absent with marginal cost pricing. But high own price elasticities are insufficient. The cross elasticities must also be high.

The entry of an additional product has several effects. It increases the surplus from the new product, but lowers the demand for existing products and causes them to contract output. In terms of the surplus, there are gains and losses. The gains are the profits and the consumer surplus from the new product. The losses are reductions in the profit and surplus from the existing products. When the products are close substitutes and the cross elasticities are high, the extra surplus created by the entering product is lost through contractions of existing firms. The familiar metaphor of expanding and slicing the pie is appropriate. A new product expands the pie and causes it to be sliced into more pieces. If the cross elasticities are high, the expansion is not large. But since there is a cost (the fixed cost) of adding a slice, the costs may outweigh the benefits. These forces will be illustrated in the calculations of the next section.

### *E. Half a Loaf is Better than None*

While profitability is not the correct criterion for deciding on the entry of a product, it is, for practical purposes, the only criterion we have. Nor is it likely that the information required to provide

the correct subsidies will ever be available. One can reasonably accept profitability as a constraint, and pose the problem of product selection as that of determining the right set of products subject to that constraint. The solution to the problem includes specification of not only the products, but also the prices. The prices will typically be above marginal cost, since that may be required to increase the profitability of products to permit the entry of products that are not profitable under marginal cost pricing. In short, the solution to the second best problem will include a trade-off between numbers of products on the one hand and the inefficiency due to nonmarginal cost pricing on the other.

Roughly, that is what occurs in a monopolistically competitive market. Therefore, the monopolistically competitive equilibrium has the qualitative features of the solution to the problem of maximizing the surplus subject to the condition that all products are profitable. It can happen that the equilibrium and the second best optimum coincide.[5] But in general, this coincidence is unlikely, and the best that can be said is that the equilibrium approximates the constrained optimum. The calculations that follow will give some insight into the question of how good the approximation is.

### *F. Complements*

I want to comment briefly on complementary products. Complementary products tend to be undersupplied by imperfectly competitive industries. That is to say, the prices are too high and the number of products is too small. The reason is that the tendency to hold back quantities reduces the demand for other products and makes entry more difficult, not easier, as in the case of substitutes. This means that all forces work in the same direction. The failure of firms to price at marginal cost reduces options for other firms, and entry is retarded, as well as expansion by existing firms. One would therefore expect complementary products to be supplied by multiproduct firms.

[5] See Avinash Dixit and Joseph Stiglitz (1974) and Spence (1976).

## II. Numbers and Variety of Products: Numerical Examples

In this section, I have taken some quite simple numerical examples, in which demand functions are linear and products are symmetrically different, and calculated the market equilibrium and two different optima, for a variety of the values of the parameters. The purposes of this are twofold. First, the interaction effects discussed above can be seen to work in the examples. Second, I want to show that the fraction of the total welfare loss that is attributable to the nonmarginal cost pricing of the equilibrium products, varies considerably, and is frequently less than half of the total welfare loss. The calculations also show that the equilibrium is often a reasonably good approximation to the constrained optimum, where the constraint is that profits be nonnegative.

Briefly, the basis for the calculations is the following. The quantity of the $i$th product is $x_i$. The inverse demand for the $i$th product is

$$p_i = a - 2bx_i - 2d \sum_{j \neq i} x_j. \tag{2}$$

The cost function for the $i$th firm is

$$F + cx_i. \tag{3}$$

In the calculations, $c$ is taken to be one. The remaining parameters, $a$, $b$, $d$, and $F$ vary. $F$ is the fixed cost, $d$ is the interaction effect; $a$ and $b$ are the intercept and slope of the inverse demand for each product, when there are no other prod-

TABLE 1

ucts.[6] Note that because of the symmetry of the example, an equilibrium is described by $x$, the output per firm and $n$, the number of firms.

In Table 1, $T$ is the surplus, $N$ is the number of firms, and $X$ is the output per firm. The table shows the equilibrium, the optimum, and a constrained optimum. The constrained optimum takes the equilibrium number of firms as given and prices the goods at marginal costs. The difference between the surplus here and the optimal surplus is the loss due to the nonmarginal cost pricing of existing products. The remainder of the welfare loss is due to product selection; in this context, having the wrong number of products.

A word about the table is in order. There are six groups of calculations, distinguished by own and cross elasticities. Within each group, fixed costs increase. Thus in group I, the own slope is -1, the cross partial -.5, and the fixed costs increase from 1 to 10. The numbers reported for each case are as follows. The subscript refers to the following cases:

1 — the optimum
2 — the market equilibrium
3 — the equilibrium number of firms with marginal cost pricing.

[6] The total surplus here is

$$T = \sum_{i=1}^{n} \int_0^{x_i} p_i(x, \ldots, x_{i-1}, s_i, 0, \ldots, 0) ds_i$$
$$= \sum_{i=1}^{n} \left( a - 2d \sum_{j=1}^{i-1} x_j \right) x_i - b x_i^2.$$

When $x_i = x$ for all $i$, the surplus is

$$T = n[ax - bx^2 - d(n-1)x^2].$$

The variables are

$X =$ output per firm
$N =$ the number of firms
$T =$ surplus
$\Delta T =$ the difference between the surplus for that case and the surplus at the optimum.

Notice that $N_2 = N_3$ so only $N_2$ is reported. $\Delta T_2$ is the welfare loss in the market equilibrium. $\Delta T_3$ is the welfare loss if the equilibrium goods were priced at marginal cost.

The calculations reported in the table illustrate a number of points. First the equilibrium number of products can be above or below the optimum. Cases of too few products tend to occur when cross elasticities are low relative to own elasticity, and fixed costs are high (see Groups III and IV). I should say here that linear demands have a strong tendency to produce too many products because the profit maximizing quantity is half of that when price equals marginal cost.

The welfare loss from the nonmarginal cost pricing of existing products ($\Delta T_3$) varies considerably. Often it is less than half the total welfare loss ($\Delta T_2$). Moreover, the cases where a substantial fraction of the welfare cost is associated with the wrong number of products vary. When cross elasticities are high (Groups I, II and V), they occur when fixed costs are low. When cross elasticities are low, they occur when fixed costs are high. These are also the situations where the optimal and equilibrium number of firms differ by a large percentage.

With nonlinear demands, similar effects hold; I do not have the space to report on them. The excessively strong tendency to get too many products can be avoided with other kinds of demands.

## III. Hypothetical Products and Product Characteristics

A natural starting point for theoretical welfare analysis of monopolistic competition is the multiproduct structure of demand. For welfare purposes, preferences for actual and potential products are the proximate determinants of welfare problems. What the underlying attributes are, that differentiate the products, are not by themselves directly relevant. In terms of location problems, locations by themselves have no welfare consequences until the distribution of purchasers is specified. The same applies to products located in higher dimensional spaces of attributes.

When one turns to the task of implementing the welfare analysis of product differentiation empirically, the importance of the attribute space in which products are located, is elevated considerably. The empirical study of product differentiation requires the estimation of the demand for hypothetical or potential, as well as actual, products. This is a difficult problem, to say the least. The most natural way to approach it seems to me to attempt to estimate the structure of preferences for attributes rather than products. The rationale for taking this approach is that if the distribution of preferences for attributes in the consuming population can be estimated, then the demand for any set of products (not just the existing set) can be computed from that distribution. Attributes then, provide one way of dealing with the demand for potential products.

There is a considerable literature on this general subject, much of it centering on probabilistic discrete choices in transportation demand.

The goal of the theory is to derive functional forms for the demands for products as a function of their attributes. Attributes include price, physical and perform-

ance characteristics, aspects of service and so on.[7]

Using the attributes approach, one can in principle, compute the demand for any set of products, not just the existing set. In that sense, the conceptual apparatus permits one to compute the demand for hypothetical products, and therefore with a certain amount of cost data to draw welfare conclusions about the product differentiation aspects of industry performance. In future work, I hope to report in greater detail on the attributes approach and its application to industry and product data.

[7] For a discussion of probabilistic discrete choice models, see McFadden (1973).

NEW YORK: RIPPLE OR TIDAL WAVE?

# The New York City Fiscal Crisis: What Happened and What is to be Done?

*By* EDWARD M. GRAMLICH*

The New York City fiscal crisis as it was played out in the nation's newspapers this year had all the elements of a first class drama. There was first of all the tension—would the city make it through its periodic financial hurdles, would the Ford Administration blink, what would happen if the city defaulted? Then there were the accusations—was it the fault of Wagner, Lindsay, Beame, Rockefeller, Ford, the unions, or economic and social forces beyond the city's control? Then the controversy—the issue seemed ideally suited to split deficit spenders from budget balancers, soft-headed liberals from hard-headed accountants, eastern establishment intellectuals from the silent majority. Finally, though it did not capture as much press coverage, the crisis also graphically illustrated several basic issues in the economics of federalism that are now creeping into public finance textbooks—the proper role of local and national governments in stabilizing the economy and redistributing income, whether the federal or the state government has an obligation to protect the financial integrity of local governments, whether public expenditures can be effectively controlled in the short run. This paper discusses the city's fiscal plight in the context of all of these issues.

* The Brookings Institution and Cornell University. I have benefited from discussions with Robert Reischauer and Harvey Galper and the assistance of Jack Whiting.

## I. How Big are the Deficits?

Local governments borrow for three reasons, two of which are generally acceptable to bond holders and one dangerous. The first acceptable reason is to finance long-term capital investment projects—if a locality is building a school that will last for many years, it does not have to pay the entire bill in any one year but can spread the cost over the lifetime of the school by floating long-term debt. The second acceptable reason is to smooth out seasonal fluctuations in revenues and expenditures by short-term borrowing. The final reason, which generally is not acceptable either by a city's laws or in the eyes of bondholders, is to cover a current account deficit.

The first fact to recognize about the New York City fiscal plight is that unfortunately the city has borrowed to cover current account deficits continuously ever since fiscal 1960–61. How this was allowed to happen is still something of a mystery, but the relevant data, from the official U.S. Census figures, are given in Table 1. The first column lists the gross revenue of the city—taxes, charges and fees, grants from the federal government and New York State, and revenue from the water and transit authorities (which have been combined with the general government in this analysis). The second column lists the current general government expendi-

tures for all functions, including water, transit, contributions to the pension retirement system, and expenditures to retire maturing debt (which can be considered as the measure of capital consumption expenditures when investment is financed by long-term debt). The deficits are in the third column, the level of capital expenditures in the fourth, and net borrowing in the fifth. The large current account borrowing, particularly in recent years, was not backed up by capital formation; as a consequence it had to be done in the short-term market, and the city now has both extraordinary levels of outstanding short-term debt and extraordinarily high "uncontrollable" expenses simply to roll over this short-term debt every year. In 1973–74, for example, the outstanding short term debt was $485 per capita, much higher than any other large city, and it would now claim 32 percent of current expenditures—almost the entire controllable portion of the expenditure budget—to pay it off if new lenders cannot be found.[1]

While these are certainly not reassuring figures, they are based on the latest available Census information and understate the magnitude of the current fiscal problem in three important ways. The first is that budget data are only available up to fiscal 1973–74, which is before the onset of the current recession that cost the city dearly. Had the city's unemployment rate in 1973–74 been what it is today (11 percent instead of 6.5 percent), the deficit would have been larger by about $500 million.[2] The second is that the Census

[1] Extensive data on levels of short-term debt per capita can be found in Data Resources, Inc., "New York City Default: Some Economic Implications." Only two cities, Rochester and Yonkers, have higher levels of short-term debt per capita. Rochester has a high credit rating and seems in fairly sound position; Yonkers has also been flirting with default all year.

[2] This estimate is derived as follows. Nationally incomes are reduced by 2.8 percent for every 1 percent increase in the unemployment rate. Were this to be the case in New York City, 1973–74 incomes would have been lower by 12.6 percent in this hypothetical recession. If income and sales tax revenues decline proportionately and property tax revenues and charges slightly, the revenue loss from lower income would have been about 7.5 percent, or $400 million. On the expenditure side, the increase in unemployment translates into a 130 thousand loss of private jobs. Nationally it has been estimated that one private job loss raises the poverty population by one person—were

basically takes the city's word on the breakdown between current and capital expenditures, and it has been admitted by city officials that many current expenditures were inappropriately classified as capital items. Were the more realistic Municipal Assistance Corporation (*MAC*) figures used, roughly $700 million would come out of the capital account and go into current expenditures, raising the current deficit by the same amount. The third is that it is generally conceded that the retirement pension funds, based actuarially on mortality tables from many years ago, are underfunded, meaning that present general government contributions do not cover the annual increase in liabilities of the funds. There is no good estimate of the extent of this bias, but it is perhaps not unreasonable to say that the true contributions should be larger by 25 percent, or $200 million. Were all of these changes made, the measured current account deficit of $488 million in 1973–74—already a very large number—might have been realistically estimated to increase by about $1,400 million, giving a predicted "low employment" current account deficit of nearly $2 billion, or about seventeen percent of revenues. The anticipated deficit for fiscal 1975–76 is somewhat smaller than this—approximately $800 million for the New York City version of the current account deficit, another $600 million of operating expenditures in the capital budget, and a still unknown shortfall in pension contributions—in part because of the cutbacks mandated by the New York State Financial Emergency Control Board.[3] Even with these cutbacks, however, the general picture is one of large and growing current account deficits, persisting for long periods of time, and bound to frighten prospective lenders and threaten default sooner or later.

### II. The Composition and Growth of the Deficits

The hypotheses that have been advanced to explain these deficits can be divided loosely into two groups. One type of explanation focuses on the power of the public employee unions in New York City, the bargaining concessions that have been won over the years, and the sheer size and ability to control votes of public employee unions.[4] A second focuses on the fact that the city finances an ambitious social welfare program on its own—it funds expensive welfare, higher education, public hospital, and public housing programs, along with a persistently large transit deficit and generous contributions to employee pension funds. In other large cities these programs are either not undertaken at all by the public sector, completely financed by grants or user charges, financed by the tax revenues of independent special districts, done by an overlapping county government or done by the state. Though all programs might be desirable at the national level, and in fact many argue that the city is doing a job made necessary by the lack of adequate national or state policies in these areas, it remains an inescapable fact of federalism that if localities try to redistribute income to a much greater extent than the other locali-

this true in New York, the private job loss would raise the welfare population and net expenditures by about 13.5 percent, or $100 million.

[3] See the Joint Economic Committee Report, *New York City's Financial Crisis*, November 3, 1975, p. 30 ff.

[4] A long catalogue of the bargaining concessions is given by Raymond D. Horton. An indication of the sheer size effect is given by the fact that there are now about 450,000 full and part-time city government employees in New York City. If each was married, lived in the city, and had one close friend or relative who would vote alike on city issues, conceivably 1,350,000 votes, 30 percent of the entire voting age population and roughly half of the probable number of voters, could be marshalled in favor of making some strategic concession to, or dealing leniently with, unions.

TABLE 2—COMPOSITION OF NEW YORK CITY BUDGET DEFICIT, FISCAL 1974
(Millions of current dollars)

| | | | |
|---|---|---|---|
| Revenues | 11,291.5 | Current expenditures | 11,779.1 |
| Grants | 5,076.3 | Normal functions | 3,769.5 |
| Normal functions plus untied | 1,442.2 | Schools | 1,726.3 |
| Schools | 872.4 | Marginal functions | 6,283.3 |
| Marginal functions | 2,761.7 | Welfare | 2,587.4 |
| Welfare | 2,393.1 | Higher education | 490.1 |
| Higher education | 196.0 | Transit | 989.7 |
| Public hospitals | 135.5 | Public hospitals | 1,088.1 |
| Public housing | 37.1 | Public housing | 294.3 |
| Own revenues | 6,215.2 | Pension contributions | 833.7 |
| Taxes plus normal charges | 5,186.0 | | |
| Marginal functions | 1,029.2 | | |
| Higher education | 72.0 | | |
| Transit | 629.5 | | |
| Public hospitals | 147.3 | | |
| Public housing | 180.4 | | |
| Current account deficit | 487.6 | | |
| Normal revenues | 6,628.2 | Normal expenditures | 3,769.5 |
| School grants | 872.4 | School expenditures | 1,726.3 |
| Current account deficit | 487.6 | Marginal functions deficit | 2,492.4 |
| | | Welfare | 194.3 |
| | | Higher education | 222.1 |
| | | Transit | 360.2 |
| | | Public hospitals | 805.3 |
| | | Public housing | 76.8 |
| | | Pension contributions | 833.7 |

ties, or if they run abnormally large deficits and incur subsequent high interest and debt retirement costs, there is a good risk that the taxpaying population will simply pick up stakes and leave the locality in a fiscal situation that much more precarious.

These competing hypotheses can be tested very loosely by examining the city's budget in more detail. Table 2 decomposes expenditures into a normal component—expenditures for functions normally undertaken by city governments—school expenditures—which are usually financed out of the budgets of independent school districts in other large cities—and the net deficit of each of these six "marginal functions"—marginal in the sense that they do not normally drain revenue from the city government. The total deficit on these marginal functions came to the enormous total of $2,492 million in 1973–74, almost five times the measured current account deficit.[5] It is of course true that often the deficits in the accounts of these marginal programs are related to union pressure, particularly in the case of pensions but also in the case of transit, hospitals, and higher education, but as an overall impression it does appear that the city's problems stem

[5] The Census gives total public welfare expenditures of $2,587 million and grants of $2,393 million in 1973–74, leading to a net deficit on the welfare account of only $194 million. Adjusting this figure to a 1975–76 basis would perhaps add another $100 million. This Census estimate of the drain due to welfare is just one-third of that given by a recent Congressional Budget Office report on New York City, which relied both on program information and on information from *MAC*. The difference is apparently caused by the fact that Census must be putting some medicaid expenditures into the public hospital category, but not medicaid grants. Correcting this problem with the Census data would alter the composition of the marginal functions deficit between welfare and public hospitals, but not the overall total. See Congressional Budget Office.

TABLE 3—THE GROWTH OF THE NEW YORK CITY BUDGET, FISCAL 1960–74
(Millions of current dollars)

| Fiscal Year | Normal Revenue plus School Grants | Normal Expenditures | School Expenditures | Marginal Functions Deficit | Current Account Surplus |
|---|---|---|---|---|---|
| 1960 | 2,154.5 | 1,170.3 | 415.0 | 526.1 | 43.1 |
| 1970 | 4,956.5 | 2,655.5 | 1,284.6 | 1,557.9 | −541.5 |
| 1974 | 7,500.6 | 3,769.5 | 1,726.3 | 2,492.4 | −487.6 |
| | | Per Annum Growth Rates (%) | | | |
| 1960–70 | 8.3 | 8.2 | 11.3 | 10.8 | — |
| 1970–74 | 10.6 | 8.8 | 7.4 | 11.8 | — |
| 1960–74 | 8.9 | 8.4 | 10.2 | 11.1 | — |

*Source:* U.S. Bureau of the Census, *City Government Finances*, various issues.

more from the fact that it subsidizes a broad array of functions than from the fact that the employees are gaining very high wages for performing normal public services.

This point is reinforced by examining growth rates over the 1960–74 period, as is done in Table 3. Over this time the net marginal functions deficit has grown by 11.1 percent per annum, more than expenditures either on the normal functions or on schools. Normal expenditures have grown by 8.4 percent, roughly 2.1 percent of which is a growth in employment, 2.4 percent is a growth in real wages per employee, and 4.0 percent is a growth in prices in New York City. School expenditures have grown by 10.3 percent—3.7 percent employment, 2.6 percent real wages, and 4.0 percent prices.[6]

### III. Comparison with Other Cities

It is also instructive to compare the New York City budget with that of the twenty nine other largest cities. This comparison can illustrate first the degree to which New York City is unique, and secondly the risk that the New York fiscal disease may spread to other cities.

Budget data for the general governments of the thirty largest *U.S.* cities for 1973–74 are given in Table 4. The budgetary items are grouped into normal and marginal functions categories, as was done in the bottom panel of Table 2, and are all expressed in per capita terms. Per capita expenditures on schools in the city are also shown in the table, even though New York City, Washington, Buffalo, Baltimore, Boston, and Memphis are the only other cities where school expenditures are actually in the general government budget.[7]

The table indicates first that only two large cities had current account deficits in 1973–74—New York City and Washington. But where New York City had to finance its deficit by borrowing from the bond market, Washington did not at the time have home rule and could borrow with federal guarantees (though this situation has changed as of January 1, 1976). Of the other cities, only Philadelphia had

[6] If the city's contribution to the pension fund were added into wages, the growth in real wages per employee would be slightly higher—2.6 percent and 2.8 percent respectively for normal and school categories.

[7] In the remaining cities schools are financed by an independent school authority. The data for schools comes from a different Census source that is not yet published for fiscal 1973–74. Thus data for the previous fiscal year are used throughout. Note that Honolulu has no local expenditures of any sort for schools because in Hawaii the schools are run by the state government.

TABLE 4—COMPARATIVE BUDGETS, THIRTY LARGEST U.S. CITIES, FISCAL 1973–74
(Dollars per capita)

| | Normal Revenue | Normal Expen-ditures | School Expen-ditures | Marginal Functions Deficit | Current Account Surplus |
|---|---|---|---|---|---|
| New York City | 962.1 | 493.0 | 207.0 | 325.9 | −63.8 |

[a] Excluding New York City, Washington, and Honolulu from sample.

a current surplus that was small enough relative to revenues that it would have been converted to a deficit had the city's 1973–74 unemployment rate been as high as it is now.

In terms of composition, it is again the marginal functions where New York City stands out. The net deficit on these marginal functions was $326 per capita in New York City, roughly the same as Washington, which is also a state government and therefore has a large budget for welfare, higher education, and public hospitals. The only other cities that have marginal functions deficits of more than $60 per capita are San Francisco (large transit subsidies and pension contributions), Boston (large pensions and public housing), and Detroit (large pensions).

Table 5 makes this comparison more systematically. The top panel compares New York's per capita budget figures with the mean for the twenty-seven other large cities (all those listed in Table 4 except New York, Washington, and Honolulu). New York's normal expenditures are $219 more than average, school expenditures are above average, and the marginal functions deficit is $286 more than average. Revenues are fortunately also $382 more than average, but the current account deficit is still $130 more than average.

It can be argued that these comparisons are misleading because New York City is not an average large city. Its racial composition, income levels, employment growth, and age are not extraordinary as cities go, but its population size and density clearly are (the population density in New York City of 25,000 per square mile is 2.5 times as great as the next highest). One way to correct for those factors in making budgetary comparisons is to run regressions for the twenty-seven city sample, explaining budgetary variables as a function of independent variables such as population size and density, income and poverty levels, federal and state grants, and regional and governmental structure dummy variables. Values for New York City can then be inserted in the regressions and budgetary totals "predicted" for a hypothetical city with all of New York's properties.

When this comparison is made, it cuts down but does not eliminate the deviations of New York's actual budgetary values from their predicted values. Information in the second panel of Table 5, based on regressions explaining the four right-hand budgetary variables, leads to a positive residual of $121 for normal expenditures, $228 for marginal functions, and $62 for the current account deficit. Information based on regressions for all five budgetary variables, estimated in a way that insures the budget identity is preserved, leads to positive residuals of $132 for normal expenditures, $227 for marginal functions, and $136 for the current account deficit.[8] However this comparison is made, New York runs a substantially greater current account deficit than is predicted on the basis of other cities, has somewhat greater expenditures on normal functions, virtually no greater expenditures on schools, and much greater deficits for marginal functions.

## IV. The Bond Ratings

One of the interesting sidelights in the gradual progression of the city toward default was that an investor looking solely at the ratings of New York City bonds would have gotten rather misleading information. Back in the early 1960's, when the city first experimented with current account deficit spending, the city's bonds were rated *A* by both Moody's and Standard and Poor's Investors Services—of "upper medium" quality. In 1965–66, when the deficits had persisted for five

[8] The two sets of regressions are reported in Appendix A.

years, both services downgraded the city's bond rating to *Baa*—of "lower medium" quality (the classification is labelled *BBB* by Standard and Poor's, but it means the same as *Baa* for Moody's). This caused a 50 to 75 basis point increase in borrowing costs and raised a continuing popular outcry by city officials and congressmen against the private rating services, even despite the fact that the market itself was at this time forcing New York to borrow at much higher rates than other *Baa* borrowers.[9] The lengthy political campaign eventually seemed to pay off, however, and in December 1972, Moody's upgraded the city bonds again to *A*, despite the fact that the very large current account deficits were just then beginning. Standard and Poor's behaved even more curiously, holding out against upgrading the city until December 1974, but then upgraded the city's bonds to *A* just as the early signs of a potential default were being raised.[10]

The rating services are private agencies, and though they publish voluminous information on the budget of borrowing governments, it is impossible to tell exactly how they arrive at their ratings. A statistical attempt to explain their ratings by Carleton and Lerner turned up population size, the debt-assessed value ratio, the average tax collection rate, and whether or not the borrowing agency was a school district as statistically significant independent variables, but still left a large random component to the ratings.[11] The school dummy and population variables were only included to measure the lower rating given smaller and more unknown borrowers—if the examination was confined to a sample of large city general governments, the ratio of gross outstanding debt to the assessed value of property in the district would be the only controlling factor. While it is certainly one good indication of credit worthiness, this measure is not fully adequate for several reasons—it contains no adjustment for grants from state or the national government, no adjustment for changes, income, or sales taxes, no account of the ability of the city to alter tax rates on assessed value, and it only recognizes indirectly whether the city is or is not actually running current account deficits.

It is possible to estimate whether, or when, Moody's was being fair to New York City by their own standards in much the same way as before. A regression was fit to data from the 19 other largest cities (excluding New York and Washington), using pooled cross-section data for 1955, 1965, 1970, and 1974. The dependent variable was a rating index (1 for *Baa,* 2 for *A*, 3 for *Aa*, and 4 for *Aaa*) and the independent variable was the debt-assessed value ratio. The results, in Table 6, indicate that *by their standards* Moody's did indeed appear to be penalizing the city in the 1965–72 period—the "predicted" rating throughout this time was *A*. In retrospect, of course, this penalty was quite deserved. However, even *by their standards,* the value of New York City securities began dropping in 1972, just when the city's rating was upgraded, and this *A* rating was retained right up until the city could no longer market any securities in April 1975. This shift in the rating was difficult to justify then, impossible now.

The more fundamental question, of course, regards the standards. It is difficult and possibly unfair to make a very

[9] In 1971 New York was forced to pay 7.75 percent for twenty-year *Baa* bonds, while Greenwood, Mississippi, paid only 5.8 percent for twenty-year bonds of the same quality. A fascinating account of this whole experience is contained in a "Background Paper" by John E. Petersen.

[10] This situation is described in more colorful terms by a news release of Senator Thomas Eagleton, November 26, 1975.

[11] See William T. Carleton and Eugene M. Lerner. Their results are corroborated in broad detail by other studies (see Petersen, Ch. 7).

TABLE 6—PREDICTED AND ACTUAL RATINGS, NEW YORK CITY BONDS
(Current dollar totals in millions)

| Date | Gross Debt Outstanding | Assessed Value of Property | Ratio of Debt to Assessed Value | Actual Rating[a] | Predicted Rating[b] | Predicted Less Actual |
|---|---|---|---|---|---|---|
| 1955 | 4,845.8 | 20,277.8 | .239 | 2.0 | 2.30 | 0.30 |
| 1965 | 7,459.2 | 29,752.7 | .251 | 1.0 | 2.27 | 1.27 |
| 1970 | 8,690.8 | 34,292.3 | .253 | 1.0 | 2.27 | 1.27 |
| 1974 | 13,508.7 | 38,529.2 | .351 | 2.0 | 2.05 | 0.05 |

*Source:* U.S. Bureau of the Census, *City Government Finances;* various issues. Moody's Rating Service, various issues.

[a] Scale used is as follows:
*Baa* = 1.0
*A* = 2.0
*Aa* = 3.0
*Aaa* = 4.0

[b] On basis of the regression:

$$\text{Predicted Rating} = 2.824 - \underset{(1.6)}{2.197}\,(\text{Debt/Ass. Val.}), \qquad R^2 = .03$$
$$SE = .85.$$
sample size = 76

The dependent variable was measured in the scale used in footnote a, and the regression was fit to pooled cross-section observations on the nineteen largest cities, excluding New York City and Washington, in 1955, 1965, 1970, and 1974.

forceful criticism of the rating services—no general obligation bonds rated by the services have defaulted in the postwar period, and their information and stamp of approval has surely played a role in that good record. As the New York City case illustrates, however, there is always a first time, and in retrospect the information provided by the rating services in this particular case was not so good. They correctly penalized the city in the 1965–72 period, but incorrectly backed down in 1972. This faulty information may reflect a possible weakness in the criteria apparently used by the rating services—specifically, the fact that the deficit position of the current account budget appears to have little or no direct role in the ratings—or it could also reflect the possibility that the ratings may have been influenced by political pressures from city officials.

## V. Impact on the Economy

The present fiscal difficulties of New York and other cities arise in part because of the economic recession, but there is also some reverse feedback. If the city defaults, or flirts with default, this may set in motion a chain of events that will threaten the recovery from the recession. It then becomes important to try to determine whether there are any such multiplier effects for the New York situation.

The most immediate problem is the capital losses on bonds in default. If the city were to be unable to meet all its obligations, in all likelihood bondholders would be the ones to take the first losses. A large share of the outstanding bonds are held by banks in New York, and there was for a time thought to be a risk that the losses would be so great as to trigger a flight of deposits from the city banks. Most of the risk from this quarter seems to have passed, however. It never was highly likely,[12] and now that the federal government has agreed to make short-term loans to the city, and the Federal Reserve to make discount loans to any banks in difficulty, the risk of a chain reaction col-

[12] See the Congressional Budget Office Report, p. 19, and Robert Samuelson, "Troubled Friend at Chase Manhattan," *The New Republic,* November 15, 1975.

lapse of banks because of the New York fiscal crisis is relatively slight.

A second possible way in which the New York fiscal situation could retard the recovery is through the direct cutbacks or tax increases required to balance the city's budget. The New York State Emergency Financial Control Board plan for balancing the city's budget calls for expenditure cutbacks of about $100 million in fiscal 1975–76, $500 million in fiscal 1976–77, and $700 million in fiscal 1977–78. This comes on top of a previous 6 percent expenditure cutback and 7 percent revenue increase already made by the city, and a further $200 million tax increase as part of the package which induced the Administration to agree to short term federal loans to the city. New York State, with its own financial problems, has also recently raised taxes by $600 million. The net effect of all of these actions seems likely to reduce the aggregate demand stimulus contributed by state and local governments by about $2 billion, leading to a reduction in *GNP* of approximately $4 billion below what would otherwise be the case.[13]

A third factor that must be considered is the impact on the state and local bond rate. This impact can be tested as follows. A regression was fit of the form

$$CORP\ (1-t) - RATE = a_0 + a_1 U + a_2\, TIME,$$

where *CORP* is the corporate *Aaa* rate, *RATE* is the municipal bond rate in the appropriate risk class (*Aaa, Aa, A,* or *Baa*), $t$ is the estimated average personal and corporate marginal tax rate among state and local bondholders, $U$ is the unemployment rate, and *TIME* is a time trend. The regression explains the rate differential between the after-tax corporate bond rate and the relevant municipal rate as a function of the unemployment rate (since state and local governments must borrow relatively more in a recession, their rate would rise relative to the corporate rate) and time (since municipal rates have been falling relative to the corporate rate over time). The equation was fit to halfyear data from 1955-74, and then extrapolated to 1975 to see how values predicted by the regression compare with actual municipal rates in 1975.

The comparisons are given in Table 7. For the *Aaa* rate, the actual municipal rate has averaged 13 basis points above the predicted rate throughout 1975, 20 basis points in the third quarter. For bonds in the more risky categories, the residuals are much larger, rising to a total of 103 basis points in the third quarter for *A* bonds and 96 for *Baa* bonds. This difference in risk spread demonstrates what Treasury Secretary William E. Simon calls a "flight to quality" in these hard times.[14] The problem, of course, is that in many cases the lack of quality might not be a function of the locality's own fiscal behavior but reflect the impact of outside uncontrollable forces such as the economic recession.

It is not clear whether the entire residual in 1975 actual municipal bond yields can be blamed on New York City, but it seems likely that a large component can. The residual is greatest in the higher risk borrowing classes the city is typically classified in and has become greatest when the news about the city's fiscal problems was the most alarming. If we make the extreme assumptions that the entire residual is caused by the New York situation and that the corporate rate is not *lowered* by

[13] These estimates accord with those of the Joint Economic Committee, p. 55.

[14] See Simon's statement of September 24, 1975. Among other things, the statement is ironic for the degree to which it downplays the risk that state and local interest rates will rise for high quality borrowers. Simon spent the first half of the year warning of the danger that federal deficits will raise interest rates for all borrowers and crowd them out of credit markets.

TABLE 7—PREDICTED AND ACTUAL STATE AND LOCAL BOND RATES, 1975
(In percentage points, by months)

[a] From the equation

$$CORP\ (1 - t) - RATE = a_0 + a_1 U + a_2\ TIME,$$ where *CORP* is the *Aaa* corporate rate, *RATE* stands for the four risk classifications above, $U$ is the unemployment rate, *TIME* is a time trend, and $t$ is an estimated average income tax rate. The equation was fit by half years from 1955–74. In all categories a value of $t=.2$ gave the lowest standard errors. The estimated coefficients (with $t$-ratios in parentheses) were as follows:

| RATE | $a_0$ | $a_1$ | $a_2$ | $R^2$ | $SE$ |
|---|---|---|---|---|---|
| *Aaa* | .021 | .003 (.1) | .038 (7.2) | .58 | .19 |
| *Aa* | −.096 | −.014 (.4) | .042 (7.5) | .78 | .21 |
| *A* | −.424 | — | .046 (7.6) | .78 | .23 |
| *Baa* | −.857 | −.015 (.4) | .064 (9.1) | .83 | .26 |

these troubles in the municipal market, the New York situation will reduce the extent to which state and local governments borrow to finance capital construction projects. Weighting the third quarter residuals by the proportion of borrowing in each risk class leads to an increase in the state and local bond rate of 63 basis points, which should by itself reduce state and local construction by about $4.5 billion.[15] The *GNP* impact of this would be about $9 billion in the first year or two, and when added to the impact of the direct cuts discussed above, both together would reduce *GNP* by .7 percent and raise the unemployment rate by about .25 percentage points over what it would otherwise be.[16] This is quite a large effect for the fiscal difficulties of just one city, large enough by itself to offset the tax cut recently passed by Congress.

Moreover, focusing only on this surprisingly large macroeconomic impact can obscure two points. The first is that if the city does default, and if that default does threaten the solvency of major New York

[15] Using an estimate derived in Gramlich and Galper, Table 4. This estimated construction effect is about the same as that given by F. Gerard Adams and James N. Savitt, though they anticipate a larger rise in state and local interest rates and use a smaller interest rate elasticity for construction.

[16] The interest rate effects are larger than those found by Ronald W. Forbes and John E. Petersen, because I have allowed the municipal *Aaa* rate to be affected by the New York City problem. I have not included observations from 1975 in the regression (as they did), and I have worked in the impact of the tax exemption of state and local interest payments (as they did not). The analyses also differ in that my calculation focuses on the probable effect on state and local borrowing and investment, whereas theirs focuses on the rise in interest payments, assuming that borrowing is unaffected.

banks and cause a loss of deposits, the situation becomes much more uncertain and the risk of a general collapse of borrowing and investment much greater. In this context, one great advantage of bailing out the city is precisely this—it keeps the general economic risks predictable and manageable.

The second point is that this estimate of the impact of any New York default is only manageable for the country as a whole—the impact on the economy and the citizens of the city itself will be extremely painful. Table 5 showed that per capita taxes are already much higher in New York than in other cities, and the measures taken to put the city on a sounder fiscal footing will raise them further, increasing the risk of a flight of the taxpaying businesses and households to other localities. On the expenditure side, the *MAC* figures project that by fiscal 1978 55 percent of the city's expenditures will be "uncontrollable"—mandated for interest, debt service, welfare, and pension payments. This forces very deep cutbacks in the remaining controllable portion, estimated by the Joint Economic Committee to be 18 percent in real terms. Even with a freeze on money wages, these are severe cutbacks. And even these severe cutbacks might not be adequate to balance the city's budget by 1978 if they lead to other reductions in federal and state grants mandated for the programs cut back or if they reduce levels of economic activity and revenues in the city.

## VI. What is to be Done in the Short Run?

It is generally easier to analyze what went wrong than to say what to do about it. Several principles do emerge from the preceding facts, however, and I will try to highlight the pertinent ones.

The first is that the city itself is ultimately responsible for its financial woes—the budget deficits started long ago, in part because of official underestimates of the severity of the problem; the deficits were large even before the current recession, and not caused by any one particular program but a host of them. The second is that even though the problem is of the city's own making, things have reached such a point that now the city simply cannot correct the problem by itself—tax burdens in the city and state are already extremely high, uncontrollable expenditures are extremely high, and the cash expenses necessary to roll over the short-term debt when the market will not are excruciating. Even with the severe cuts in expenditures mandated by the Emergency Financial Control Board, it will take the city three years to restore balance in its budget, and only then under relatively optimistic assumptions regarding future revenues.

The question facing the national government is whether to take steps to avoid the city's having to default on the bonds it must retire in the near future.[17] If this were not done, there is at least some chance that a financial panic could develop, and some chance that the economic recovery could be aborted even if a panic did not develop. There is also an excellent chance that the delivery of vital services in the city—police, fire, sanitation, health, education—could be temporarily or permanently disrupted by default, and that it would be very difficult to pick up the pieces. Minimizing each of these fears is essentially the rationale for not allowing the city to default.

On the other side, the advantage of a default is that the city has in fact signed certain contracts that it is simply unable to meet, it has to improve its budget pro-

[17] Default in this sense means having the court, and not the Emergency Financial Control Board, take over the reconciliation of inconsistent claims on the city. In a narrow legal sense, one could argue that the recent state action to substitute *MAC* bonds for some of the maturing city debt implies that the city is already in default.

cess and reduce its deficits, and it never will unless it is forced to go through the default process. The last assumption is the key one—by this time the state itself and through its Emergency Financial Central Board has exerted so much control on the city that it effectively lost its budgetary autonomy and will have to abrogate some contracts, whether or not there is a default. Given this, these marginal benefits of a default are probably unimportant and it seems almost foolish to risk the possible severe dangers of allowing the city to go under. By this time, all but the most hard-nosed conservatives appear to agree with this position.

## VII. Long-Term Measures

The city's plight does illustrate several more long-term issues, however, and it is well to emphasize them before such crises recur. The first is that better state and local financial accounting is urgently needed. There is no obvious reason why the budgets of large state and local governments could not be more quickly made available to the financial community, tabulated in standard form, using official conventions on what is current and what capital spending, on the increase in pension fund liabilities, on the size and maturity of outstanding debt. Whether the bond rating authority is then brought under the Securities and Exchange Commission, as Senator Eagleton wishes, there should also be much more explicit statement of why bonds are rated as they are, the criteria used, and the data behind these criteria.[18] As a specific suggestion, the rating agencies have apparently relied solely on stock figures such as the ratio of debt to assessed property values; it would seem that flow figures such as the recent size of current account surplus, the controllable portion of the budget, and the dangers in not being able to roll over short term debt should also enter in.

A second point regards the intrinsic financial difficulties of state and local governments when macroeconomic conditions change. State and local revenues are now composed largely of income and sales taxes—those two sources comprised 60 percent of own revenue in 1973—and net expenditures for welfare and medicaid have also become very large. When aggregate conditions change, state and local budgets will tend to operate in an automatically stabilizing manner just as will the federal budget. The only difference is that the inability to run current account deficits at the state and local level forces the stabilizers to be offset by other spending costs or tax increases. It can, of course, be argued that governments should have had the foresight to build up a stock of liquid assets for just such an emergency. This argument is not terribly persuasive in a time like the present, however, when the business cycle decline is so much steeper than any government could possibly have anticipated. In any case to illustrate the problem, a special Joint Economic Committee survey of eighteen large cities found only five that did not raise taxes or cut spending in the past year.[19] This is both counterproductive from a macro standpoint and, more importantly, it leads to instability in the delivery of services at the state and local level. A sensible remedy would be to give out revenue sharing money on a countercyclical basis, as Senator Muskie wants to do. It was emphasized above that the recession was not at the heart of New York's woes, and these woes would have only been modestly ameliorated by a countercyclical revenue sharing program, but they would have been ameliorated and the program would still seem to have appeal in a cyclical economy.

[18] See, for example, the Twentieth Century Fund.

[19] Joint Economic Committee, p. 29.

A final point involves the redistributive nature of the city's social programs. As was argued earlier, New York's difficulties can in large part be traced to the fact that it was doing too much on its own. In some cases—pension contributions, higher education, transit subsidies, public hospitals—the choice was the city's own; in others—welfare and medicaid—the choice was made by the state and mandated on the city's budget. Laudable as these choices may be from a social standpoint, local governments do have to be careful in a federal system, first, not to laden taxpayers with too much debt and forced debt service payments, and, second, not to undertake too much redistribution at the local level. If these programs are to be done, they must at least be financed on a national scale. In this sense, the New York experience can also be interpreted as something of a setback for the new federalism, which some advocates interpret as turning functions such as income redistribution back to the states and localities.

# The Effects of Family Background on Earnings

By Mary Corcoran, Christopher Jencks and Michael Olneck*

Men with socially and economically privileged parents usually earn more as adults than men with less privileged parents. There is no reason to suppose that men with privileged parents have a stronger preference for cash as against psychic income from their work. If anything, the contrary seems likely. It follows that men with privileged parents are either more valuable to "rational" employers, search more effectively for lucrative jobs, or benefit from positive discrimination by employers based on either background per se or its correlates. This paper tries to assess the importance of each of these factors.

Both the size and apparent causes of earnings differentials between men from different backgrounds depend to a considerable extent on how you define background. We will begin with a set of parental characteristics that are widely believed to enhance a child's life chances: being white, being born in the United States, having a lot of education, engaging in high-status occupations, having a substantial income, living in the North rather than the South, living in an urban area rather than on a farm, having relatively few children, and not being separated or divorced. The top rows of Table 1 list four national surveys of men aged 25–64 that provide data on most of these parental characteristics. The data cover only males.[1]

The standard deviation of the natural logarithm of earnings (LnEarnings) is higher in the first and last of these four surveys than in the two intervening surveys. This is due to methodological differences. The two intervening surveys were conducted by Survey Research Center (*SRC*) and cover only heads of households. This eliminates some very low earners. *SRC* also locates fewer household heads who report very low earnings. This may be because *SRC* at the University of Michigan has a lower response rate than the Census or Current Population Survey (*CPS*), or because Census and *CPS* respondents (who are often wives) understate the household head's earnings more than *SRC* respondents.

Almost all the parental advantages

| Sewell et al. (1967) | Wisconsin | Nonfarm men who reached 12th grade in Wisconsin | 27(±1) | 2,069 | 3, 4, 6, (7), (8), 11 | Yes | .532 | .051 (.009) | |

[a] *CPS* = Current Population Survey, U.S. Bureau of the Census; Talent = Project Talent, American Institutes for Research, Palo Alto; *SRC* = Survey Research Center, University of Michigan; *NORC* = National Opinion Research Center, Chicago.
[b] 1 = white, 2 = father born in United States, 3 = father's education, 4 = father's occupation (Duncan scale), 5 = father white collar, 6 = mother's education, 7 = son's region of birth, 8 = son raised on farm, 9 = number of siblings, 10 = son not living with father when 15, 11 = parental income at 17. Variables in parentheses have no variance due to sample restrictions.
[c] Values predicted using all background variables in column 6, including significant nonlinearities and interactions.
[d] (column 8) $(r_i)^{1/2}$, where $r_i$ = intraclass $r$ in parentheses.
[e] Ln Income.
[f] Ln Hourly Wage.
[g] These regressions include age. Without age $R^2$'s are .055 for Kalamazoo and .051 for *NORC*.

listed above had positive effects on men's earnings. The only surprise is that men with foreign-born fathers earn about 10 percent more than men with American-born fathers in the three surveys that measure father's place of birth. This advantage disappears once we control region of residence and community size, but even then no disadvantage emerges. Almost all the background traits had essentially linear effects on LnEarnings. The exception was family size. Additional siblings always lower a man's expected earnings, but the negative impact diminishes as the absolute number of siblings increases. While a few other nonlinearities were significant in at least one survey, none had a consistent sign across all the samples and none was significant in more than one.

Since different surveys measured different background characteristics, the multivariate results are not strictly comparable. But no multiplicative interaction between different parental characteristics was consistently significant across surveys, or even had a consistent sign. Taken together, nonlinearities and interactions never accounted for more than .6 percent of the variance in LnEarnings in any survey, so we will ignore them hereafter.

If one compares the first two national surveys of men aged 25–64 to the last two, the variance explained by background characteristics declines from a weighted average of 17 percent in 1961–

64 to 11 percent in 1971–73. Given the many differences between samples and variables, this change proves nothing in itself. But *CPS* also conducted a meticulous replication of the 1962 Occupational Changes in a Generation (*OCG*) survey in 1973. Featherman and Hauser, using untransformed earnings, report that for married men aged 25–64, the coefficient of variation was the same in 1972 as in 1961, but the percentage of variance explained by father's occupation, farm upbringing, and number of siblings fell by 40 percent. This suggests that we should not write off the decline in $R^2$ in Table 1 as a methodological artifact.

Column 9 of Table 1 shows the standard deviation of predicted earnings for each sample. This indicates the degree of inequality we might expect if the parental advantages and disadvantages measured in these surveys were the only source of inequality in sons' earnings. The standard deviation of predicted incomes was .334 in 1961. Men whose parents ranked in the bottom quintile earned 60.4 percent of the national average. Those whose parents ranked in the top quintile typically earned 1.48 times the national average. Assuming a 40 percent decline in the variance traceable to parental advantages between the early 1960's and the early 1970's, the standard deviation of predicted incomes should have been .258 in 1972. This is quite close to the observed standard deviation of predicted earnings for 1971, which was .264 in the Panel Study in Income Dynamics (*PSID*). It is higher than the 1973 estimate from the National Opinion Research Center (*NORC*) brothers survey, which was only .220. But the *NORC* brothers survey included only 300 respondents, so the discrepancy could easily be due to sampling error.

None of the national surveys listed in Table 1 measured parental income. The one survey that does include this information covers Wisconsin high school graduates. In that sample average parental income when the son was 17 to 21 (taken from state tax records) had a significant impact on the son's earnings at age 27; a 1 percent increase in the parents' income was associated with an .08 percent increase in son's earnings at 27 years.[2]

More accurate measurement of father's education, mother's education, and especially the father's job characteristics might also increase the apparent explanatory power of parental status. But we doubt that correcting these problems would raise the variance explained by these traits by more than 50 percent. It would have less effect on the explanatory power of traits like race, region of birth, farm upbringing, and number of siblings which are already quite accurately measured and account for as much of the variance in earnings as parental education and occupation. We therefore suspect that even if we measured the parental traits listed in Table 1 altogether accurately, we would not be able to explain more than about a sixth of the variation in earnings today.

But why should backgrounds explain even a sixth of the variance in earnings? Our data suggest that employers hire and promote largely on the basis of the applicant's own characteristics. Controlling test scores and educational attainment makes the coefficients of father's education, father's occupation, number of siblings, and coming from a broken home extremely small and usually insignificant. Southern birth and farm upbringing exert some effect even among men with similar test scores and education, but these effects become negligible once we control the size of the community and region in which the respondent now lives. This suggests that

[2] These results are based on unpublished materials supplied by William Sewell and Hauser.

employers pay very little attention to whether a man is southern or farm born. These men are handicapped partly because they get less education and have lower test scores, and partly because they usually remain in communities where everyone is paid less than in the urban North.

The only background characteristic that has a substantial effect on earnings with *everything* controlled is race. Race is, of course, not just a characteristic of the respondent's parents but a visible characteristic of the respondent himself. The fact that employers paid blacks less than whites with the same test scores and the same amount of education strongly implies that in this instance employers engaged in "pure" discrimination.

So far we have concentrated on the effects of measured parental advantages. If these were the only parental characteristics that affected a child's earnings, we would expect children who had had the same measured advantages to end up as much alike as children who were actually raised in the same home. To determine whether this is true, we have looked at several surveys of brothers. Table 1 describes the samples. Even allowing for a secular decline in the impact of parental status, measured background characteristics explain less of the variance in earnings in our three samples of brothers than in our larger national samples. In the case of the *NORC* brothers this is probably just a matter of random sampling error. In the case of the Kalamazoo brothers, the target population may be atypical. (Note the severely restricted variance of LnEarnings.) In the case of the Talent brothers, the respondents are only 28, and no variable correlates as well with earnings at 28 as later. Whatever its causes, the low explanatory power of measured background characteristics implies that the correlation between brothers in these three samples may be lower than it would be in a representative national sample. Our suspicions on this score are strengthened by the fact that Brittain of the Brookings Institution obtained an intraclass correlation of .436 between the earnings of 151 men from 66 families from the Cleveland area. If we ignore the Talent sample on the grounds that it is too young to prove much, and pool the *NORC*, Kalamazoo, and Brittain results, we get an estimated intraclass correlation between brothers' earning of .23, with a standard error of about $\pm$ .04.

Unless brothers exert a direct effect on one another's earnings, the intraclass correlation between their earnings is equal to the percentage of variance we would be able to explain if we regressed earnings on all the genetic and environmental factors that brothers have in common. The intraclass correlations are at least twice as large as $R^2$ in each of our samples of brothers. This suggests that unmeasured background characteristics exert as much impact on earnings as the measured characteristics discussed earlier. Note, however, that most of the variance in eventual earnings is still within families.

If the unmeasured family characteristics that produce resemblance between brothers were similar in character to the measured characteristics that produce such resemblance, we would expect the unmeasured characteristics to exert most of their influence indirectly, via test scores and educational attainment. The data in Table 2 show that this is not the whole story. If the *NORC* brothers' earnings were alike solely because their educational attainments were alike, for example, the correlation between their earnings would be only (.356) (.528) (.356) = .067, not .129. If test scores and education together accounted for resemblance between brothers' earnings, the correlation between Kalamazoo brothers would be .113, not .220. This means that

TABLE 2—CORRELATIONS BETWEEN BROTHERS' CHARACTERISTICS

| | $X$ | $Q$ | $U$ | $Y$ | $X'$ | $Q'$ | $U'$ | $Y'$ |
|---|---|---|---|---|---|---|---|---|

| | — | — | .171 | .129 | .124 | — | .355 | 1.000 |
| $Y'$ | .197[a] | .169 | .269 | .220 | .200 | .366 | .409 | 1.000 |
| | .094[a] | .216 | .210 | .207 | .096 | .356 | .356 | 1.000 |

*Note: NORC* (top row), Kalamazoo (middle row), Talent (bottom row).
$X$ = respondent's report of father's occupational status at 15 (Duncan score)
$Q$ = test score prior to school completion
$U$ = Highest grade completed
$Y$ = LnEarnings
Primes denote the second member of a given pair. All correlations were computed from files in which every pair appears twice, with order reversed. This makes product-moment correlations equal to intraclass correlations.

[a] In a few cases where reports of father's occupation were missing, the report of a brother was substituted. Therefore, the correlation between $X$ and $X'$ is slightly higher than the reliability coefficient.

unmeasured background characteristics must affect earnings in some way that is independent of test scores and educational attainment.

We can think of at least two ways in which unmeasured family characteristics could affect men's earnings independently of test scores and educational attainment. One possibility is that certain families socialize their children and develop noncognitive skills which are largely independent of test scores and educational attainment but still valuable to employers. If we accept the notion that "like produces like," then children who have these interpersonal skills are likely to come from homes where parents also possess these skills. If employers value these interpersonal skills, then parental traits which produce these skills should be correlated with parental status.

Another possibility is that some fami-

lies encourage their children to maximize earnings, while others encourage their children to maximize other forms of psychic income, even at the expense of earnings. If this were the case, we would expect the unmeasured family characteristics that maximize earnings net of test scores and educational attainment (i.e., parental values) to be quite different from those that maximize test scores and educational attainment. Indeed, the correlation might well be negative.

If one constructs a hypothetical variable to account for resemblance between brothers' test scores, another to account for resemblance between their educational attainments (over and above what is expected on the basis of test score similarity), and a third to account for resemblance between earnings (over and above what is expected on the basis of similar test scores and education), the last of these variables has a very weak, sometimes negative correlation with the other two, also with father's occupation. This suggests that our hypothetical variable does not primarily measure parental noncognitive skills valuable to employers. Rather our hypothetical variable may to a large extent be a proxy for familial values, and may be picking up a preference for monetary rather than nonmonetary rewards.

Our analyses appear to support three conclusions:

(1) Employers do not often discriminate directly against employees on the basis of parental characteristics other than race.

(2) Parental characteristics exert considerable influence on children's test scores and educational attainment, which in turn influence their earnings.

(3) Unmeasured parental characteristics also exert considerable impact on son's earnings, independently of test scores and educational attainment. The unmeasured characteristics that create these effects are almost uncorrelated with measured advantages that we and other investigators have found to influence men's earnings. This suggests that parents may influence children's preferences for cash versus psychic income.

# Intergenerational Transmission of Income and Wealth

By Jere Behrman and Paul Taubman*

Parents can transmit income and wealth to their offspring directly through bequests and gifts of financial assets. Parents can augment a child's skills and traits through the provision of, for example, education, diet and doctors. Biological parents also supply the genetic endowments which provide skills useful in the labor market. Although practically a virgin territory, it is important to estimate the effects of genetic endowments and common (mostly family) environment on earnings and on other indices of individual attainment in order to gauge the effectiveness of programs designed to improve equality of opportunity. Also if genetics and common environment are not controlled for, biased estimates of regression coefficients of observable variables, such as years of education, often are obtained.

In this paper we first summarize some evidence relating to the relative contribution of genetics, common environment, and other environment (as well as covariance terms) to the total variance of four indicators of individual attainment: years of education ($ED$), socioeconomic status of initial civilian occupation ($SES_0$), socioeconomic status of occupation in 1967 around age 45, ($SES_{67}$), and earnings in 1973 around age 50 ($Y_{73}$). We then present regression results for these four indicators, in part to illustrate the importance of biases introduced by ignoring genetic and environmental factors.

For both parts of the paper the empirical estimates are based on the National Academy of Science—National Research Council twin sample which is drawn from white male, veteran twins born between 1917 and 1927. The sample consists of about 2000 twin pairs, roughly evenly divided between monozygotic ($MZ$ or identical) and dizygotic ($DZ$ or fraternal) twins (see Taubman for more details). For both parts of the paper a recursive model is assumed among the above four indicators: education affects socioeconomic scores and earnings, initial occupational status affects mature occupational status, and mature occupational status affects subsequent earnings.

## I. Contributions of Genetics and Environments to Total Variance of Four Indicators of Individual Attainment

In addition to the recursive structure described above, this analysis assumes that there are genetic indices ($G$), two environmental indices ($N$) and four random variables ($v_i$) in the system. The random variables are assumed to be uncorrelated across brothers and equations, with direct effects only on their own indicator. We also assume that genetic effects are additive, that mating is random, that the noncommon environment of one $DZ$ brother is not correlated with his brothers' genes, and that the correla-

TABLE 1—PERCENTAGE OF TOTAL VARIANCE ACCOUNTED FOR BY GENETICS AND ENVIRONMENT

| Variable | $\rho$ | Genetics | Total Environment | $G$ and $N$ Covariance | Common Environment |
|---|---|---|---|---|---|
| Education | .65 | 42% | 58% | 0% | 37% |
| | .62 | 28 | 53 | 10 | 33 |
| | .60 | 13 | 50 | 19 | 30 |
| Initial occupation *SES* | .11 | 13% | 86% | 1% | 9% |
| | .13 | 8 | 88 | 2 | 11 |
| | .16 | 4 | 91 | 4 | 15 |
| Later occupation *SES* | .00 | 50% | 50% | 0% | 0% |
| | .10 | 37 | 55 | 4 | 6 |
| | .24 | 4 | 66 | 15 | 16 |
| Ln 1973 earnings | .11 | 52% | 48% | 0 | 5% |
| | .20 | 38 | 53 | 5 | 11 |
| | .30 | 5 | 61 | 17 | 18 |

*Note:* The first entry in each cell is at the maximum genetic contribution, the next at the approximate midpoint of the $\rho$ estimates, and the bottom one at the minimum genetic contribution. $\rho$ is the correlation in the brothers' environment.

tion between brothers' environment is the same for *MZ* and *DZ* pairs. If this correlation is greater for *MZ* than *DZ* pairs, our estimates of genetic effects are upper bounds.

Although the *G*'s and *N*'s are unobservable, we can estimate their variances and covariances and obtain consistent estimates of the coefficients of the measured variables by using data on twins (for details see Behrman and Taubman and Taubman). Each indicator can be expressed in a reduced form containing only *G*'s, *N*'s, $v_i$'s and structural coefficients. Furthermore, in each reduced form, we can collapse the *G*'s into one weighted genetic index and the *N*'s and $v_i$'s into one weighted environmental index. From any one reduced form, we can calculate *ranges* for the proportions of total variance of each indicator accounted for by genetics, environment and their covariance, the correlations in the brothers environment ($\rho$), and the proportion of the variance accounted for by common environments (see Taubman for details). The proportion accounted for by noncommon environment is identified.[1]

Table 1 presents these ranges. In general, the variance of total and common environments are restricted to narrow ranges while genetics and the covariance term cover wide bounds, almost including 0. However, to allow us to summarize this material briefly, we only comment on the midpoint results. At the midpoints, environment by itself accounts for roughly 90 percent of the variance in *SES* in initial occupation and 50 percent of the variance of everything else. Common environment is most important for education at 36 percent, while at 11 percent or less for the other three variables. Since much education occurred when the brothers generally had a relatively large proportion of the environment in common (e.g., living in the same household), the relatively great impact of common environment on

[1] The proportion of the variance accounted for by noncommon environment is the variance due to total environment minus that due to common environment, and is easily calculated from the table.

TABLE 2—BETWEEN AND WITHIN SEMILOG PAIR EQUATIONS[a]

| Dependent Variable: Natural Logarithm of | Between or Average | | | | | | | | Within or Difference | | | | | | |

[a] *ED* = years of education; *SES* = socioeconomic score census code; *Y* = annual earnings; *ED1 DUM* and *ED2 DUM* are dummy variables for more than 16 years of education (19 years in the earnings equation) for the first and second brothers, respectively. The subscripts are *F* = father's, *o* = original or initial civilian occupation, 67 = 1967 (or 1972) occupation, and 73 = 1973. The absolute values of *t* statistics are in parentheses beneath the point estimates.

education seems plausible. Genetics by itself accounts for roughly 30 to 40 percent of everything except initial occupation, where it accounts for 8 percent. This last pattern suggests that initial job determination is subject to considerable uncertainty, but that observations over time (including responses to on-the-job training) improve the identification of genetically based characteristics.

If we split up the covariance term proportionately to the variances, we find that *genetics plus common environment* account for 79 percent of the variance in education, 20 percent of the variance in *SES* in initial occupation, 45 percent of the variance in *SES* in later occupation and 53 percent of the variance in subsequent earnings. Alternatively these estimates imply the noncommon environment including measurement error accounts for 21 percent of the variance in education, 77 percent of the variance in initial occupational status, 50 percent of the variance in mature occupational status, and 43 percent of the variance in subsequent earnings.

## II. Regression Results for the Four Indicators of Individual Attainment

Table 2 contains simple semilog[2] regression results for the recursive model described in the introduction. Because of apparent nonlinearities, the years of education variable is supplemented by dummy variables with a value of one if the first or second brother has more than 16 years (19 years in the earnings equations) of formal education. In addition to the observable variables discussed above, these regressions include the socioeconomic status of the fathers ($SES_F$).[3]

This table contains separate panels for *MZ* and *DZ* twins, with equations estimated both for within and between pairs. The within pair results hold constant

[2] The semilog form is presented here because it commonly is utilized in the literature and, in this sample, generally dominates both the nonlog and log-log forms in terms of the degree of consistency with the variance in the dependent variables and in terms of not implying significantly nonzero interaction terms (see Taubman for a test of the latter).

[3] Space precludes the discussion in this paper of other variables considered (e.g., age, hours worked) except to note that their exclusion does not significantly alter the estimates included in Table 2.

genetic endowments and common environment for the *MZ*'s and common environment for the *DZ*'s. The between equations only control for these factors with fathers' *SES*. Comparisons of the within and between results indicate the extent to which there are genetic and common environmental factors that determine the indicators of individual attainment, that are correlated with the right-hand side variables, and that are not adequately proxied by fathers' *SES*.[4]

The between equations suggest that the recursive model in which early occupational attainment affects later occupation which affects earnings is valid. The corresponding *MZ* and *DZ* between equations are similar, as should be expected.[5] There is, however, a tendency for fathers' *SES* to have algebraically large coefficients for *DZ* pairs. Since *DZ* pairs on average come from lower *SES* families, this may indicate that the effect of our *SES* index is not linear. In any case fathers' *SES* tends to make a contribution even when education and other variables are included.[6]

The within equations yield qualitatively similar, but quantitatively disimilar results.[7] Comparison of the between and within and *MZ* and *DZ* estimates suggest that (1) the returns to education in terms of initial occupational status are substantially overstated if common environment is not controlled for and are somewhat overstated if genetics are not controlled for; (2) the returns to education in terms of later occupational status are somewhat overstated if common environment is not controlled for;[8] and (3) the returns to education in terms of earnings are somewhat overstated if common environment is not controlled for and are substantially overstated if genetics are not controlled for.

## III. Concluding Remarks

Several qualifications to this study need be made. (1) The results given in Section I assume random mating, additive genetic effects, independence of the noncommon environment of one *DZ* brother from his sib's genes, and identical correlations between brothers' environments for both types of twins. (2) The results need not generalize to the population as a whole because the distribution of genetics and/or environment may vary for other cohorts. (3) The sample eligibility requirements and differential response rates may have caused the sample to have different distributions of $G$ and $N$ than in the population, although it is not obvious in which dimension the sample is more atypical. We are conducting future work to explore the importance of some of these qualifications.

Subject to the caveat that such explorations do not lead to significantly different results, however, some important conclusions emerge. The results in Section II suggest that the contributions of education, traditionally thought to be one of the most important policy tools in our society for assuring equality of opportunity, are significantly overstated by most estimates in regard to both occupational

[4] There can be other genetic and environmental variables that determine the indicators of attainment, but are not correlated with the right-hand side variables. Also the implied biases are overstated since the variance of measurement error is almost surely a larger portion of total variance in the within variables.

[5] Statistical testing of their similarity is now underway.

[6] The direct effect of $SES_F$ on $SES_{67}$ is negative for both *MZ* and *DZ* twins, but the reduced form indicates that the total effect in both cases is positive.

[7] As previously mentioned, the measurement error problem is probably more severe for the *MZ* equations. However, extremely large measurement errors would be needed to explain the results.

[8] For this indicator the net effects of controlling for genetics in addition to common environment depends on the number of years of education because the coefficient of years of education is larger for the *MZ* cases, but the nonlinear terms are larger for the *DZ* estimates.

status and earnings. The results in Section I, moreover, imply that genetics and common environment (in substantial part, in the home) determine almost four-fifths of the variance in years of education. Thus, to the extent that education does have an impact on occupational and earning mobility, for the most part the degree of education is determined by family characteristics, both genetic and environmental. These family characteristics also have very substantial impact on the variance in mature occupational status and earnings.

Subject to the same caveat, this study suggests to us that an economic-political system that is basically free enterprise will be one in which economic inequality will be passed on from one generation to another via genetic endowments and family environment. Moreover we suspect that the common environment effect includes much more than differential family access to financial markets. Thus policies that go no further than the elimination of money market imperfections will not substantially reduce inequality within or between generations. Of course one might be less concerned about our findings if $G$ and $N$ are distributed independently but we believe that they are positively correlated if for no other reason than family income is correlated with diet and material goods used within the family.[9]

[9] Paradoxically allowing for a positive $G$ and $N$ covariance reduces the genetic contribution (even after apportioning the covariance).

# EXCHANGE VERSUS GRANT TRANSACTIONS IN ENVIRONMENTAL MODELS

# Incentive for Innovation as the Basis for Effluent Charge Strategy

*By* LLOYD ORR*

As a basis for sound environmental policy, most economists favor effluent charges or some similar market surrogate. This appears to stem from the common view of prices as effective communication and incentive mechanisms and the substantial difficulties—experienced and foreseen—of implementing efficient regulatory schemes over space, over different classes of pollutants, and over time. However, effluent charges have been subjected to challenge and debate. Questions have been raised concerning both theoretical efficiency and practical problems of implementation.

Ronald H. Coase has argued that where negotiation is costless the *efficiency* of the result is not dependent on the assignment of property rights to those damaged by an externality. He makes the further argument that when negotiation is not possible the imposition of taxes, or taxes and subsidies respectively on the producers and consumers of a damaging externality, may not be the most efficient policy. This conclusion appears to stem from two related considerations: (1) it may be cheaper for the consumer to protect himself from the damage than for the producer to eliminate it, and (2) the extent of the damage is dependent on consumer as well as producer behavior. Laundries affect the amount of damage from factory smoke by their location decisions and, indeed, in the presence of a subsidy will tend to locate near the factory in greater than optimal numbers.

Several authors have expanded on this theme and elaborated on implications of group size and the presence of some form of market power. Conclusions tend toward the view that simple tax or tax-subsidy schemes could not be expected to yield efficient solutions to externality problems. In a synthesis of this literature Ralph Turvey concludes that when negotiation is not possible, "the theorist should be silent and call in the applied economist"—suggesting that no prescriptions of a general nature are possible.

Economists who are accustomed to thinking that allocative efficiency is associated with the payment of marginal cost for use of a factor may well find themselves uncomfortable with this particular branch of the literature on externalities. Indeed, William Baumol has provided a substantial basis for skepticism. Using a simple general equilibrium model he demonstrates that the optimal price for an externality-generating product is its marginal private cost plus its marginal external cost. The correct prescription is a "Pigouvian" tax on the externality without com-

* Associate Professor of Economics, Indiana University.

pensation to those damaged. His interpretation is a simple and clear statement of the public goods problem applied to negative externalities. Just as efficiency requires the producer of a positive externality to be compensated at price equal to marginal cost, the producer of a negative externality should be similarly charged. Also, since the consumer of a positive "public" externality adds nothing to cost, the appropriate price is zero, and similarly since the consumer of a negative public externality detracts nothing from the damage done to others, his appropriate compensation is also zero. Lump sum transfers are, of course, excepted from this prescription.

Baumol attributes the difference in his conclusion from that of Coase to the existence of local maxima in the Coase example that would prevent achievement of the global maximum through use of a Pigouvian tax. He also attributes some difficulties in the Coase argument to confusion between technological and pecuniary externalities.

Given the inordinate amount of information needed to identify the global maxima required for optimal effluent charges and related problems such as the lack of perfect competition, many writers have fallen back on the position of using effluent charges, established through an iterative process, as an effective means of reaching preestablished standards of environmental quality. Baumol and Wallace E. Oates have shown that such a strategy will achieve the standard at minimum cost provided only that firms produce whatever output they select at minimum cost.

There are, however, many practical problems associated with the implementation of these effluent charge structures. To mention a few, there are monitoring difficulties, problems of geographical differences in charge structures, and the possibility of excessive adjustment costs associated with the iterative search for appropriate charge levels. Anthony Dorcey has noted that the iterative process could lead to the very sort of protracted bargaining and regulatory problems from which effluent charges are supposed to provide an escape.

However the basic difficulty that I have with the effluent charge literature is quite different. It is the tendency to concentrate excessively on short run problems of allocative efficiency. It seems to me that the greatest advantage of effluent charges relative to alternative control mechanisms is in their provision of decentralized incentives for technological change. It also strikes me that it is most appropriate to view the environmental problem as one of dynamic adjustment to increasing relative scarcity of a resource. Technological adaptation rather than resource allocation becomes the key to an effective solution.

Technological change is nearly always mentioned in discussions of effluent charge strategies, and it occasionally (see Richard O. Zerbe) becomes an integral part of the analysis. What is missing is the view that environmental policy is fundamentally the need to establish a framework that provides *continuous* and *detailed* technological adaptation to the impacts on the environment of growth, change in product mix, and change in process technology. It is in this context that effluent charges and other strategies should be evaluated—both in terms of effectiveness and political feasibility. In essence, emphasis shifts from welfare economics to growth with exhaustible resources.

## I. Technical Change with Exhaustible Resources

One positive impact of the recent doomsday models is that they have stimulated some good work in the economics of "exhaustible" resources. Of particular interest here is the literature on growth paths with

exhaustible resources.

Although the notion of an exhaustible resource seems intuitively clear, it turns out to be a bit slippery when you try to tie it down. A definition might be the following: given current prices and technology, if the rate of use of a resource stock exceeds its rate of renewal, then the resource is exhaustible. P. Dasgupta and Geoffrey M. Heal note that this creates a "problem" only under the further condition that the resource is "essential"—that is, production declines to zero in its absence.

It is easy to place environmental quality under this concept of exhaustible and essential resources, and thus to assert the relevance of recent growth models for environmental analysis. Deterioration in environmental quality signals that the "stock" of resources is being depleted and thus that use exceeds renewal. The necessity of survival for a wide variety of biological species signals the essentiality of determinable minima in at least some dimensions of environmental quality.

My interest in the growth models with exhaustible resources lies in the focus they provide on the avenues of escape from resource limitations (Robert M. Solow). As one might intuit, escape depends crucially on the elasticity of substitution between renewable and exhaustible resources and on technical progress that reduces the exhaustible resource input per unit of output. Doomsday occurs if a resource remains in the essential category and if there is some upper bound on real output per unit of the resource that is not too far from our present position.

Economic historians provide us with valuable additional focus on these matters.[1] In their traditional concerns with technical progress as a response to relative factor scarcities and with the question of factor "bias" in innovation, the analytical distinction between technological change and factor substitution is extremely difficult to maintain. In Rosenberg's words (1973), "*Today's* factor substitution possibilities are made possible by *yesterday's* technological innovations." We thus see the problem of ease in substitution as essentially one of innovation in creating substitution possibilities, and the problem of relief from future resource scarcities comes to rest squarely on our ability to induce technological response.

There is another dimension in which historians have something important to say about our response to future resource scarcities. In their assessment of the importance of technological change in past growth, they have provided valuable documentation (1) on the vast range of technological response possibilities to particular resource scarcities, and (2) on the *detailed adaptation to such scarcities over time under the spur of decentralized cost incentives.*[2]

It is not possible to demonstrate with certainty that allocative efficiency is less important than technological innovation in solving a particular resource problem at a particular time—especially since the two are not independent. However, where the problem is one of continuous and long run adjustment to growing scarcity of an essential resource, as it clearly is in the case of environmental quality, a very strong case can be made for a shift in emphasis in policy formation from allocative efficiency to long-run technical adaptation.

## II. Experience with Effluent Charges

Although data on experience with effluent charges are only beginning to accumulate, there have been a variety of reports as to their effectiveness. These reports have usually been in connection with muni-

[1] See Nathan Rosenberg (1972, 1973) and Paul A. David, pp. 57–91.

[2] Rosenberg (1973), G. Hueckel.

cipal sewer charges and in-plant water and waste charges.

Reports on the experience of individual firms or municipalities frequently show dramatic impacts from the imposition of effluent charges.[3] Response begins soon after imposition and effectiveness increases over time. Reductions of 60 percent or more in biochemical oxygen demand (*BOD*) load occur over periods of one to three years. Technological response by individual firms frequently results in *favorable* effects on cost that are in addition to the reduction in sewage charges.

Ralph D. Elliott and Seagraves have studied the impact of surcharges on industrial waste using a pooled time series and cross-section sample of 198 observations from 34 cities. Although there was a great deal of "noise" in the data, the negative price-quantity relationship showed a substantial impact following the imposition of moderate waste charges. In an interpretive statement it is suggested that a 45 percent reduction in *BOD* demand would follow from the imposition of a "modest" surcharge of 2.7 cents per pound of *BOD*.[4]

Some caution needs to be used in interpreting these reports. The statistical results are less conclusive than one might wish, and the case study selections may be somewhat biased toward the dramatic. Also the in-plant charges and sewage surcharges do not represent comprehensive effluent charge schemes. In general we do not know what happened to the residuals that are no longer dumped into the sewage system. If there were adequate charges covering atmospheric and solid waste disposal and direct release of treated or untreated wastes into water courses, the results might not have been so dramatic.

However, the reports do illustrate some characteristics of the cost incentives that are inherent in effluent charges. The setting of these charges close to social optima would be a chance occurrence, since information for such charge levels was generally lacking. Nevertheless, we see managers responding to resource cost in a variety of ways that are suited to their own particular circumstances. The nature of the response would be difficult to predict—either for someone trying to plan a specific result, or even for the waste dischargers themselves. The reports strengthen the notion that environment-saving technology is a sparsely explored area that yields quickly to the proper set of incentives. The result is that charges have been effective, their effectiveness has increased with time, and they apparently have not been excessively disruptive. The strength of the partially qualitative and less than conclusive nature of these results is enhanced by the strongly negative assessments of current environmental regulations with respect to incentive structures and technological change.[5]

### III. Effluent Charge Policy

One might well ask why the distinction between allocative and innovative impacts of effluent charges is deserving of emphasis. Clearly, effluent charges designed to meet allocative criteria would, in their reflection of relative scarcities, create incentives for innovation in the proper directions. My response is twofold. First, the importance of innovation makes the extent of our ignorance as to proper price structures more clearly recognizable. The required information for establishing

[3] James A. Seagraves, p. 875; Allen V. Kneese and Blair T. Bower, pp. 168, 170–172; Hearings, testimony by Robert H. Haveman, L. Kimball, and J. Kinney.

[4] Pages 3, 27–28. It is noted that this level can only be achieved after an elapse of time required for adaptation. It is suggested (p. 6) that case studies of industrial groups subjected to effluent charges for several years "should permit description of major adjustments in industrial processes."

[5] A. Myrick Freeman and Haveman.

theoretically correct price structures is not merely inordinately difficult to acquire—it is nonexistent. Second, emphasis on the need for thorough, detailed, and continuous adaptation to the social costs of using common property resources highlights the most compelling advantage of effluent charges in comparison with alternative environmental policies. Taken together these two factors bring about a shift in the criteria for a "good" effluent charge strategy. The result should be a reduction in both the political and economic problems of implementing an effective policy.

Recognition of the difference between allocative and innovative price structures is important. If we could establish a set of Pareto-optimal prices, or even a time pattern of prices designed to maintain given effluent standards, they would not in general be the appropriate prices for optimal innovation. Optimal innovation prices presumably would be those that induce innovative activity that maximizes discounted net returns. Quite apart from the intractable problems of selecting an appropriate social discount rate, the parameters for the production function of knowledge cannot be known.[6] Therefore, the data necessary for calculating the "correct" price cannot be generated.

Our inability to "fine tune" environmental quality should be obvious regardless of the policy approach. But, awareness of the limits of our knowledge should not lead to paralysis or the abandonment of environmental policy to traditional styles of regulation. It rather suggests gradualism as a means of minimizing the uncertainties of transition cost and flexibility in response mechanisms as a means of inducing effective use of current and prospective knowledge and as a guard against massive changes in a complex milieu where side effects are largely unknown.[7] Effluent charges become very imperfect tools, but, in my view, clearly superior to known alternatives as a *basic* policy.

Emphasis on establishing a long run framework of technological adaptation effectively reduces some of the economic and political problems associated with the implementation of effluent charge strategies. For example, many of the economic and political problems of effluent charges are related to transition costs. Gradual implementation of charges in predetermined steps over a period of years should provide the needed inducement for innovation while minimizing short term disruptions. Rather than being faced with highly uncertain levels of effluent charges, the waste discharger responds to a fairly stable profile of charges extending several years into the future. Environmental quality standards may still be relevant, but the *direction* and *rate of change* in environmental quality are criteria that should be of more continuing importance.

As the above implies, there can be a marked reduction in the current stress on cumbersome and potentially costly iterative adjustments in charge structures. Proper charge levels remain an important question, and there are substantial information requirements for establishing a desirable *ordering* of charges for the major pollutants and levels that will induce an initial response. The reported experiences we have noted suggest that this may be surprisingly easy. The iterative process would still be useful where

[6] Rosenberg (1972, p. 172).

[7] C. Holling and Michael A. Goldberg note the similarities between complex economic (urban) and ecological systems. Both appear to have considerable stability within certain bounds, but, when the complex balance is disturbed by intervention, they can generate unexpected and undesirable results. Policy actions that are limited in scope and diverse in nature are suggested, using principles based more on recognition of ignorance than the presumption of knowledge about the nature of the system.

initial charge structures fail to elicit adequate response or where the burdens are clearly onerous and not justified by actual or anticipated response. Errors will still need to be corrected, but the abandonment of fine tuning ambitions carries with it a marked decrease in the use of an iterative process.

Another implication of emphasis on innovative response is a decrease in the importance of regional differences in charge levels. The possibility that regional differences in charges will seriously affect the competitive position of plants *within* an industry at different locations is likely to make substantial differentials politically unacceptable. Also, in the absence of knowledge on technological response to a basic nationwide charge level, we cannot know that the gain in allocative efficiency from differential charges, based on current parameters, would be worth the costs of disruption and relocation. Thus for both political and economic reasons it seems wise to start with a gradual implementation of nationwide charges. If the short-run transition burdens from the charges are still regarded as too heavy, other business taxes could be reduced. This would provide general relief without destroying the incentive to reduce effluent or the valuable differentiation (allocative and innovational) *between* industries on the basis of quantity and quality of waste discharge. Local governments with special problems may want to provide supplementary charges or regulation. This is clearly appropriate, especially since they are likely to be more sensitive to the consequences of their actions than the federal government.

Ignorance is not a good thing, but its *recognition* can be very valuable in helping us to avoid serious errors. The strength of effluent charges lies in their ability to move things in generally desirable directions even when we lack the knowledge to provide price structures that are efficient in either the allocative or innovative sense. The diversity of impact, continuous incentive properties, and relatively high degree of self regulation serve to limit the undesirable (and unforeseen) side effects and the perverse incentives that are associated with many regulatory policies. The relevant concept is *robustness*—the ability to function effectively in the face of the often serious differences between the ideal of the model and the reality of operative policy. This concept is relevant to all policy formulation and its serious consideration should, it seems to me, prevent some of the disaffection with the government sector that follows from recurrent policy failures.

# Federal Environmental Policy and R&D on Water Pollution Abatement

*By* HAROLD J. BRUMM, JR. AND DANIEL T. DICK*

Keynes once asserted that the current economic cant of politicians represents the doctrine of some academic scribbler of an earlier day. We suspect he would have been tempted to disavow ever having made that claim if he had had the opportunity to witness the development of federal water pollution control policy over the past two decades, because it is painfully apparent that the writings of economists (past and present) have had precious little impact on the formulation of that policy (Edwin S. Mills and Frederick M. Peterson). The four central components of federal water pollution control policy are: (1) prohibition of discharge of any refuse into navigable waters without a permit from the Army Corps of Engineers; (2) subsidies of up to 75 percent of the construction costs of municipal water treatment facilities (*WTF*'s); (3) ambient standards (e.g., the amount of dissolved oxygen in parts per million) on all navigable waters in the United States; and (4) a five-year tax amortization of additions to industrial waste treatment plants.[1] This grants and regulations strategy has been thoroughly scored by several economists, who have urged instead that greater reliance be placed upon effluent charges, i.e., taxes levied on pollutants discharged into watercourses (see, e.g., Kneese and Schultze, William Baumol and Wallace Oates, and A. Myrick Freeman).

The twofold purpose of this paper is to briefly review the environmental policy recommendations which appear to have widespread support in the economics profession, and to examine their implications for investment in water pollution abatement technology. In addition, we shall proffer a modest policy recommendation that we have not encountered anywhere in the literature.

## I. The Justification for Government Intervention

The existence of a federal pollution control policy raises two questions. First, why is government intervention required at all? Several writers (Ronald H. Coase, James Buchanan and W. Stubblebine, Otto A. Davis and Andrew B. Whinston, Harold Demsetz, and Dean Worcester to name a few) have argued that government intervention may not only be unnecessary, but ineffectual at best—particularly if the policy is based on a Pigouvian tax-subsidy scheme. Evidently it is their view that bargaining, which is a form of market exchange solution, holds greater promise for a socially efficient allocation of resources. However, Dick (forthcoming) shows in a review and synthesis of the literature critical of the voluntary approach that private bargaining is unlikely to yield optimal results re-

* Research Staff Member, Institute for Defense Analyses (*IDA*), and Senior Economist, Resource Development Associates, respectively. The publication of this paper does not indicate endorsement by *IDA*, nor should the contents be construed as reflecting the official position of that agency. [1] For a discussion of the history of federal air and water pollution legislation, see Allen V. Kneese and Charles L. Schultze.

gardless of liability placement, except in states of nature that are extremely improbable. Any realistic assessment of real world problems in which income effects, transactions costs, and nonseparabilities abound rules out reliance on voluntary modes of control. F. Trenery Dolbear, Ezra J. Mishan, Alan J. Randall, William C. Wheaton, and David K. Whitcomb have provided further sobering thoughts on the efficacy of nongovernmental solutions to problems created by external diseconomies.

Given, then, that the unhappy case is made for governmental solutions being the only viable alternative to internalizing various externalities which create environmental problems, a second question arises. What policy instrument (or combination of instruments) should the government employ, in order to achieve a level of pollution abatement that is socially desirable (however defined)? The various collective strategies available for this purpose include (1) regulation, (2) prohibition, (3) subsidies, and (4) effluent charges (Mishan, pp. 14–16).

## II. An Evaluation of Alternative Government Strategies for Water Pollution Control

The static inefficiencies of direct regulation are well known to economists. For example, a regulation requiring all polluters to make the same percentage reduction in waste discharges violates the *intersource* efficiency condition that private marginal costs of abatement be equalized for all pollution sources (Dick, 1974, pp. 67–70). Moreover, a regulation requiring that certain abatement devices or processes be used does not satisfy the *intrasource* efficiency condition that the polluter's marginal costs of abatement be equalized for all pollution control devices or processes which he chooses (Dick, 1974, pp. 70–72). Finally, direct method regulation can be expected to have perverse incentive effects on the invention and development of new pollution control technologies. If, instead of mandating that only one particular abatement method be employed, the government were to announce that a particular standard would have to be met but the use of a wide range of alternative methods would be allowed, we may anticipate that there would be a greater number of competitors in the market for pollution control *R&D*, thereby enhancing the possibility that truly significant abatement technologies would be developed.

Outright prohibitions of pollution activity are, in general, economically inefficient because they ignore possible tradeoffs between different levels of environmental quality and other valued goods and services. In a wide range of circumstances pollution should be reduced only up to the point where the social cost of additional abatement equals the social benefit derived from the reduction in damages resulting from that additional abatement. However, in certain cases the prohibition strategy may make sense. An example would be a circumstance of extreme uncertainty about irreversible effects of growing concentrations of a given pollutant.

In evaluating subsidies versus charges there exists a potentially serious "moral hazard" problem (Kenneth J. Arrow, p. 142) inherent in a subsidy scheme. Specifically, a subsidy policy may make it profitable for a firm to pollute more than it otherwise would have, in order to qualify for large subsidy payments; conceivably an enterprise which in the absence of a subsidy scheme would not be economically viable might find the waste-making business profitable (M. Kamien, Nancy Schwartz, and Dolbear; and D. Bramhall and Mills). Another perverse incentive of a subsidy scheme is the in-

ducement it provides for overinvestment in *WTF*s relative to other modes of pollution control. Since up to 75 percent of the construction costs of *WTF*s is borne by the federal government, purchasers of *WTF*s have an incentive to meet standards based on their perceived capital costs of *WTF*s—costs which are net of the federal subsidy. Another objection to a grants scheme is that the change in perceived capital costs it induces invites a capital-intensive bias to production in subsidized firms and municipalities. As a result, waste reduction will be accomplished at the expense of alternative input combinations which may represent a more efficient allocation of society's scarce resources. (The current federal policy of extending the tax advantage of accelerated depreciation to additions to industrial *WTF*s is, of course, a particular type of subsidy; as such, it is susceptible to the foregoing criticisms.)

In summary, one principal liability for the long term of a strategy utilizing prohibition, regulation, or subsidies is that such an approach does not impact on private economic incentives in a way that would encourage the discovery and adoption of new and better technologies for improving water quality. By contrast, as Kneese and B. Bower (Chs. 6 and 7) have pointed out, a water management system relying heavily on effluent charges not only would tend to adjust the degree of pollution reduction required of each activity so as to minimize the total cost of cleanup of the watercourse, but would exert a continuing incentive on polluters to adopt new technologies, as they become available, which are designed to achieve still further reductions in discharges of waste residuals.

On the basis of the foregoing theoretical arguments, it would appear that effluent charges are superior to other water pollution control policy instruments. However, Baumol and David Bradford have alleged that detrimental externalities of sufficient strength will result in a breakdown in the convexity of the social production set. These externality-induced nonconvexities would seem to rob the pricing mechanism of its normative usefulness. Advocates of Pigouvian taxes can take comfort, therefore, from Vernon K. Smith's analysis which demonstrates that the imposition of effluent charges can induce technological changes which serve to ameliorate those nonconvexities, and from Jacob Schmookler's findings that economic incentives have a positive influence on technological innovation. Accordingly, it seems clear that one of the principal advantages of a strategy which relies heavily on effluent charges is its implications for advancement in water pollution abatement technology. Kneese and Schultze have summarized the point succinctly: "Over the long haul, perhaps the most important single criterion on which to judge environmental policies is the extent to which they spur new technology toward the efficient conservation of environmental quality" (p. 82).

Finally, it should be noted that the distributional consequences of subsidies and effluent charges differ. Government expenditures to make subsidy payments must be financed by withdrawing resources from the private sector through increased taxes or borrowing, if the level of nonenvironmental publicly provided goods and services is to remain constant. On the other hand, if effluent charges are employed, the initial burden of the cost falls on the polluters. However, the ultimate incidence of the pollution abatement cost under either an effluent charge or a subsidy policy cannot be determined a priori. In this regard it is worth mentioning that Thomas Havrilesky (p. 327) has argued that the burden of pollution abatement, as a percentage of income, is

borne most heavily by the poor, under a subsidy scheme (or under regulation).

Even if one accepts Smith's argument that the difficulties caused by externality-induced nonconvexities can be overcome, there remain other potentially serious drawbacks to the implementation of effluent charges. For example, Kneese and Bower (Ch. 6) have pointed out numerous problems, including the possibility of nonseparabilities: various wastes discharged into a given watercourse may interact chemically, with the result that the external cost of one pollutant cannot be determined unless the level of discharge of the others is known. A related limitation concerns the measurement of environmental quality and extent of culpability for environmental damage. More generally, the informational requirements of a socially optimal level of effluent charges raise implementation costs to very high levels. (The same problem arises with any other policy instrument, however.) Indeed, since actual measurement of social welfare is impossible, and since the pollution abatement level required for the attainment of a social optimum is unknown except at very high costs, one cannot determine if a given variation in effluent charges will move society toward that optimum. (For detailed critique of the effluent charges strategy, see Susan Ackerman.)

In light of the foregoing arguments, it is clear that optimal effluent charges are an extremely expensive way to achieve effective water pollution control. However, just because there exist problems with the application of effluent charges in the real world, it does not necessarily follow that they should be summarily ruled out. A more sensible approach is the Environmental Pricing and Standards (*EPS*) system suggested by Baumol and Oates (Ch. 10). The *EPS* system entails establishing (somehow) an ambient quality standard, setting a tax on effluents discharged, and then raising the tax rate (which induces polluters to curtail their discharges of wastes) until the preestablished standard is met. A problem with this approach is common to the provision of virtually any public good, namely, determining what the socially optimal level of provision is. In this regard, Baumol and Oates (pp. 149–150) have provided some useful insights.

Under the *EPS* system the standard is set (perhaps through the political mechanism) and the effluent charge is successively raised until the standard is met. That way, whatever standard is met, at least it is met in a least cost manner. The informational requirements of the *EPS* approach are relatively small when compared to those required for setting optimal effluent charges, because for the latter scheme one must have considerably more knowledge of both the basin-wide marginal damage function and the basin-wide marginal cost function. This is the tremendous informational cost requirement that led Baumol and Oates to advocate the *EPS* system in the first place.

We propose that an allocative gain could be made by comparison with the *EPS* system at an informational cost that is a fraction of that associated with the optimal effluent charges plan. This gain can be achieved by charging a variable rate per unit of effluent based on the basin-wide marginal external damages function. While knowledge of the basin-wide marginal external damages function is required, this approach does not require knowledge of the basin-wide marginal abatement cost function. Herein lies the informational cost advantage. If the effluent concentration is monitored at frequent intervals and the charge varied accordingly along the marginal damages function, an equilibrium will be achieved automatically. The allocative gain accrues

because, while the basin-wide authority does not know what abatement costs are, the private decision-making units do. If there are private gains to be had through abatement at the current effluent tax, polluters will exploit these gains and the charges will then be adjusted downward. This process will continue until no further private gains can be achieved through extra abatement and therefore the charge will not be further adjusted.

It should be pointed out that for this scheme to work, the monitoring and adjustment of charges must be made at frequent intervals. This is necessary to avoid having irreversible overabatement take place if early charge levels are high, or underabatement if they are low. Whether or not the informational cost of acquiring knowledge of the marginal damages function is worth the allocative gain achieved over an *EPS* system cannot be determined a priori.

### III. Conclusion

We have attempted to briefly summarize the literature addressing alternative policy instruments for water pollution control, and to reaffirm the case for implementing a policy based on effluent charges. Policy options that rely on private bargaining or regulatory devices will be faced with greater problems of information acquisition, transaction costs, and creation of perverse economic incentives.

From a practical standpoint, the *EPS* approach has considerable appeal, in terms of overcoming some of the aforementioned problems. However, if the basin-wide marginal damage function is known, a system of progressive charges based on this function will improve allocation compared to that of the *EPS* system. The costs of this allocative gain are those associated with determining the marginal damage function. This means that if the basin-wide marginal damage function is known, one need not expend resources to determine the basin-wide marginal cost function, in order to use a charges scheme with optimality properties.

# The Anatomy of Nonmarket Failure: An Examination of Environmental Policies

*By* RON D. WHITE*

In a very well-known article Francis M. Bator synthesizes the work of many other economists and develops a structure for discussing the phenomena of market failure; he distinguishes five modes of market failure and, subsequently, identifies three causes for these failures. Rather than "solving" the problem of market failure, Bator gives us a new set of perspectives from which to study the situation. There is a parallel need to identify and distinguish various modes and causes of failure in our nonmarket mechanisms. Public policy analysts need to make an effort to generalize about the circumstances under which public policies fail. Although many analysts have discussed various aspects of institutional failure, there has been no attempt to organize the topic and provide a typology from which further analysis can proceed. This paper first discusses problems encountered in defining nonmarket failure, then develops a classification system for such failures, and applies this framework to environmental policy.

Academic work has gone on for years to describe the circumstances in which markets fail in the distribution of goods and incomes. Most public finance texts spend considerable time in developing these models. By comparison, there is almost no analysis of the circumstances in which public programs and policies have failed. Well-organized assessments of the performance of publicly supplied services and/or publicly financed programs, which one would expect to find, are usually missing from the texts.

It is hardly the case that analysts have failed to find fault with various public programs. Rather, the problem is that these criticisms have never been systematically synthesized and used as an alternative to the "market failure" approach. The market failure literature is informative but, because it analyzes markets, it is of limited usefulness as a basis for public policy. The most important question for policy makers and policy analysts is: How does existing nonmarket decision making compare with an idealized nonmarket system? This query has not been pursued in any systemic fashion. The purpose of this work is not to present answers, but to try to focus attention on the question.

## I. Definitional Problems

Nonmarket failure does not have any agreed upon definition and the term is not one in standard usage. Because public policies are criticized by such a variety of scholars with diverse disciplinary attachments and political perspectives, no widely-used definition has emerged. Nor is there a standard analogous to "market efficiency" against which nonmarket institutions can be judged. In a typical policy-making situation, where redistribution occurs or will occur, there are no purely

* Director, Center for Business and Economic Research, Wichita State University, and The Federal Energy Administration.

economic criteria available. Yet, there may be considerable agreement—although not unanimity—that specific policies have failed. Thus the development of a typology for nonmarket failure is feasible so long as complete agreement is not required in the definition of "nonmarket failure."

On the other hand, market failure has a rather well-accepted definition which is a central part of modern welfare economics and which requires the acceptance of some strong assumptions about taste, technology, and other factors. Nonmarket failure has no similar, formal definition. Bator does provide a basis from which to proceed, however. His first definition of market failure is: ". . . the failure of a more or less idealized system of price-market institutions to sustain 'desirable' activities or to estop 'undesirable' activities" (p. 351). A parallel definition of nonmarket failure can be stated. Nonmarket failure is a breakdown of the system of taxation, transfers, and expenditures which results in the lack of progress toward stated goals or the active pursuit of unsanctioned aims. The system of taxation, transfers, and expenditures is, of course, the stuff of empirical public finance. Yet the usual textbook approaches these questions from the market-system perspective.

The nonmarket conceptualization of these processes is quite different. Kenneth E. Boulding's classification of "exchange relationships" and "threat-submission" relationships and "integrative" relationships is very useful here. Exchange is the basic market relationship in which participants mutually agree to trade resources. Threat-submission relationships involve the extraction of resources by use of negative sanctions. Integrative situations are those in which resources are distributed or redistributed on the basis of status. The market, or exchange, approach to public policy has been shown to be unsatisfactory by formal analysis and—it is contended here—gives an unduly limited perception of what governmental behavior is all about (Richard G. Lipsey and Kelvin Lancaster). The public sector involves, legitimately, both threat and integrative relationships. The grants economics literature shows that taxes, transfers, and expenditures take on an expanded meaning when viewed as something other than voluntary exchanges. Nonmarket failure takes its place as unsatisfactory behavior in threat and/or integrative relationships.

Defining this unsatisfactory behavior, at the root, is a problem of the relationship between the positive and normative elements of economics. This topic is important to environmental policy because the adoption of the polluter pays principle involves conflict rather than harmony. In this matter there are no value-free policy proposals nor are there enduring "solutions." Similar conditions obtain for the bulk of public policies involving taxes, transfers, and expenditures. Grants economics is openly normative and it needs an openly normative theory of nonmarket failure. Just as some public finance economists insist upon exchange model benefit taxation, there are environmental economists who have confused themselves and sometimes convinced others by making policy proposals, or stating principles for public policy, based on exchange economics. If such work is to be continued as something besides a purposefully sterile exercise, then the assumptions of the market model need to be made explicit and be proven to exist in reality. Given the current state of our knowledge about market theory, especially the theory of the second-best, it is fair to interpret market mechanism policy analysis as being either naive or purposefully deceptive. That is, the competitive model implies

harmony of interests and thus—when its assumptions are not met—constitutes a value premise. Values then become implicitly imbedded in both the diagnosis and the recommendation. From the perspective of grants economics, the problem is not one of determining whether or not a normative economics rabbit can be pulled from a positive economics hat, but clearly specifying the necessary value premises and supporting those chosen by reference to either ethical standards or prior public policy decisions. This is not to say that such reference is where the matter will end, quite the contrary. The arena of public policy has only been *entered*. It is the nature of these conflict situations that they do not have solutions. They do not have solutions because they are not closed-end puzzles. In the event that a legislative action on a policy matter fails to mollify one party at interest (or a coalition of parties), the contestants may turn to the judiciary. Now where normative policy is involved not only are economic *qua* exchange answers absent, but noneconomic solutions are lacking also. Rather than solutions or answers, the results of a legislative or judicial process are a set of working rules for an explicit societal agreement that is subject to change by reform or revolt. These arrangements are temporary. Though they may have quite long lives, they are not immortal. As values change, our perspective on public policy may be altered and, for example, effluent charges may become a more or less acceptable policy.

This mutability of values is the prime reason for the statement above which asked only consensus, rather than unanimity, in defining nonmarket failure. Nonmarket activity can only be judged by comparing public policies with moral standards and general societal working rules which have been previously established (John R. Commons). This approach to defining policy failure is compatible with the need for flexibility in policymaking. A policy may be unsatisfactory and be the wave of the future, the way of the past, or simply an aberration.

Using the language of grants economics, nonmarket failure is the breakdown of either the threat-submission system or the integrative system. Breakdown is judged by comparison with existing, though evolutionary, ethical standards and/or public policies.

## II. The Case of Effluent Charges

By examining many instances of failure, a set of common factors can be identified and a classification system developed. The reasons for nonmarket failure which emerge from an examination of policy critiques are these: (1) failure of structure, (2) failure of legitimacy, and (3) failure of information. Failure of structure is exemplified by policies which do not recognize the structure of federal, state, and local government and do not take into account the differential assignment of functional responsibility. Failure of legitimacy occurs when benefits of government activity accrue to only a few individuals rather than the public. In other words, where illegitimate redistribution occurs in the system. Failure of information brings about mistaken policy when: (a) the flow of information does not encourage foresight, (b) the flow of information is inappropriate to the organization's agenda, and (c) policies are pursued which have conflicting goals. In the space which remains each of these types of nonmarket failure will be discussed in terms of establishing and administering a set of effluent charges.

### *A. Failure by Structure*

Successful environmental policy must begin from an awareness of the structure of government. Local and/or state govern-

ment policies could be frustrated by federal initiatives. Effluent charges are too often prescribed without any clear notion of which level of government should levy such charges and whether or not such levies might have some relationship to other fundamental responsibilities of the levying unit, adjacent units, noncoterminous overlying units, or other units in the hierarchy. The merits of decentralization must be weighed not only against the ability to internalize externalities, but some reckoning with the other tasks of the unit can only be postponed and cannot be avoided. The levying of effluent charges could degenerate into a competitive situation among local governments or even states. Experience with competitive underassessment in the property tax field is instructive here. Assigning the responsibility for levying effluent charges to the unit with the real property assessment function offers the creative administrator some interesting opportunities for competing with other locales for manufacturing or service industry.

### *B. Failure by Legitimacy*

The distribution question, pursued by Martin Pfaff, is raised here in terms of its impact on public sentiment toward government. What sort of redistributional impact will be perceived as legitimate by the citizenry? We must not only try to answer the empirical question as to incidence, but we must also investigate the legitimacy of the impact. It seems likely that the populace would prefer that the polluter pay. There is evidence that economic literacy has progressed to the point that public discussions of burden shifting are possible. The public perception of the burden and the linkage of burden with specific products is bound to be an important issue. The public will likely consider illegitimate any policy that ignores burden shifting.

There is another dimension to the question of legitimacy. The public is easily convinced that the polluter should pay. Daily confrontation with the externalities generated by the behavior of others has made "polluter pays" a principle which is probably easier to agree upon than to achieve. The arrival at a consensus position is most important in policymaking, if not in model building, and economists ought to take heart and pursue the empirical work on incidence.

### *C. Failure by Information*

The possibility for failure by information seems to be a very real obstacle in the path of those who seek to develop a set of effluent charges. It is most important that data well beyond that generated by monitoring be available to decision makers. Information as to the changing composition of the effluent and the experiences of other governments levying similar charges needs to be considered. The levying of these charges can be expected to have something akin to income and substitution effects on the producer. Such information will permit a certain amount of foresight as to likely changes and likely responses to those changes. The flow of information must be appropriate to the agenda of the unit of government levying the charges. That is, information must be available to decision-makers which pertains to the relationship between the various public services provided (highways, education, etc.) and the effluent producing industry on which the charges are being levied. Certain variables are within the purview of local decision makers. If effluent charges are to accomplish a specific goal, then information must be available about other programs (such as the level of economic activity) so they may judge the impact of charges in the context of their other responsibilities. A related, but separable, issue is the availability of

information which might indicate that a government was pursuing conflicting goals. The levying units must be aware of the impact of effluent charges on economic growth and development so that a conscious decision about the socially tolerable level of emissions can be arrived at. Without this ability, effluent charges might be levied at too low a level and the community would be attracting polluters through this policy while their economic development efforts were being subverted. Goal conflicts are a considerable problem in many realms of policy making and the development of a set of effluent charges is not substantially different.

# DISCUSSION

JANOS HORVATH, Holcomb Research Institute, Butler University: Projecting the searchlight of grants economics on environmental problems, we obtain a clearer perception of three things. Firstly, we can trace some implicit income and wealth transfers. Secondly, we can observe the mechanism by which such grants may affect productive efficiency and distributive equity. Thirdly, from this understanding we can design policy tools to induce environmentally desirable technological changes.

The papers of this panel have made commendable starts toward exploring what good and bad those grants can do to environmental quality and how they should be harnessed. I will attempt to examine to what extent their propositions have contributed to staking out the role of exchange versus grant transactions in environmental models.

What we ought to strive for is a broad enough framework within which all the various environmental policy problems could be integrated. In the realm of generalities, the first question is to detail the production and consumption functions of the economics of the coming spaceship earth, wherein the goal will no longer be to maximize output but rather to minimize throughput. Having perceived the spaceship earth, i.e., the environment, as the significant limiting factor, our task is to conduct human activities without wrecking ecological equilibrium. The fundamental environmental problem is, therefore, to achieve a reduction in the per capita use of the environment as a waste receptor.

In paving the way toward a comprehensive methodology of environmental policy problems, I recommend as building blocks, some pertinent concepts of grants economics. Herein I outline, for the sake of illustration, three scenarios.

*Scenario One: Implicit Grant to the Pollutor.* The pollutor gains through the non-abatement of the nuisance he causes, and in this sense he is the beneficiary of an implicit grant. The grantor is the inconvenienced neighbor, or nature to the extent that it absorbs the pollutant. The propensity to pollute is positively correlated with the capturable implicit grants. Alternatively, in a situation where the pollutor is no longer allowed to capture the implicit grant stemming from the non-abatement of external diseconomies, then his propensity to pollute is likely to decline.

The imposition of effluent charges will accomplish just that. Two of the papers at hand propose actions along those lines. Lloyd Orr proves quite convincingly that the halting of an implicit grant to the pollutor sets in motion technological innovations conducive to environmental improvement. Brumm and Dick show that subsidies for water treatment facilities are suboptimal or often counterproductive. In a sense, both papers argue against certain pathological grants which harm the environment. An exception to this is the transitional period toward the pollutor-pays-principle, when interregional dislocations may still warrant an elaborate network of explicit and implicit grants, as considered by Martin Pfaff.[1]

*Scenario Two: Implicit Grant from Nature to the Mineral Exploiter.* Natural resource exploitation is a composite economic transaction wherein the true value of the material is more than the cost of production (extraction). The ore itself is accepted as a gift from nature, which does not ask for a *quid pro quo* price. The exploiter becomes the recipient of an "implicit grant from nature." The fact that this is shared by the miner, the material processor, and the consumer, does not negate the idea that there is a grant from nature which, in turn, means that natural resources are undervalued. Certainly, the pivotal question is how to determine the size of this grant from nature via minerals. For this purpose we may make a distinction between the market value versus the surrogate value, and in a parallel fashion between the market price and the surrogate price. The market price is, of course, known. The other, the surrogate price, will approximate to a level where such large

[1] [Editor's note: I regret that Pfaff's paper for this session is not being published because the revised version did not reach my office in time. —R.F.]

quantities of the mineral would be produced that the supply function could become very elastic within the relevant range.

My proposition is substantiated by some recent advances in the science of mineral resources. The old school of natural resources held that minerals will sooner or later run out, or at least, that prices will rise sharply in the future. But the notion is naive because the entire planet is composed of minerals. There is evidence that vast quantities could be mined as either prices go up or as extraction costs go down pursuant to technological improvements. With only negligible exceptions, the volume of mineable materials could increase significantly—not by a factor of five or ten, but by a factor of 100 or 1000. Consequently, the problem boils down to finding that particular price level at which the supply function of the mineral continues to remain highly elastic throughout all possible ranges of demand shift. This surrogate price level serves then as the baseline for identifying the grant from nature, which will be the difference between the surrogate price and the prevailing market price. This latter idea has its antecedent in Ricardo's differential rent.

Considering, for example, that aluminum sold at 25-cents-a-pound price on ingot, and assuming that its surrogate price would be at 55 cents, then the grant from nature amounts to 30 cents. Since the global aluminum consumption from current mining was around 16 million tons during 1972, the world during this year was the beneficiary of an implicit grant from nature in the sum of about $9.6 billion. The corresponding sum for the United States would approximate to $3.2 billion.

Once perceived, the grant from nature may be employed as a policy tool in the resolution of various environmental problems. The level of pollution would decline if society reallocated the grant from nature by channeling part of it away from the heavy pollutor to the lesser pollutor; for instance, from bottle manufacturing to bottle recycling, or from copper to aluminum, as the case may be. The user in the socially-less-desirable or more polluting branch of the economy would receive the message in higher prices while the less objectionable branch would be signalled via lower prices.

*Scenario Three: Implicit Grants for Developing Solar Energy Technology.* Some futurologists envision the world's energy prospects as follows. During the next 15 years petroleum and gas will be utilized as the main source with simultaneously increasing reliance on coal. After about 25 years nuclear and solar energy will take the lead. Eventually a move away from fossil and even nuclear fuels is bound to ensue. What will cause this increased reliance on solar energy is that it constitutes a grant from the sun. By not satisfying more of its energy needs through the utilization of solar power—but capturing only a fraction of one percent beamed upon the earth—mankind foregoes an opportunity. Such a prodigious behavior is made possible through the availability of long accumulated solar energy, stored in the fossil fuels. Nuclear resources could of course offer new prospects, but the recurrent opposition to nuclear power calls for the consideration of alternative energy systems, such as solar energy.

As long as mankind continues to burn fossil fuels and uses up nuclear resources, it depletes a "stock grant" instead of living off a "flow grant." The long-run energy strategy can be viewed as a search for the ways to achieve a reduction in the use of stock grants while shifting to reliance on flow grants. A precondition to such a change in the utilization of energy resources is the development of suitable technology. In order to guide the direction and pace of technological change, a variety of policy tools are employed which are encompassed by the nomenclature of grants economics. Other things being equal, this optimal policy path would be to minimize marginal grant outlays per marginal energy output. This process also promises contributions to two other objectives: pollution abatement and fossil fuel preservation.

From the new technology we may expect lower costs so that solar power could become competitive in a wide range of uses. The downward move of the average cost functions and the outward shift of the supply functions will cause the price fall. As the economies of scale

are reaped, solar energy could compete with other alternatives. This stage is perhaps as near as five years in the heating of certain buildings and perhaps several decades away in the production of electricity and liquid hydrogen. The transition can be expected to be slower or speedier depending on the less or more judicious implementation of grant policies.

In concluding I should underscore that although the qualification of grant elements and the assessment of their leverage are novel techniques in economic analysis, explicit and implicit grants are as old as human communities. The economic history of the United States abounds with illustrations, such as the governmental underwriting of semiconductor research, civilian nuclear power, telestar, aviation, shipbuilding, trucking, or the railroadization a hundred years ago. Today's priority programs—the protection of the environment in general and the provision of energy and minerals in particular—may appear more formidable than any of the predecessors. Yet the measuring tools and normative principles of grants economics hold out the prospect for orchestrating a gamut of transactions about which Martin Pfaff wrote: cash grants, transfers in kind, concessionary leasing and lending, tax relief, relaxed rules, etc. Through quantifying the grant elements within each transaction and after calculating the tradeoffs between alternative choices, policy decisions could emerge with less uncertainty.

AMERICAN ECONOMIC ASSOCIATION

# PROCEEDINGS

OF THE

# EIGHTY-EIGHTH

# ANNUAL

# MEETING

DALLAS, TEXAS

DECEMBER 28-30, 1975

# THE JOHN BATES CLARK AWARD

*Citation on the Occasion of the Presentation of the Medal to*

DANIEL MCFADDEN

*December 29, 1975*

Daniel McFadden has been one of the most complete economists of his generation. He works in several different styles. He has written theoretical essays, worked on the development of new econometric tools, and undertaken large scale empirical inquiries. His investigations have ranged across production relations, decision making under uncertainty, development planning, welfare economics, and most recently urban transportation. There has been a certain uniform spirit behind all of his work—that the task of economists is to explain real economic phenomena. His work in pure and econometric theory has been conditioned by his appreciation of empirical reality. We honor him both for his seriousness about subject matter, and for the care and rigor which characterize all of his work.

# MINUTES OF THE ANNUAL MEETING
# DALLAS, TEXAS
# DECEMBER 29, 1975

The Eighty-eighth Annual Meeting of the American Economic Association was called to order by President Robert Aaron Gordon at 4:05 p.m., December 29, 1975, in the Dallas Convention Center.

The minutes of the meeting of December 29, 1974, were approved as published in the *American Economic Review*, May 1975, pages 441-47.

The Secretary (Rendigs Fels) presented the report of the Committee on Elections and the certification of the new officers for 1976 as follows:

In accordance with the bylaws on election procedures, I hereby certify the results of the recent balloting and report the actions of the Nominating Committee, the Electoral College, and the Committee on Elections.

The Nominating Committee, consisting of Robert Eisner, Chairperson, Bernard E. Anderson, Robert E. Gallman, Richard W. Parks, Leonard A. Rapping, Barbara B. Reagan, and Christopher A. Sims, submitted the nominations listed below for Vice-Presidents and members of the Executive Committee. The Electoral College, consisting of the Nominating Committee and the Executive Committee meeting together selected the nominee for President-elect. No petitions were received nominating additional candidates.

*President-elect*

Lawrence R. Klein

| *Vice-Presidents* | *Executive Committee* |
|---|---|
| Barbara R. Bergmann | Robert W. Fogel |
| Harry G. Johnson | Bert G. Hickman |
| Douglass C. North | Edmund S. Phelps |
| Albert E. Rees | Alice M. Rivlin |

The Secretary prepared biographical sketches of the candidates and distributed ballots in late summer. The Committee on Elections, consisting of Shirley K. Newton, Chairperson, Tom Holbrook, and Rendigs Fels, *ex officio*, canvassed the ballots and filed the results with the Secretary. From the Report of the Committee on Elections, I have the following information:

| | |
|---|---|
| Number of envelopes without names for identification | 250 |
| Number of envelopes received too late | 54 |
| Number of defective ballots | 36 |
| Number of legal ballots | 5,885 |
| | 6,225 |

On the basis of the canvass of the votes, I certify that the following persons have been duly elected to the respective offices:

*President-elect* (for a term of one year)
Lawrence R. Klein

*Vice-Presidents* (for a term of one year)
Barbara R. Bergmann
Harry G. Johnson

*Members of the Executive Committee* (for a term of three years)
Edmund S. Phelps
Alice M. Rivlin

In accordance with the actions of the Executive Committee at its meeting on March 14, 1975, amendments to Article I, Section 2; Article I, Section 3, Sentence 3; and Article V of the bylaws were submitted to the members in a mail ballot in conjunction with the balloting for officers. The ballots were canvassed by the Committee on Elections. On the basis of the canvass, I certify that the amendments were approved. As amended, Article I, Section 2, now reads:

2. There shall be nine classes of members other than honorary: regular members with the academic rank of assistant professor or lower or with annual incomes of $12,000 or less irrespective of rank, paying an annual fee of $25.00; regular members with the academic rank of associate professor or with annual incomes above $12,000 but not more than $20,000 paying an annual fee of $30.00 unless qualifying for a lower fee; regular mem-

bers with the academic rank of full professor or with annual incomes above $20,000, paying an annual fee of $35.00 unless qualifying for a lower fee; family members (two or more living at the same address, second membership without subscription to the publications of the Association) paying an annual fee of $5.00; junior members (available to registered students for three years only) paying an annual fee of $12.50; subscribing members paying an annual fee twenty percent higher than otherwise; contributing members paying an annual fee one hundred percent higher than otherwise; and life members comprising those who qualified for life membership by making a single payment of the designated amount prior to January 1, 1976, and exempt from annual fees.

As amended, Article I, Section 3, Sentence 3, now reads:

> In addition, the Executive Committee may elect additional Distinguished Fellows, but not more than two in any one calendar year, from economists of high distinction in the United States and Canada.

As amended, the previous text of Article V is now numbered 1 and the following has been added:

> 2. A resolution adopted at the annual meeting in which less than five percent of the membership of the Association has voted thereon shall be submitted within ninety days to a vote by mail ballot if a majority of the Executive Committee determines that, because of the nature or consequences of the resolution, all members should have the opportunity to participate in the final decision. Upon such a determination by the Executive Committee, the resolution shall cease to be effective and shall not become effective unless and until approved by a majority of the mail ballots cast. Mail ballots shall be accompanied by (1) a brief statement by the sponsor or sponsors in support of the resolution, (2) a brief statement of the views of the Executive Committee and, if the Committee favors or takes no position on the resolution, (3) a brief statement by a person or persons whom the Committee designates to represent opposing views.

In accordance with the action of the Executive Committee at its meeting of March 8, 1974, an amendment to Article I, Section 4, was submitted to a mail ballot in the spring of 1974. The ballots were canvassed by the 1975 Committee on Elections. On the basis of the canvass, I certify that the amendment was approved. As amended, Article I, Section 4, now reads:

> 4. Every member is entitled to receive, as they appear, the following publications of the Association: The *American Economic Review*, the *Journal of Economic Literature* and the *Directory of Members*.

A report by the Secretary-Treasurer had been distributed in advance of the meeting. He reviewed the report and moved adoption of the following resolution:

> BE IT RESOLVED that 80 percent of the dues of regular members with the rank of assistant professor or lower or with annual incomes of $12,000 or less irrespective of rank be considered payment for a year's subscription to both the *American Economic Review* and the *Journal of Economic Literature* and the same dollar amount of the payment by subscribers (nonmembers) and other regular members be considered payment for subscriptions to the *Review* and the *Journal*, with the remainder a contribution toward the Association's exempt functions, such as annual meetings and various economic research projects and programs. In the event that the Executive Committee under the authority of Article I, Section 2, changes the dues schedule and income brackets, the figure of $12,000 in this resolution will be considered to have been adjusted accordingly.

The motion was seconded and PASSED.

The president announced that Fels would be succeeded by C. Elton Hinshaw as Secretary, effective January 1, 1976, but would continue as Treasurer and Editor of the *Papers and Proceedings*. He then read the resolution adopted by the Executive Committee on December 27, 1975, and incorporated in its minutes.

The Managing Editors of the *American*

*Economic Review* (George H. Borts) and the *Journal of Economic Literature* (Mark Perlman) discussed their written reports, which also had been distributed in advance of the meeting and were to be published in the *Proceedings*. The Director of *Job Openings for Economists* (Hinshaw) read his report, likewise to be published in the *Proceedings*.

The Secretary presented the following resolutions, which were adopted unanimously:

> This meeting would like to record a special vote of thanks to Ralph T. Green, Chairman, and the other members of the National Convention Committee for their hard work, dedication and efficient management of the 1975 annual meetings of the Allied Social Science Associations.
>
> This meeting commends Franco Modigliani and the members of the Program Committee for planning a program intellectually stimulating, appropriately varied, and high in quality.

At this point, President Gordon introduced the new President, Franco Modigliani, who took the chair, commended his predecessor, and moved the thanks of the Association to him, a motion which was adopted by acclamation.

The new President gave an oral report on behalf of the Committee on Political Discrimination. David M. Gordon distributed copies of the statement, previously presented to the Executive Committee, entitled "Taking Political Discrimination Seriously" and proposing a resolution that would broaden the functions of the Committee on Political Discrimination. The President said that the statement would be referred to the Committee on Political Discrimination and subsequently would be considered by the Executive Committee. D. M. Gordon elaborated on the statement and the reasons for the proposed resolution. He explained that the resolution was considered not in order because it had not been submitted thirty days in advance of the annual meeting, but the reason was that the Committee on Political Discrimination had not finished its deliberations in time. David Barkin also spoke in favor of the statement and the resolution.

Oscar Goodman moved that future program chairmen of the American Economic Association not schedule any sessions in the future that conflict with the business meeting. The motion was seconded and PASSED. D. M. Gordon advocated steps to ensure larger attendance at the business meetings.

It having been pointed out that attendance at the business meeting was low, R. A. Gordon suggested that the Executive Committee at its March meetings deal with this problem. William Vickrey suggested that posters at the convention call attention to nonroutine items of business scheduled to come up at the business meeting. He also suggested that the business meetings be scheduled after the presidential address. Eric Bovet suggested that a quorum be established to force the Association to take steps to insure an adequate turnout. He also suggested that a new class of membership for retired persons be established.

There being no further business, the meeting was adjourned at 5:15 p.m.

RENDIGS FELS, *Secretary*

# MINUTES OF THE EXECUTIVE COMMITTEE MEETINGS

**Minutes of the Meeting of the Executive Committee in Washington, D.C., March 14, 1975.**

The first meeting of the 1975 Executive Committee of the American Economic Association was called to order at 9:20 a.m. on March 14, 1975, in the Washington Hilton Hotel, Washington, D.C. Present as members of the Executive Committee were R. A. Gordon, presiding, Carolyn Shaw Bell, George H. Borts, Andrew F. Brimmer, Martin Bronfenbrenner, Rendigs Fels, Walter W. Heller, Franco Modigliani, Mark Perlman, Charles L. Schultze, Paul M. Sweezy, and Burton A. Weisbrod. Absent were Irma Adelman, Kenneth J. Arrow, and Robert L. Heilbroner. Present for part of the meeting as members of the Nominating Committee were Robert Eisner, Chairperson, Bernard E. Anderson, Robert E. Gallman, Richard W. Parks, Leonard A. Rapping, Barbara B. Reagan, and Christopher A. Sims. Present for part of the meeting as members of the Committee on Honors and Awards were Lloyd G. Reynolds, Chairperson, John S. Chipman, and James W. McKie. Present as Chairperson of the Committee on the Status of Minority Groups in the Economics Profession was Marcus Alexis. Also present was the Assistant Secretary-Treasurer, C. Elton Hinshaw.

*Minutes.* The minutes of the meeting of December 27, 1974, were approved as corrected.

*Report of the Secretary* (Fels). The Secretary reported that a resolution was needed governing the application of retirement benefits to Association employees. He was authorized to approve such a resolution and put it into effect. The Secretary reported that, in response to the directive of the Executive Committee adopted at its meeting of December 27, 1974, the dates of the 1975 meetings in Dallas had been shifted from October 3–5 to December 28–30. He pointed out that the Executive Committees of different years had made three different decisions on the dates of the 1975 meetings and had made six decisions involving four changes in the site and dates of the 1976 meetings. In response to his contention that no Secretary, present or future, could live with a decision-making process leading to such vacillation, the Executive Committee VOTED to adopt the following procedure for determining sites and dates of future meetings: after consulting with the Executive Committee, the Secretary will propose the site and date, subject to the approval of the Executive Committee; decisions once made shall not be changed except in extreme cases; if a proposal of the Secretary is disapproved, the Executive Committee will not make some different decision but will instruct the Secretary to come in with a new proposal. In subsequently rejecting the Secretary's recommendation that the 1982 meetings be held in New York City on September 9–11, it made clear that it wanted the meetings held in New York City on December 28–30, thereby adhering to the letter if not the spirit of the new procedures it had just adopted.

*Report of the Treasurer* (Fels). The Treasurer reported that the budget deficit for 1975 was now projected at $155,000, compared to $129,000 in 1974; that the cash deficit for 1975 was projected at $76,000 compared to $119,000 the pre-

vious year; and that the net worth of the Association had fallen from $162,000 at the end of 1973 to a negative figure ($10,000) at the end of 1974 but was expected to rise to $54,000 by the end of the current year. Not surprisingly, the Executive Committee found these figures puzzling as well as disturbing. Considerable dissatisfaction having been expressed with the form of the financial reports, the Budget Committee was asked to reconsider budget procedures, including the investment income formula, and to report to the Executive Committee next December. The Treasurer pointed out that the 1975 projections reported above included $3,000 not yet authorized for the expenses of the Committee on Political Discrimination, which had been appointed in response to a resolution passed at the annual meeting. It was VOTED to appropriate $3,000 for the Committee on Political Discrimination. It was VOTED to approve and submit to the membership for ratification changes in the bylaws effective January 1, 1976, that would introduce progressivity in the dues structure in the following way: (1) assistant professors and those with lower academic rank would pay $25 per year, as would all members with annual incomes of $12,000 per year or less irrespective of rank; (2) associate professors and those with incomes above $12,000 but not more than $20,000 would pay $30 per year unless they qualified for the $25 rate under (1) above; and (3) full professors and those with incomes above $20,000 would pay $35 a year unless qualifying for a lower rate (all rates subject to indexation). It was then VOTED to approve and submit to the members for ratification a change in the bylaws raising the dues of family members to $5 per year effective January 1, 1976. It was also VOTED to approve and submit to the members for ratification a change in the bylaws abolishing the category of life member effective January 1, 1976, except for those already holding such membership. Finally it was VOTED to establish a voluntary page charge of $25 for articles in the regular issues of the *American Economic Review* (excluding the *Papers and Proceedings* issue) and the *Journal of Economic Literature*. The Treasurer was asked to make a greater effort to solicit advertising.

*Report of the Editor of the American Economic Review* (Borts). The Editor announced that he expected to reduce costs $12,000 a year by limiting the number of text pages per issue to 300 and eliminating free reprints. On recommendation of the Editor, it was VOTED to institute an extra charge for foreign mailings of the *Review* and the *Journal* approximately equal to the extra postage, effective January 1, 1976. It was VOTED to raise the *Review's* submission fee for nonmembers to $30, an extra $15 above the fee charged to members being applicable to dues if the author applies for membership.

*Report of the Editor of the Journal of Economic Literature* (Perlman). The Editor announced that the trim size of the *Journal* was being changed with savings estimated by the printer of $16,000 a year. He agreed to delete the index of authors of abstracts from the *Journal* for a saving of $1,400 a year. He reported on a proposal received from Knowledge Availability Systems Center (*KASC*). It was the sense of the meeting that he and the Secretary-Treasurer enter into negotiations with *KASC* and bring a proposal to the next meeting of the Executive Committee.

*Report of the Director of Job Openings for Economists* (Hinshaw). The Director reported that the excess of expenditures over revenues from subscriptions for 1974 was $12,000 and in 1975 was expected to be at least $10,000. He ex-

pressed the opinion that charges for listing vacancies should be instituted at a later time after the practice of open listing had become well established. He was asked to bring a proposal for such charges to the December meeting of the Executive Committee.

*Committee on Honors and Awards* (Reynolds). The Electoral College consisting of the Executive Committee and the Committee on Honors and Awards meeting together VOTED unanimously to award the John Bates Clark Medal to Daniel McFadden. At the suggestion of the Committee on Honors and Awards, the Executive Committee VOTED to approve a change in the bylaws, to be submitted to the members for ratification by mail ballot, removing the limit of twelve on the number of Distinguished Fellows in addition to ex-Presidents, thus permitting the election of two additional Distinguished Fellows annually.

*Nominating Committee* (Eisner). The Electoral College consisting of the Nominating and Executive Committees meeting together chose Lawrence R. Klein as the nominee for President-elect, Moses Abramovitz as Distinguished Fellow, and Robert Eisner as representative to the Social Science Research Council. The Chairperson of the Nominating Committee reported the following nominees for other offices in the 1975 election: for Vice President (two to be chosen), Barbara R. Bergmann, Harry G. Johnson, Douglass North, Albert Rees; members of the Executive Committee (two to be chosen), Robert W. Fogel, Bert Hickman, Edmund S. Phelps, Alice M. Rivlin.

*Committee on the Status of Minority Groups in the Economics Profession* (Alexis). The Chairperson distributed a written summary report on the Summer Program for Minority Students. In separate motions, it was VOTED (1) to approve a second Summer Program for Minority Students to be held in 1975, (2) to authorize the expenditure of $5,000 for the expenses of the Committee in 1975, (3) to underwrite the expenses of the 1975 Summer Program by a maximum of $5,000, and (4) to authorize the Committee to raise money for a fellowship program for graduate study in economics for minority groups.

*National Economic Association* (Gordon). The President reported on his conversations with the National Economic Association (*NEA*). It was agreed that the President in the future would invite suggestions of that organization for appointments to the Committee on Minority Groups in the Economics Profession. It was also agreed that the distinguished economists on the panel for the Visiting Scholars Program would be asked if they would be willing to help young black economists with their research and to make the list of those responding positively available to *NEA*.

*Committee on the Status of Women in the Economics Profession* (Reagan). The Chairperson reported that the size of the Committee has been reduced to seven from ten (with at least one male member).

*Committee on Honorary Members* (Fritz Machlup). Modigliani presented recommendations he had received by telephone from the Chairperson, who was prevented from attending by illness. The following foreign economists were elected Honorary Members: Edmond Malinvaud, Friedrich A. von Hayek, Don Patinkin, Trygve Haavelmo, and Nicholas Kaldor. No action was taken on the Committee's proposal to raise the maximum number of honorary members from 25 to 35, because the Executive Committee wanted more information about the reasons for the particular number recommended. The Secretary was asked to inform the Committee on Honorary

Members of its interest in electing economists from the Third World.

*Report of the Chairperson of the Program Committee* (Modigliani). The Chairperson reported on his plans for the program of the 1975 meetings.

*Resolutions Procedures* (Gordon). The President pointed out that a very small percent of the membership can pass important resolutions at the annual meetings. It was VOTED to approve and submit to the members for ratification by mail ballot a change in the bylaws under which resolutions passed at a meeting at which less than 5 percent of the members vote would be sent to all members for a vote by mail. It was agreed that the President-elect would consult the Counsel about what resolutions should be exempt from the requirement of a mail vote and about the wording of the proposed bylaw, which will be circulated to the Executive Committee prior to being submitted to the members.

*Expiration of Term of Secretary-Treasurer.* In view of the fact that the term of the Secretary-Treasurer expires at the end of 1975, the President announced that he would appoint a committee with broad terms of reference to bring a recommendation to the December meeting of the Executive Committee.

*Date of Spring Meeting.* It was agreed that the Executive Committee would meet on March 19–20, 1976, in Washington, D.C.

The meeting adjourned at 9:20 p.m.

**Minutes of the Meeting of the Executive Committee in Dallas, Texas, December 27, 1975.**

The second meeting of the 1975 Executive Committee of the American Economic Association was called to order in the Statler Hilton Hotel, Dallas, Texas, at 10:15 a.m. on December 27, 1975. The following members were present: R. A. Gordon, presiding, George H. Borts, Andrew F. Brimmer, Martin Bronfenbrenner, Rendigs Fels, Walter W. Heller, Franco Modigliani, Mark Perlman, Charles L. Schultze, and Burton A. Weisbrod. Also present were newly elected members Barbara R. Bergmann, Harry G. Johnson, Lawrence R. Klein, and Edmund S. Phelps. Absent were Irma G. Adelman, Kenneth J. Arrow, Carolyn Shaw Bell, Robert L. Heilbroner, Paul M. Sweezy, and newly elected member Alice M. Rivlin. Present as guests for parts of the meeting were Marcus Alexis, David M. Gordon, Irvin L. Grimes, C. Elton Hinshaw, Fritz Machlup, Barbara MacPhee, Barbara B. Reagan, and Lloyd G. Reynolds.

*Minutes.* The minutes of the meeting of March 14, 1975, were approved.

*Report of the Secretary* (Fels). The Secretary having expressed dissatisfaction with procedures for selecting sites and dates for the annual meetings, it was VOTED that:

> The Executive Committee should set general guidelines the Secretary should consider in proposing dates and places of annual meetings. Working within these guidelines the Secretary should make specific recommendations regarding future meeting times. (It is assumed that normally firm commitments will not extend beyond five years. Once approved by the Executive Committee, the place and dates of a particular annual meeting cannot be changed except under unusual circumstances, and a positive vote of two-thirds of the voting members of the Executive Committee would be required to effect a change.)

On recommendation of the Secretary, the Executive Committee VOTED to continue affiliation of the American Economic Association with the American Association for the Advancement of Science.

*Report of the Treasurer* (Fels). It was VOTED to approve the budget submitted

by the Treasurer and the Budget Committee subject to moderate changes. (For details of the budget, see the Treasurer's Report in the *Proceedings.*) It was agreed that a spcial committee would be appointed to reconsider the investment income formula.

*Report of the Editor of the American Economic Review* (Borts). On recommendation of the Managing Editor, the following persons were elected to the Board of Editors of the *American Economic Review* for three-year terms: Irma G. Adelman, David Baron, Robert Barro, Laurits R. Christensen, David Laidler, and Frank Stafford. The Editor was asked to reconsider the method of assessing page charges and report to the next meeting of the Executive Committee. It was suggested that the Editor commission an objective review article on the Means-Stigler controversy.

*Report of the Editor of the Journal of Economic Literature* (Perlman). On recommendation of the Managing Editor, the following persons were elected to the Board of Editors of the *Journal of Economic Literature:* George Feiwel, James Kindahl, Michio Morishima, and Charles Z. Wilson. It was VOTED to approve on a one-year trial basis an agreement with the Knowledge Availability Center of the University of Pittsburgh whereby the Association will receive 2 cents for each bibliographical reference based on the *Journal's* files and sold by the Center.

*Report of the Director of Job Openings for Economists* (Hinshaw). The Director reported that subscription revenues were very nearly equal to full costs of *Job Openings for Economists.* He therefore recommended no changes in charges. It was agreed that, in view of the early dates of the 1976 annual meetings, the possibility of a placement meeting late in 1976 or early in 1977 be explored.

*1976 Program Chairman* (Klein). The Chairman gave a brief report on plans for the 1976 program.

*U.S.-Soviet Exchanges* (Reynolds). It was VOTED to authorize the Committee on *U.S.*-Soviet Exchanges to solicit travel funds for American economists to attend the colloquium planned for June 1976 in Moscow. It was agreed that planning for a visit for Soviet economists to the *United States* in 1977 be postponed until after the 1976 visit by Americans to the *USSR.*

*Political Discrimination.* In the absence of Kenneth J. Arrow, Chairman of the Committee on Political Discrimination, Modigliani telephoned him and obtained an oral report. David M. Gordon distributed a statement entitled "Taking Political Discrimination Seriously" proposing a resolution asking that the scope of the Committee be broadened. D. M. Gordon requested that the resolution be considered either by the Executive Committee or by the membership at the annual meeting. R. A. Gordon explained that, since the Committee's functions had been determined at the 1974 annual meeting, the Executive Committee could not change its charge, and, since the resolution had not been submitted thirty days in advance, it would be out of order at the annual meeting of December 29, 1975. After suggesting that the resolution be referred to the Committee on Political Discrimination, he turned the chair over to Modigliani. Bronfenbrenner moved that an exception be made in this instance to the thirty-day rule. The motion died for lack of a second. After further discussion, it was VOTED that Modigliani would make an oral report for the Committee on Political Discrimination at the annual meeting, after which the floor would be open for discussion of the subject. It was agreed that the resolution would also be referred to the Committee on Political Discrimination. R. A. Gordon resumed the chair.

*Minority Group Economists* (Alexis).

The Executive Committee VOTED to carry forward $10,000 previously appropriated for the Committee on the Status of Minority Groups in the Economics Profession less amounts already spent and to appropriate an additional S5,000 with the hope and expectation that the funds would not be used. It was VOTED to pay the travel expenses of Alexis to Dallas.

*Women* (Reagan). It was VOTED to appropriate $9,700 for the Committee on the Status of Women in the Economics Profession for 1976. The Committee was asked to consider soliciting voluntary contributions from those associated with its activities with a view toward ultimate financial independence.

*Secretary-Treasurership* (Heller). On behalf of the Ad Hoc Committee on the Secretary-Treasurership (William H. Nicholls, George J. Stigler, and Walter W. Heller, Chairman), Heller moved that for the three-year term beginning January 1, 1976, C. Elton Hinshaw serve as Secretary and Rendigs Fels as Treasurer and Editor of the *Papers and Proceedings* (the division of duties between them to be as specified in the letter of October 10, 1975, from Fels to Heller). The motion was seconded and PASSED. It was then VOTED to approve the following resolution:

> First, that on the occasion of Rendigs Fels' decision not to be a candidate for reappointment as Secretary of the Association, the Executive Committee on behalf of the *AEA* membership expresses its warmest appreciation for the outstanding contribution he has made to the Association through his perceptive, judicious, and efficient management of the Association's affairs during an unusually demanding and difficult period.
>
> Second, that we consider ourselves most fortunate that Rendigs Fels is willing to continue to serve as Treasurer and Editor of the *Proceedings* for the coming three-year term.

*Publications*. In the absence of the Chairman of the Committee on Publications, Modigliani and Machlup reported on plans for a questionnaire surveying readers' opinions of the journals.

*International Economic Association* (Machlup). The question was raised of whether the American Economic Association should withdraw from the International Economic Association (*IEA*) in view of the latter's connection with *UNESCO* and *UNESCO*'s treatment of Israel. Machlup expressed the opinion that such action would hurt the Israelis, who regularly participate in *IEA* conferences, pointing out that Arabs seldom take part. Although this view did not command unanimous support, no action was taken.

*Bylaws* (Fels). It was VOTED to submit to the members for approval by mail ballot the following amendments to the bylaws:

*Change Article I, Section 2, to read:*

> 2. There shall be six classes of members other than honorary: regular members with the academic rank of assistant professor or lower or with annual incomes of $12,000.00 or less irrespective of rank, paying the base fee defined below; regular members with the academic rank of associate professor or with annual incomes above $12,000.00 but not more than $20,000.00 paying one and one-fifth times the base fee; regular members with academic rank of full professor or with annual incomes above $20,000.00 paying one and two-fifths times the base fee; family members (two or more persons living at the same address, second membership without subscription to the publications of the Association) paying one-fifth of the base fee; junior members (available to registered students for three years only) paying one-half the base fee; and life members comprising those who qualified for life membership by making a single payment of the designated amount prior to January 1, 1976, and exempt from annual fees.
>
> Effective January 1, 1976, the base fee is $25.00 per year. The Executive Com-

mittee may increase the dues schedule, including both the base fee and the income brackets for regular members, in proportion to the increase occurring after January 1, 1976 in relevant price and wage indexes, provided that the increase in any year shall not exceed ten percent.

*Change Article I, Section 3, to read:*

3. Foreign economists of distinction, not exceeding twenty-five in number, may be elected honorary members of the Association. Past presidents of the Association and members who have been awarded the Walker Medal shall be Distinguished Fellows. In addition, the Executive Committee may elect additional Distinguished Fellows, but not more than two in any one calendar year, from economists of high distinction in the United States and Canada. Candidates for Distinguished Fellowships shall be nominated by the Nominating Committee or the Executive Committee, and they shall be elected by the combined vote of the two committees. The Nominating Committee shall solicit and give due consideration to the recommendations of the Committee on Honors and Awards. The Nominating Committee is free to make no nominations in any particular year. However, it is not limited as to the number of candidates it may nominate in any year. Election to Distinguished Fellowship does not preclude election to any office of the Association.

*Change Article II to read:*

The Board of Trustees shall be composed of the voting members of the Executive Committee.

*Delete Article III, Section 2.*

*Renumber Article III, Section 3, and change it to read:*

2. The Association shall have the following officers who shall be appointed by ing officers who shall be appointed by the Executive Committee: a Secretary, a Treasurer, and a Managing Editor of the *American Economic Review,* a Managing Editor of the *Journal of Economic Literature,* and a Counsel. The terms of office of each of these officers shall be three calendar years.

*Renumber Article III, Section 4, to become Section 3.*

*Change Article IV, Section 2, to read:*

2. Before October 1 of each year, the President-elect of the Association shall appoint a Nominating Committee for the following year, this Committee to consist of a past officer as Chairman and not less than five other members of the Association. In addition to appointees chosen by the President-elect, the Committee shall include any other member of the Association nominated by petition including signatures and addresses of not less than 2 percent of the members of the Association, delivered to the Secretary before December 1. No member of the Association may validly petition for more than one nominee for the Committee.

The names of the Committee shall be announced to the membership immediately following its appointment and the membership invited to suggest nominees for the various offices to the Committee. The Nominating Committee for each year shall be instructed to present to the Executive Committee on or before March 31 a nominee for the President-elect and two or more nominations for each other elective office to be filled, except the presidency, all these nominees being members of the Association. The members of the Nominating and Executive Committees shall constitute an Electoral College which shall consider the nominee of the Nominating Committee for the President-elect and select a single candidate for that office. In the voting in the Electoral College, each member shall have one vote provided that the number of members of the Nominating Committee present does not exceed the number of members of the Executive Committee present; otherwise the members of the Nominating Committee present shall have fractional votes such that their sum equals the number of members of the Executive Committee present.

The Secretary shall inform all members of the Association of the actions of the Nominating Committee and the Electoral College not later than the June issue of the *American Economic Review.* An additional nomination for any office may be

made by petition, delivered to the Secretary by August 1, including signatures and addresses of not less than 6 percent of the membership of the Association for the office of President-elect and not less than 4 percent for each of the other offices. No member of the Association may validly petition for more than one nominee for the Executive Committee, one nominee for Vice-President, and one nominee for President-elect.

The election of officers by the membership shall take place by a mail ballot conducted by the Secretary each year. The ballot shall list all nominees alphabetically, with indication "nominated by petition" where applicable. Space shall be provided on the ballot for the individual voter's alternative choices for all offices. The Secretary shall mail the ballots to all members as soon as practicable after August 1 and set a deadline for receipt of ballots in the Secretary's office no earlier than October 1 and no later than November 30. The candidates with the highest number of votes for the various offices will be elected. The results of the election shall be certified and announced by the Secretary at the annual business meeting or in the *American Economic Review*.

*Renumber Article IV, Section 3, to become Section 4, and add as Section 3:*

3. The President-elect shall be responsible for the program for the annual meeting of the year in which he serves. He may at his discretion appoint a Program Committee to assist him.

*Renumber Article IV, Section 4 to become Section 5.*

*Renumber Article IV, Section 5, and change to read:*

6. The Executive Committee shall have the control and management of the funds of the corporation. It may fill vacancies in the list of officers, and may adopt any rules or regulations for the conduct of its business not inconsistent with this constitution or with rules adopted at the annual meetings. It shall act as a committee on time and place of meetings and perform such other duties as the Association shall delegate to it. A quorum shall consist of five voting members.

*Renumber Article IV, Section 6, and change to read:*

7. The Managing Editors shall, with the advice and consent of the Executive Committee, appoint members of Editorial Boards to assist them. They shall be *ex officiis* members and chairpersons of their respective Boards, which shall have charge of the publication of the *American Economic Review* and the *Journal of Economic Literature*.

*Renumber Article IV, Section 7, to become Section 8.*

*Change Article V, Section 1, to read:*

1. The annual meeting of this corporation shall be held at such time and place as may be determined by the Executive Committee. Notice of such time and place shall be given by publication in the *American Economic Review,* at least three months prior to such meeting.

*Change Article V, Section 2, to read:*

2. A resolution adopted at an annual meeting in which less than five percent of the membership of the Association has voted thereon shall be submitted within ninety days to a vote by mail ballot if a majority of the Executive Committee determines that, because of the nature or consequences of the resolution, all members should have the opportunity to participate in the final decision. Upon such a determination by the Executive Committee, the resolution shall cease to be effective and shall not become effective unless and until approved by a majority of the mail ballots cast. Mail ballots shall be accompanied by (1) a brief statement by the sponsor or sponsors in support of the resolution, (2) a brief statement of the views of the Executive Committee and whether the Committee favors, opposes, or takes no position on the resolution, and (3) a brief statement by a person or persons whom the Committee designates to represent opposing views.

*Change Article VI to read:*

Amendments, after having been approved by a majority of the Executive Committee, may be adopted by a majority of votes cast in a mail ballot.

*Richard D. Irwin, Inc.* (Grimes). The Vice Chairman of Richard D. Irwin, Inc., proposed a settlement of the Association's claim for $34,000 under which the Association would receive $10,000 and all the remaining copies of the books in the foreign translation series (about 13,500 copies in all) to be shipped to any destination at the expense of the Association. Grimes was asked to investigate the possibilities of (1) bulk remaindering of the entire stock and (2) remaindering of the stock by the Association with Richard D. Irwin, Inc., holding it and filling orders at a cost estimated at 50 cents per copy. It was agreed to take the matter up again at the next meeting of the Executive Committee.

*Expiration of Terms of the Managing Editors.* It was VOTED that the incoming President appoint a small committee to make a report in March 1976 on reappointment of the present Managing Editors, whose terms expire at the end of 1977, or appointment of new ones.

The continuing members of the Executive Committee having expressed thanks to the retiring members for their service, the meeting was adjourned at 10:10 p.m.

RENDIGS FELS, *Secretary*

# REPORT OF THE SECRETARY FOR 1975

*Annual Meetings.* In 1976 the annual meetings will be held at the Chalfonte-Haddon Hall in Atlantic City on September 16–18, with the employment service beginning operations on the 15th. This is a departure from the traditional Christmas holiday dates. The departure resulted from a referendum of the membership in 1970, which could not be acted on earlier because hotel accommodations for large meetings need to be reserved five to eight years in advance. (In the case of the 1975 meetings, in Dallas, it had proved possible to change the dates from Christmas to early October, but the decision to do so was reversed by the Executive Meeting at its meeting on December 27, 1974.)

The schedule for meetings after 1976 is: December 28–30, 1977, in New York City with headquarters at the New York Hilton Hotel; August 29–31, 1978, in Chicago with headquarters at the Conrad Hilton Hotel; December 28-30, 1979, in Atlanta with headquarters at the Atlanta Hilton; September 5–7, 1980, in Denver with headquarters at the Denver Hilton Hotel; and December 28–30, 1981, in Washington, D.C. with headquarters at the Washington Hilton Hotel and the Sheraton-Park Hotel. No decision has been made for 1982. The Executive Committee has made a tentative decision to meet in San Francisco December 28–30, 1983.

*Membership.* The total number of members and subscribers, shown in Table 1, reached an all-time high of 26,787 at the end of 1975. The previous peak had been at the end of 1970, just before dues and subscription rates were doubled. By the end of 1972, the number had fallen from 26,173 to 24,489. Since then the total has been rising. The number of subscribers is still slightly below 1970, reflecting the greater increase in subscription rates than dues in the 1970–75 period. The number of regular (annual) members is also a little lower, the increase in the total having come in the minor categories of membership.

TABLE 1—MEMBERS AND SUBSCRIBERS
(End of year)

| | 1970 | 1972 | 1975 |
|---|---|---|---|
| Class of Membership | | | |
| Annual | 16,075 | 14,462 | 16,011 |
| Junior | 2,077 | 1,886 | 2,367 |
| Family | 289 | 262 | 335 |
| Complimentary | 160 | 345 | 449 |
| Life | 291 | 315 | 383 |
| Honorary | 16 | 72 | 19 |
| Total Members | 18,908 | 17,342 | 19,564 |
| Subscribers | 7,265 | 7,147 | 7,223 |
| Total Members and Subscribers | 26,173 | 24,489 | 26,787 |

*Permission to Reprint and Translate.* Official permissions to quote from, reprint, or translate and reprint articles from the *American Economic Review* and the *Journal of Economic Literature* totaled 204 in 1975 compared to 180 in 1974. In addition, permission was granted to reprint 263 abstracts from the *Journal.* Upon receipt of a request for permission to reprint an article, the publisher or editor making the request is instructed to get the author's permission in writing and send a copy to the Secretary as a condition for official permission. The Association suggests that authors charge a fee of $150, but they may charge some other amount, enter into a royalty arrangement, waive the fee, or refuse permission altogether.

*Visiting Scholars Program.* The Visiting Economics Scholars Program, modeled on the Visiting Scientists Program in Economics formerly supported by the National Science Foundation, was inaugurated in the academic year 1974–75 and has continued under the direction of C. Elton Hinshaw. Its purpose is to facilitate visits by leading economists to smaller colleges emphasizing teaching. During 1974–75 there were eight such visits.

*Committees and Representatives.* Listed below are those who served the Association during 1975 as members of committees or as representatives. Years in parentheses indicate the final year of the term to which they most recently have been appointed. On behalf of the Association, I wish to thank them all for their service.

# REPORT OF THE TREASURER FOR THE YEAR ENDING DECEMBER 31, 1975

Table 1 gives budget data for 1975 and 1976. The budgets are compared with the actual results for 1974 and with the results anticipated for 1975 at the time (December 27, 1975) that the 1976 budget was approved by the Executive Committee. The actual results for 1975 are given below in the financial statements following the Auditors' Report. Since the Treasurer's Report is sent to the printer before the audit takes place, the final results cannot be known at the time this report is written. Ordinarily actual results differ from anticipated by a significant margin. Nevertheless, it is clear that a substantial improvement in the financial position of the American Economic Association took place in 1975, thanks to actions taken by the Executive Committee at its meeting in March 1975, cost cutting by the managing editors of the two principal publications, and the rise in the stock market.

At the end of 1974, the net worth of the Association was negative by nearly $10,000. In March 1975, just before the meeting of the Executive Committee, the expected deficit for 1975 on the basis on which the Association's accounts have been kept during recent years was $155,000. (See Table 1.) Actions taken at the March meeting in response to this situation and recorded in the Minutes printed above, together with underspending by the managing editors, sharply reduced the 1975 deficit compared to what had been expected and brought the deficit expected for 1976 down to a very low figure. The deficits for 1975 and 1976 include provision for a reserve for a future *Directory* and part of the real capital losses incurred in 1973–74 but not recognized until 1975 and 1976. Without these items, there would be surpluses.

Table 1 is mainly on an accrual basis. Table 2 shows the cash budget for 1976. An increase in cash of $83,000 is expected. The first line in Table 2 repeats the deficit shown in Table 1. The next two items represent adjustments to eliminate the reserve for the *Directory* and the real capital losses which are included in Table 1 but do not involve a change of cash. The fourth item, the manufacturing cost of the four volumes of the *Index of Economic Articles* to be published in 1976, will use cash but will be recovered from sales in future years. Line 5 shows a substantial expected increase in deferred income associated with the increase in dues for high-income members which went into effect January 1, 1976. The Association collects dues and subscriptions in advance, which are shown on the books as deferred income, a liability. Whenever there is an increase in dues and subscription rates, the associated increase in deferred income generates cash.

The rise in the stock market in 1975 was faster than the rise in the *GNP* deflator and therefore generated real capital gains. The Association recognizes only one-third of the real capital gains or losses from equities in the year in which they occur, recognizing the other two-thirds in the income statements for the two subsequent years. Consequently, Table 1 does not fully reflect the gain in the value of the Association's portfolio in 1975 (nor do the figures for 1974 fully reflect the

[a] As approved by the Executive Committee, December 27, 1975. Does not include minor changes made subsequently in accordance with Executive Committee actions and policies.

[b] The projections of revenues shown in the 1975 budget are as revised in March in the light of the actual results for 1974. The estimates of expenditures take account of the actions by the Executive Committee at its meeting on December 27, 1974, and by the membership at the Annual Meeting of December 29, 1974. Actions taken by the Executive Committee at its meeting on March 14, 1975, however, are not included in the estimates of revenues and expenditures; they account for much of the disparity between the budget and the actual results.

[c] Estimates prepared in November 1975 of revenues and expenses for the entire year.

[d] Includes $50,000 in each of the years 1975 and 1976 set aside as a reserve for a future *Directory*. The $69,000 in 1974 and the other $5,000 in 1975 represent actual expenditures for the 1974 *Directory* in excess of the reserve accumulated previously.

losses). But the balance sheet (printed below following the Auditors' Report) shows the current value of the portfolio. The negative figure for net worth in the balance sheet at the end of 1974 resulted partly from the decline in the stock market during that year, and the rise in the stock market in 1975 is fully reflected in the net worth, which is now significantly positive. But it is low relative to annual expenditures and relative to the highest deficit ($242,000 in 1970) ever experienced.

The accumulated deficits for 1969–75 totaled nearly half a million dollars. With the net worth as low as it is, the Association must cease having deficits, and it needs to run surpluses for several years until the ratio of net worth to annual expenditures is built up to an adequate level. The change in the dues structure instituted at the beginning of 1976 is intended to achieve this result.

RENDIGS FELS, *Treasurer*

# REPORT OF THE FINANCE COMMITTEE*

The accompanying inventory summary lists the securities held by the American Economic Association as of December 31, 1975, with costs and market values as of that date. The total market value of the securities portfolio at year end was $490,672. After making adjustments for cash additions and withdrawals (including a sizeable withdrawal of $65,000 made from the portion of the Fund represented by the Ford Foundation grant), we estimate that the Association's investment portfolio (on a total return basis) increased in value by 30.6 percent during 1975. During the same period, the Standard & Poor's 500 Index provided a total return of +37.2 percent. Utilizing a longer term period of time (from the end of 1967 to December 31, 1975), which includes both recoveries and recessions and rising and falling securities markets, the account's total return was + 34.2 percent while the Standard & Poor's 500 Index experienced a total return of +23.4 percent and an unweighted average of all of the stocks on the New York Stock Exchange actually declined on a comparable basis during this period by 27 percent.**

It should be remembered that the $490,672 figure referred to above includes a Special Grant that was made by the Ford Foundation in January of 1969 and subsequently commingled with the Association's account. As of December 31, 1975, the Association's portion of the aggregate account was $390,022, or 79.5 percent and the Special Grant represented the remaining $100,650, or 20.5 percent of the total. These calculations are after taking the $65,000 withdrawal from the Special Grant into consideration.

During the past twelve months, several changes were made in the equity component of the account. The most important of the changes that were made involved the sale of 200 Atlantic Richfield, 2,200 Rank Organisation, 400 ERC, 1,000 Hoerner Waldorf, 800 Manufacturers Hanover, 4,601 Capital Opportunities Fund, and 400 Xerox; and new purchases of 400 Abbott Labs, 500 Philip Morris, and 600 Seven Up. It should be noted that a significant proportion of the sales listed above were undertaken because of the

* The Report of the Finance Committee is informational and is not an audited financial statement. Consequently, there may be some discrepancies between figures in the Report of the Finance Committee and the Auditors' Report which follows.

** The unweighted average of all the common stocks on the New York Stock Exchange was adjusted to include the yield on the Standard & Poor's 500 Index.

large withdrawal made from the Special Grant category.

In terms of the outlook for 1976, the Finance Committee is looking forward to a good year. It is our view that during the next twelve months the economy should continue to recover, the level and quality of profits should continue to improve, the pace of inflation should continue to moderate, and interest rates should continue to stabilize around the lower levels established during the last quarter of 1975. These positive expectations have led the Committee to the judgment that, while equities are clearly not as deeply undervalued as was the case a year ago, the environment for common stock investment nevertheless appears, on balance, quite favorable.

However, it is also the judgment of the Committee, reached only after careful consideration, that an investment program of rolling over high-grade six month commercial paper is, over time, a satisfactory way to protect investable funds from erosion by inflation and that our previous policy of investing only in equities should be replaced by a new policy designed to include a combination of both common stocks and commercial paper.

On the basis of this judgment, the Committee is planning to take advantage of the anticipated strength in the stock market during 1976 to shift one-third of the long term investment account from equities to high-grade commercial paper. Ultimately the Committee intends to have one-half of the portfolio invested in commercial paper, but in view of the likelihood of an up-market trend for common stocks during 1976, the Committee has decided to move only two-thirds of the way toward the target during the next year. In the context of this policy, the Association's investment portfolio will be continuously monitored; and, should events proceed in a way which would justify a shift in emphasis, adjustments will be made in our investment position.

BERYL W. SPRINKEL, *Chairperson*

# AUDITORS' REPORT

*To the Executive Committee of*
*The American Economic Association:*

We have examined the statements of assets and liabilities of THE AMERICAN ECONOMIC ASSOCIATION (a District of Columbia corporation, not for profit) as of December 31, 1975 and 1974, and the related statements of revenues and expenses, changes in general and restricted fund balances and changes in assets and liabilities for the years then ended. Our examination was made in accordance with generally accepted auditing standards, and accordingly included such tests of the accounting records and such other auditing procedures as we considered necessary in the circumstances.

In our opinion, the accompanying statements present fairly the assets and liabilities of The American Economic Association as of December 31, 1975 and 1974, and its revenues and expenses, changes in fund balances and the changes in its assets and liabilities for the years then ended, in conformity with generally accepted accounting principles consistently applied during the periods.

ARTHUR ANDERSEN & CO.

Memphis, Tennessee
February 26, 1976.

THE AMERICAN ECONOMIC ASSOCIATION
STATEMENTS OF ASSETS AND LIABILITIES—DECEMBER 31, 1975 AND 1974

THE AMERICAN ECONOMIC ASSOCIATION
NOTES TO FINANCIAL STATEMENTS
FOR THE YEARS ENDED DECEMBER 31, 1975 AND 1974

## (1) Significant Accounting Policies:

*Investments—*

The Association accounts for its investments on a market value basis. Under the method used by the Association to value investments, the change in market value of corporate stocks during the year, after adjusting for an inflation factor (6.4 percent in 1975 and 11.8 percent in 1974), is recognized in income over a three-year period. The changes in market value of investments are allocated to the general and restricted fund balances as described in Notes 3 and 4.

*Accrual for Directory—*

Approximately every three to five years, the Association publishes a directory which lists, among other things, the names and addresses of its membership. This directory was published in 1974 and distributed at no cost to the membership. In order to match more properly the publishing cost of the directory with revenue from membership dues, the Association provides, annually, amounts which in the aggregate will approximate the actual directory expense in the year of publication.

*Deferred Income—*

Payments for membership dues and subscriptions to the various periodicals of the Association are deferred when received; these amounts are then recognized as income as publications are mailed to the members and subscribers.

Life membership dues are also deferred when received; income is recognized over the estimated average life of these members.

## (2) Investments and Investment Income (Losses):

Investment losses recognized in revenues and expenses for the years ended December 31, were as follows:

| | 1975 | 1974 |
|---|---|---|
| Treasury bills and commercial paper— | | |
| Interest | $ 22,449 | $ 23,720 |
| Decline in market value | — | (11,680) |
| | 22,449 | 12,040 |
| Corporate stocks— | | |
| Cash dividends | 15,019 | 16,256 |
| Decline in market value recognized (Note 3) | (113,311) | (117,154) |
| | (98,292) | (100,898) |
| Investment losses allocated to a restricted fund (Note 4) | 27,718 | 32,799 |
| Investment losses included in revenues and expenses | $ (48,125) | $ (56,059) |

## (3) Unrecognized Change in Market Value of Investments:

As described more fully in Note 1, the Association recognizes in income over a three-year period changes in the market value of its corporate stocks. The following summarizes the years in which market value changes in stocks occurred that affect 1974 and 1975 revenues and the amount of these market value increases (declines) that will be recognized in income in future periods.

| Year of Market Value Change | Recognized In Income In | | To Be Recognized In | | Unrecognized Change December 31 | |
|---|---|---|---|---|---|---|
| | 1974 | 1975 | 1976 | 1977 | 1975 | 1974 |
| 1972 | $ 25,069 | $ — | $ — | $ — | $ — | $ — |
| 1973 | (58,509) | (58,509) | — | — | — | (58,509) |
| 1974 | (83,714) | (83,714) | (83,715) | — | (83,715) | (167,429) |
| 1975 | — | 28,912 | 28,913 | 28,914 | 57,827 | — |
| | $(117,154) | $(113,311) | $(54,802) | $28,914 | $(25,888) | $(225,938) |

Included in the above unrecognized changes as of December 31 are declines of $7,456 and $68,007 in 1975 and 1974, respectively, which have been allocated to a restricted fund. The amounts allocated are based on the percentage of the Association's total stock portfolio owned by this restricted fund.

## (4) Restricted Fund:

In 1968, the Association entered into an agreement with the University of Colorado relating to the Ford Foundation grant for the Economics Institute which provides, among other things, that the Association invest a portion of the funds received and allocate any income and market value adjustments therefrom to the restricted fund. In accordance with this agreement, the following adjustments were allocated to the restricted fund:

| | 1975 | 1974 |
|---|---|---|
| Net investment losses (Note 2) | $(27,718) | $(32,799) |
| Market value adjustments arising from inflation | 7,210 | 21,773 |
| | $(20,508) | $(11,026) |

## (5) Retirement Annuity Plan:

Employees of the Association are eligible for participation in a contributory retirement annuity plan. Payments by the Association and participating employees are based on the employee's compensation. Benefit payments are based on the amounts accumulated from such contributions. The total pension expense was $11,910 and $6,798 for 1975 and 1974, respectively.

## (6) The Association:

The American Economic Association files its Federal income tax return as an educational organization, substantially exempt from income tax under section 501(c)(3) of the U.S. Internal Revenue Code. As required by Section 511(a) of this Code, the Association provides for Federal income taxes on certain revenues which are not substantially related to its tax exempt purpose. This "unrelated business income" includes income from advertising and the sale of mailing lists.

The Association has been determined to be an organization which is not a private foundation.

EXHIBIT I
THE AMERICAN ECONOMIC ASSOCIATION
STATEMENTS OF OTHER GENERAL AND
ADMINISTRATIVE EXPENSES
FOR THE YEARS ENDED DECEMBER 31, 1975 AND 1974

| | 1975 | 1974 |
|---|---|---|
| Mailing list file maintenance and periodic mailing expenses | $14,658 | $13,598 |
| Accounting and legal | 7,600 | 7,500 |
| Office supplies | 10,942 | 8,998 |
| Postage | 11,863 | 11,475 |
| Dues and subscriptions | 2,819 | 2,800 |
| Telephone | 2,802 | 3,130 |
| Provision for Federal income taxes (Note 6) | 12,200 | 3,371 |
| Investment counsel and custodian fees | 2,780 | 2,783 |
| President and president-elect expenses | 3,000 | 4,200 |
| Travel and entertainment | 1,732 | 1,327 |

| Uncollectible receivables | 51 | 586 |
| Currency exchange charges (credits) | 1,443 | (55) |
| | $72,873 | $60,450 |

# REPORT OF THE MANAGING EDITOR AMERICAN ECONOMIC REVIEW

The number of manuscripts submitted in 1975 was 742, slightly more than last year, and it corresponds to the average rate of the last three years. We printed 112 papers in all, 13 less than last year. The comparative statistics for the last twenty years are shown in Table 1.

TABLE 1—MANUSCRIPTS SUBMITTED AND PUBLISHED, 1955–75

| Year | Submitted | Published | Ratio of Published to Submitted |
|---|---|---|---|
| 1955 | 245 | 41 | .17 |
| 1956 | 242 | 48 | .20 |
| 1957 | 215 | 40 | .19 |
| 1958 | 242 | 46 | .19 |
| 1959 | 279 | 48 | .17 |
| 1960 | 276 | 46 | .17 |
| 1961 | 305 | 47 | .15 |
| 1962 | 273 | 46 | .17 |
| 1963 | 329 | 46 | .14 |
| 1964 | 431 | 67 | .16 |
| 1965 | 420 | 59 | .14 |
| 1966 | 451 | 62 | .14 |
| 1967 | 534 | 94 | .18 |
| 1968 | 637 | 93 | .15 |
| 1969 | 758 | 121 | .16 |
| 1970 | 879 | 120 | .14 |
| 1971 | 813 | 115 | .14 |
| 1972 | 714 | 143 | .20 |
| 1973 | 758 | 111 | .15 |
| 1974 | 723 | 125 | .17 |
| 1975 | 742 | 112 | .15 |

The backlog of accepted papers is slightly smaller than last year. As of November 15, there are 63 accepted papers which have not yet been published. Twenty-five will appear in the March issue, and the remainder in June and September 1976.

As Table 2 indicates we printed 112 papers this year, 53 main articles and 59 shorter papers. The latter include short articles, notes, comments, and replies. The size of the *Review* was reduced to 1068 pages this year from 1146 pages last year. The purpose of the reduction is to control and cut printing costs. This accounts for the smaller number of papers printed, particularly shorter papers.

## Subject Matter of Submitted and Printed Manuscripts

Table 3 presents a distribution of manuscripts classified by subject matter. The most popular fields are microeconomics, labor, welfare theory, macroeconomics, international economics, and monetary theory. These six fields have dominated the distribution for some time.

In addition to submitted papers, the *Review* publishes papers which are com-

TABLE 2—SUMMARY OF CONTENTS, 1974 AND 1975

| | 1974 | | 1975 | |
|---|---|---|---|---|
| | Number | Pages | Number | Pages |
| Articles | 49 | 684 | 53 | 730 |
| Shorter papers, including notes, comments, and replies | 73 | 386 | 59 | 279 |
| Special articles | 3 | 4 | 1 | 2 |

| Welfare programs, consumer economics, urban and regional economics | 57 | 2 |
| Total | 742 | 112 |

missioned by the editor, or specially chosen for pedagogical purposes.

Under the first heading are commissioned reviews of the annual report of the Council of Economic Advisers. This year there were three reviews: by Harold Carter on the food and agriculture section of the report; by William Poole on the report's analytic content; and a radical critique of the report by Leonard Rapping and James Crotty. It will be recalled that the purpose of commissioned reviews is to stimulate discussion of long-run policy issues, and to satisfy an expressed need for such material by readers who want more policy in their diet. There is no commitment, however, to a permanent annual review of the Council report. Rather than freeze the mold I have decided to experiment with other types of policy discussion. For example, I have commissioned papers on British inflation, to appear later in 1976.

Papers chosen for pedagogical purposes include the Nobel Award addresses delivered by American recipients of this prize.

### Administrative Changes

The financial deficits of the Association in 1974 and 1975 made it necessary to reduce printing and mailing expenses and to increase the Association's revenues. The *Review* was a vehicle for many of these changes. While they will also be discussed in the Treasurer's Report, my report will deal with those which specifically affect the operation of the *Review*.

(a) As indicated earlier, the size of the *Review* has been reduced from 1146 to 1068 net pages. While this required a reduction in the number of papers printed, in the long run control of the length of accepted papers should cut their size and permit a larger number of papers to be printed.

(b) The submission fee for articles and manuscripts is $15 for members and $30 for nonmembers, with the extra fee applicable to membership dues, should the author wish to join. The purpose of this charge is to encourage membership in the Association. A tabulation for the period July 1–October 31, 1975 indicates

TABLE 4—COPIES PRINTED, SIZE, AND COST OF PRINTING AND MAILING IN 1975

| | Copies Printed | Pages | | Cost | | |
|---|---|---|---|---|---|---|
| | | Net | Gross | Issue[b] | Reprints[c] | Total |
| March | 27,500 | 258 | 304 | $ 31,350.37 | $ 425.80 | $ 31,776.17 |
| June | 27,500 | 274 | 296 | 30,072.44 | 571.52 | 30,643.96 |
| September | 27,500 | 258 | 288 | 31,305.89 | 750.00[a] | 32,055.89 |
| December | 27,500 | 278 | 320 | 34,800.00[a] | 200.00[a] | 35,000.00[a] |
| Total | 110,000 | 1,068 | 1,208 | $127,528.70[a] | $1,947.32[a] | $129,476.02[a] |

[a] Estimate.
[b] Includes allocated cost of preparing mailing list.
[c] Costs are reduced by a credit resulting from charges to authors for additional reprints.

that the policy does work. Of 277 papers submitted in that period, 9 authors paid the $30 nonmember fee. It is more significant that 31 authors became new members, or renewed their membership.

The practice of using the submission fee to encourage membership is not a monopoly of our Association. It is also employed by the Royal Economic Society and the Canadian Economics Association.

(c) We have discontinued the distribution of 100 free reprints/offprints to authors. They will be sold to authors if desired.

(d) We have introduced a page charge for articles, shorter papers, notes, comments and replies. This charge of $25 per page is payable by the institution or granting agency supporting the research. Payment of the charge is not a prerequisite for publication, nor are authors expected to pay the charges themselves. Moreover, articles are accepted without prior knowledge of financial support which the author may have. If the author or his institution cannot pay the charge, it is no obstacle to publication.

The purpose of the page charge is to take advantage of the willingness of government sponsoring agencies and foundations to defray the expenses of publishing research in scholarly journals. Page charges are regarded as a legitimate item in the budgets of research grants, and

TABLE 5—ACTUAL AND BUDGETED EXPENDITURES, 1968–76

| | Printing and Mailing | Payments to Contributors | Office Expenses | Total |
|---|---|---|---|---|
| 1968 | $ 92,948 | $2,140 | $29,155 | $124,243 |
| 1969 | 97,183 | 600 | 26,765 | 124,548 |
| 1970 | 111,227 | | 36,336 | 147,564 |
| 1971 | 120,120 | | 43,524 | 163,644 |
| 1972 | 107,196 | | 44,473 | 151,669 |
| 1973 | 117,873 | | 49,121 | 166,994 |
| 1974 | 137,653 | | 58,386 | 196,039 |
| 1975[a] | 165,742 | | 65,911 | 231,653 |
| 1975[b] | 129,476 | | 63,371 | 192,847 |
| 1976[a] | 145,000 | | 69,216 | 214,216 |

[a] Budget.
[b] Actual (estimated).

journals in other disciplines have taken advantage of this source of revenue for some time.

### Expenses—Printing and Mailing

The 1975 costs of printing and mailing the *Review* are shown in Table 4 and for other years in Table 5. The net pages shown include only pages listed in our table of contents. Advertising and index pages then make up the difference between gross and net. The 1975 printing and mailing expenses fell $35,000 short of the budget approved last December. There were a number of reasons: The reduction in net pages (78); the elimination of employment service pages (44); and the failure of a possible increase in printing charges to materialize. The proposed printing and mailing budget will be higher next year, because I expect an increase in mailing charges and in printing costs.

### Office Expenses

Office expenses rose in 1975, because of higher salaries, fringe benefits, and supply costs. I expect a further increase in 1976.

### Board of Editors

Six members of the Board of Editors complete their terms at this time: Bela Balassa, Ann Friedlaender, Stephen Goldfeld, Robert Hall, Leonard Rapping, and Joseph Stiglitz. I wish to thank them for their high standards, hard work, and cooperation.

I should like to express my thanks to the continuing members of the Board of Editors: Eugene Fama, Martin Feldstein, Robert J. Gordon, Bent Hansen, James Melvin, William Nordhaus, Stephen Resnick, Anna Schwartz, Jerome Stein, S. C. Tsiang, Finis Welch, and Marina Whitman.

I am submitting to the Executive Committee the names of six nominees to serve three-year terms until December 31, 1978. They are: Irma Adelman, David Baron, Robert Barro, Laurits Christensen, David Laidler, and Frank Stafford.

The following assisted me this year as editorial consultants: Ernst Berndt, Roger Betancourt, Alan Blinder, Byron Brown, Dennis Epple, Allan Feldman, Donald Frey, William Haley, James Hanson, John Kennan, Edward Lazear, David McNicol, J. David Richardson, Robert Rohr, José Alexandre Scheinkman, Robert S. Smith, John Taylor, Hal Varian, Warren Weher, and Charles Wilson.

I have received valuable proofreading and mathematical assistance from: Clemens F. J. Boonekamp, Marvin Goodfriend, Robert King, Chon Pyo Lee, and Hiroshi Ono. I am grateful to Wilma St. John for her fine work as Assistant Editor, and to Carol Chapin, Editorial Assistant.

In addition to the members of the Board and the editorial consultants, I have sought and received the assistance of a large number of economists during the course of the year. I wish to thank them for their cooperation and high standards in reading and evaluating manuscripts. They have eased the work load that would otherwise fall on the Board of Editors. The following have assisted as referees:

GEORGE H. BORTS, *Managing Editor*

# REPORT OF THE MANAGING EDITOR JOURNAL OF ECONOMIC LITERATURE

In keeping with this year's shibboleth, "pare costs," this annual report will be somewhat briefer than those of previous years.

At the December 1974 Executive Committee Meeting I was directed to reduce expenditures in any possible way while at the same time maintaining the integrity of the Journal's contents. Members are aware that one way we achieved this goal was to change the shape of the quarterly issues. We reduced the page size slightly but we maintained the same amount of printing on each page. It was the margins that suffered. The monetary savings to the Association were considerable, however. They were achieved because the new size permitted use of a high speed Bookweb press which printed more than six times as fast as the previous press printed. Moreover, the new press used rolls of paper rather than cut sheets. Apparently there are significant economies in omitting the cutting step prior to printing. Finally, our printers, the Kingsport Press, have more sophisticated supplementary machinery (signature folding and arranging) associated with the Bookweb press than they had in the Marioni press complex.

Besides changing the format, we eliminated the Index of Authors of Selected Abstracts section in the June and September issues. It is possible to ferret out where various selected abstracts can be found—instructions are available within each issue of the *Journal* regarding the method to be used—but we have received several strong objections about this decision.

I believe that the editorial office of this Journal has always been run with an eye to cost saving. The trade-off between accuracy and economy means that we proofread our material thoroughly only once. I am told that such weekly news magazines as *Time* proofread their material ten to twelve times; moreover, we use University of Pittsburgh students, rather than professional proofreaders, for this task. During calendar 1975 we continued our usual monitoring of intra-office productivity; I do not think it correct to report that we increased our cost consciousness, but the Associate Editor did reallocate her time (involving extra work) to make sure that the "learning curve" associated with annotators and classifiers was steepened. Moreover, the Assistant Editor (again by working longer hours) took increased care to steepen the learning curve of student personnel involved in proofreading. The Assistant Editor and the Associate Editor also increased their duties in order to speed up the production of the annual indexes (details about this will come later in this report). Our secretarial staff (Mrs. Lyndis Rankin, Mrs. Margaret Yanchosek, and Miss June Cox) plus a regular but temporary secretary (Miss Ninamary Sawich) worked hard and long in order to process not only the four quarterly issues but also the material for the forthcoming annual indexes.

Table 1, JEL-Index Expenditures 1971 through 1975, does not perfectly reflect the productivity picture. Our office expenditures were less than was authorized, even though we processed a great deal of material for the aforementioned annual indexes. As of this time of writing, it seems likely that we will have spent on

[b] Includes mailing, addressing, and gross cost of reprints.

printing, including mailing, addressing, and gross cost of reprints, less than we spent in 1974 and considerably less than we were authorized to spend in 1975 (before the decision to change to the Bookweb press had been made).

I have mentioned the annual indexes. Unlike the quarterly journal where journal articles are classified according to a 3-digit 100-pigeon hole system, the annual indexes (index for articles appearing in a particular calendar year) are classified according to a compatible 4-digit 300-pigeon hole system. These annual indexes include not only the material found in the quarterly issues of the *Journal of Economic Literature* but also essays appearing in *Festschriften*, collections of reprinted works, and the like. For some years we also have selected government documents, including particularly testimony before Congressional Committees.

The 1970 *Index* which has been at the printers since the fall of 1974, is now finally in page proof. The 1971 *Index* is in galleys. We anticipate now that the

[a] Includes, in addition to listed pages, classification systems, table of contents, indices, journal subscription information, etc.

Kingsport Press has mastered the production problems, its end of the printing process will proceed more rapidly, and the other volumes that are ready for the printer, 1969 and 1972, will also appear in 1976. The speed with which further volumes can be published is dependent on the supply of part-time labor plus the ability of the editorial staff to train and supervise the additional employees and of the entire full-time staff to process the material. However, by 1977 index production should be as current as technically feasible; that is, the final receipt, classification, and publication preparation of all journals and books for a calendar year should be completed within a two-year period.

Table 2 illustrates the subject matter covered in the 1975 volume. We fell short of four survey articles by one. On the other hand, we published about the number of essays and review articles that we normally anticipate. We did not publish a section in the September issue listing journal information. For this omission, there were two reasons; one was the omnipresent concern regarding cost paring, the other was a realization that during periods of price inflation, price information regarding subscriptions tends to become quickly obsolete.

Perceptive readers will note that we have somewhat fewer journal issues listed and indexed in the 1975 volume (compared to the two previous years). For the most part this reduction has been the result of completion of the "catching-up" process in journal listing. During the previous two years we had improved our ability to ensure orderly receipt of the necessary materials from our 220 journals. We have also speeded up the publication process—we classify, list, and index with less time-lag in our editorial office. But if we have processed somewhat fewer journal issues, we have at the same time increased the ratio of abstracts of articles to total listings (in 1974 about 22.4 percent of the listed articles were abstracted; in 1975 about 24.1 percent).

We anticipate that the contents of the 1976 journal will include four survey articles (all of which are in fairly advanced stages of preparation), four articles on an individual scholar's reaction to literature emerging in his (her) field, and possibly one essay on the role of economics journals within the profession. Such has been our objective in the past; I think in 1976 we should have no trouble in meeting it.

Tables 3 and 4 are self-explanatory. Table 3 indicates that the objective of eschewing difficult articles has been somewhat better met this year than in previous years. Table 4 reveals (if compared to the similar tables in previous years) that we have broadened the spectrum (number of categories treated).

The Chancellor and Dean of the Faculty of Arts and Sciences of the University of Pittsburgh have once again allocated some University of Pittsburgh support to the *Journal*. Their willingness to do so, particularly in a period of tight budgets, illustrates an understanding of and a devotion to scholarly work in the economics discipline. I have regularly thanked them privately and take this opportunity again to do so publicly.

[a] Review articles on books, general essays on all literature.

Three members of the Board of Editors have completed their terms. They have been splendid colleagues, and I wish to convey to them publicly (although I have privately) my great appreciation. Professor Martin Bronfenbrenner (Duke University), Professor Anne O. Krueger (University of Minnesota), and Professor Allan H. Meltzer (Carnegie-Mellon University) have been the quintessence of what every managing editor wants. The other members of my Board have also been superb colleagues. I look forward to my continuing association with them. I have nominated several people to replace the departing three; it is, however, premature for me to announce the names in this report (the procedure is for me to nominate but for the Executive Committee, which meets after this report has been prepared, to confirm my nominations).

I wish also to thank the following economists (plus three who chose to remain anonymous) for advice and assistance in the commissioning, refereeing, and revising articles:

MARK PERLMAN, *Managing Editor*

# REPORT OF THE DIRECTOR
# JOB OPENINGS FOR ECONOMISTS

During 1975, 567 employers advertised 1,383 openings in *Job Openings for Economists* (*JOE*). Of these, 1,243 were jobs not previously listed. About 66 percent of the new positions were classified as academic and about 34 percent were nonacademic. As expected the December issue carried the largest number of listings. It contained 30 percent of all jobs listed during the year and 35 percent of the new ones. Table 1 shows the total listings, total jobs, new listings, and new jobs by type for each of the 1975 issues.

Universities with graduate programs and 4-year colleges were the major advertisers of jobs—43 and 40 percent of employers respectively. Nonacademic employers accounted for approximately 17 percent. Table 2 shows the number of employers by type for each issue.

The field of specialization most in demand was general economic theory (020), followed by econometrics (210). Generalists with a strong background in mathematics and statistics who can teach one applied area appear to be the type of economists that employers are seeking. The specific applied area seems to be of secondary importance. Table 3 lists the number of citations for each issue during 1975 for each of the broader field classifications. General economic theory led with 22 percent of the total number of citations, followed by business administration, finance, marketing and accounting (13 percent), monetary and fiscal (11

percent), welfare and urban (10 percent), and econometrics and statistics (10 percent).

*JOE* is now virtually self-supporting. The estimated 1975 deficit is $451 (see Table 4 for the details of expenses and revenues). Total revenues are estimated to be $17,615 and total expenditures $18,066. The costs include an allocation of salaries and fringe benefits from the budget of the Secretary-Treasurer's office equivalent to one full-time staff employee, but do not include an allocation for overhead (utilities, space, telephone, etc.). The Secretary-Treasurer agrees that an allocation of overhead is not warranted.

TABLE 4—PROJECTED REVENUES AND EXPENSES FOR 1975 AND 1976

| | 1975 | 1976 |
|---|---|---|
| Revenues: | | |
| Subscriptions | $17,167 | $19,000 |
| Mailing List | 361 | 300 |
| Advertising | 87 | 50 |
| Total | $17,615 | $19,350 |
| Expenses: | | |
| Addressing and Postage | $ 4,171 | $ 5,420 |
| Printing | 3,857 | 4,000 |
| Computer Time | 1,145 | 1,200 |
| Allocated Salaries | 8,893 | 9,230 |
| Total | $18,066 | $19,850 |
| Deficit | $ (451) | $ (500) |

The projected deficit for 1976 is $500. Revenues are estimated to be $19,350, and expenses to be $19,850. Subscription revenues are estimated conservatively. The projection is based on the current number of subscribers (1,662 at the end of November 1975), and assumes no change during the coming year. Experience indicates that the number will increase. From December 1974 to August 1975, subscribers increased from 2,182 to 2,752. A similar pattern of growth will probably occur in 1976.

Because *JOE* is now essentially self-supporting, I do not recommend an increase in subscription rates or the initiation of a charge for listing at this time. Continued close scrutiny of costs should be sufficient to maintain a balanced budget for at least one more year.

All the comments we have received indicate that *JOE* performs a valuable service for the Association, and that it is an important addition to the flow of information about the job market. According to a survey of placement officers for Ph.D. granting departments, *JOE* ranked third (out of eight) as the original source of information about jobs eventually accepted by their students. It ranked below informal contacts and departmental placement services, but above the placement facilities at the annual meeting.

We expect an expanding role for *JOE* as a source of job information for economists.

C. ELTON HINSHAW, *Director*

# REPORT OF THE COMMITTEE ON THE STATUS OF WOMEN IN THE ECONOMICS PROFESSION

Four years ago the American Economic Association (*AEA*) took a firm stand on the need (a) to support and facilitate equality of opportunity for women economists in all aspects of economists' professional activities and (b) to help eradicate any institutional or personal discrimination against women economists. In May of 1972 the Committee on the Status of Women in the Economics Profession (*CSWEP*) came into being as an *ad hoc* committee of the Association, and in March of 1974, *CSWEP* was made a standing committee of *AEA* in recognition of the fact that the problems addressed by *CSWEP* require long-run efforts. Throughout the four years, it has been a very active committee. This year the committee size was reduced from 10 to 6 members as an economy measure, and we have rotated committee membership. The reduction in size has made it difficult to have as wide geographic representation in any one year as would be desirable and has increased the burden of members on the smaller committee. I want to thank the committee members who have worked so diligently in 1975 to carry out the mandate of the Association.

I want to thank the Carnegie Foundation for its $21,600 grant to us to plan and execute a national, working research conference on occupational segregation and to disseminate the results. I also want to thank the German Marshall Fund of the United States for a S1,500 grant to enable us to enrich the program at the *AEA* annual meeting this year by bringing Baroness Nancy Seear from the London School of Economics to speak on her research on employment conditions in the United Kingdom with particular emphasis on the status of women workers.

The number of women economists identified by *CSWEP* and associated with our activities has continued to grow. By last year, we had identified nearly 1,400 women economists through questionnaires to all colleges and universities with economics departments, letters to government agencies and businesses, and information from the informal network. Then, in November 1974 the *AEA Directory of Members* came out. We requested a list of women from that source. A comparison of the two lists added 313 more names. We contacted these women, and only one or two asked not to be added to our roster of associate members.

We also obtained new names from the 1975–76 Universal Academic· Questionnaire, wherein each fall new hires are reported as well as other data for an analysis of the academic labor market. Our analysis of the data by sex is in the final section of this report.

The total number of women economists now identified is about 1,800. Of these, 20 percent are in government and business (12 percent and 8 percent, respectively). We know that for the moment we have nearly all women members of the American Economic Association, plus an additional group of women economists who do not belong to *AEA*. About 20 percent of those on our roster do not belong to *AEA*. We suspect that there are still more women economists in the government and in business whom we have not identified. We are working on this. In Sep-

tember we met with members of the National Economists Club in Washington, D.C. to report on our research findings and to identify more women economists who would like to register with us. We encourage growth of local subgroups of women economists. Such groups identify more of the women economists, and increase *AEA* membership.

During the past year *CSWEP* has continued to improve the operation of the market for economists, has increased the effective supply of women economists, and has added to the research information on the status of women.

### I. CSWEP Newsletter

Four *CSWEP Newsletters* have been written during 1975 and sent to 1,800 women economists. The newsletter improves the working of the market by listing job openings for economists submitted to us by prospective employers. This activity fills a need most appreciated by agency and department heads. The *CSWEP Newsletter* lists requests for articles, conference and program plans and participants, grant and fellowship opportunities, and notices of regional activities for women economists. It is also a mechanism by which the Committee can ask the reader for help in various *AEA* projects. The newsletter clearly has helped to widen the informal network and to support our women colleagues who often have felt isolated in our profession.

### II. Roster

The roster of women economists developed and computerized by this Committee has been maintained this year. It has been updated by sending to all women economists listed copies of the material they had previously supplied us and asking for the most recent information on their area of specialization, highest degree in economics, professional grade or rank, and address. The roster has been used to provide prospective employers with a list of women economists who meet specified criteria such as particular field of specialization, degree, and rank. The prospective employer may then write to these economists, ask them to supply detailed career data, and finally follow up with interviews if desired. This service is being provided for a fee to help defray committee costs, and its use is growing.

### III. Research Function

An explicit charge to collect and analyze data relevant to the status of women economists and to further the theoretical and applied research related to the status of women in general helps set the work of the standing committee of *AEA* apart from caucuses in some other professional associations. This research dimension is one that *CSWEP* feels is vital for professional associations to undertake to help build a solid foundation for policy prescriptions related to reappraisal of women's place in society. I want to mention in particular this year work on four of our research projects.

*Workshop Conference on Occupational Segregation.* This was jointly sponsored in May 1975 by *CSWEP* and the Center on Research on Women in Higher Education and the Professions at Wellesley College and funded by the Carnegie Corporation of New York. The idea to hold a workshop conference on this topic evolved from *CSWEP*s desire to make a research contribution to International Women's Year on a topic central to an improvement of the status of women in American society.

The papers which we commissioned for that conference plus some additional analysis will be published by the University of Chicago Press in a book supplement to

the new journal, *Signs,* in about March 1976, and subsequently as a separate book *Women in the Workplace, An Analysis of Occupational Segregation,* Martha Blaxall and Barbara B. Reagan (eds.). This will fulfill our promise to disseminate the research results beyond the small working group at the conference. We thank the Carnegie Foundation for making this effort financially possible. Clearly women's economic status in a macro sense is of critical importance to women economists, as well as to the nation. An improvement in women's economic status cannot be realized without a diminution of occupational segregation and a better understanding of the forces behind it. Even within our profession of economics, some fields of specialization are deemed more appropriate for men and others for women. Sexism in occupational segregation is pervasive down to micro levels.

*1974–75 Survey of Economics.* With the development of a roster of women economists and the new *AEA Directory of Members,* it became possible to conduct a survey of both male and female economists to compare educational attainment, employment history, and salaries. Preliminary results from the 1974–75 Survey of Economists were reported in the May 1975 *American Economic Review.* Subsequently, data collection from the men economists in the paired sample was completed. *CSWEP* is now in process of completing the study of 1,240 male and female economists who were paired by selecting a male economist from the same graduate class of a woman economist at the school from which she got her highest degree. The major finding so far is that salaries of women economists are substantially below those of their male counterparts even when their educational attainments and work histories are similar. Excluding the few who were not working, the average income for the women in 1973-74 (7 years after their Ph.D.s) was $15,310. For men in the comparable group of Ph.D.s who were working, it was $19,025 or 24 percent higher. Only 16 percent of the women made more than $25,000, whereas 30 percent of the men economists in the matched group did. Untangling the factors that might explain this income difference is obviously the next step. It clearly isn't difference in formal education in economics—either in amount or quality of school attended. Discrimination against women is morally and legally untenable.

The Committee feels that increased efforts on its part should be directed to reducing the existing discrepancies. The pending exemption of universities and colleges from the affirmative action regulations makes an increased effort on the part of the Committee and the Association even more imperative.

Other findings from the paired sample are of interest to those involved in training economists. For example, the length of time to complete the Ph.D. degree is not significantly different between women and men—15 percent of women and 15 percent of men finished in 3 years or less, 45 percent of the women and again 45 percent of the men finished in 4 or 5 years; 26 percent of the women and 24 percent of the men took 6 or 7 years; 8 percent of the women and 10 percent of the men took 8 or 9 years; and 7 percent of the women and 6 percent of the men took 10 or more years to finish. Considering the averages, women took 5.6 years and men took 5.5 years to complete the Ph. D.

Marriage and increasing family size, however, may contribute to a small delay in starting a Ph.D. The average number of years between the B.A. degree and the Ph.D. in economics was about 8 years for men but 9 years for women. A counterbalancing factor was that the women had

TABLE 1—DEGREES GRANTED IN ECONOMICS BY TYPE OF DEPARTMENT AND SEX, 1974–75

(Departments reporting by December 10, 1975 on 1975–76 Universal Academic Questionnaire)

gotten their B.A. degrees at an age a year younger than the men had.

*Session at AEA Meetings*. At the 1975 annual *AEA* meetings, a session on the economic status of women in the United States and in the United Kingdom was presented. Two papers surveying current research on employment of women were commissioned, and the policy implications of the research were discussed.

*Academic Labor Market, 1974–75*. For the first time in four years, the proportion of women among those receiving undergraduate degrees and M.A. degrees in economics increased.[1] In 1974–75, of the B.A. degrees in economics 22 percent were earned by women. (See Table 1.) In the two previous years, women comprised only 16 percent of the economics undergraduate majors. The proportion of M.A. degrees earned by women in 1974–75 was 18 percent, compared with 14 percent the two previous years. This increase occurred in those departments that offer both Ph.D. and M.A. degrees. The proportion of Ph.D. degrees earned by women was 11 percent in 1974–75, compared with only 8 percent last year, and with 12 percent the two previous years.[2]

Nearly 75 percent of the full-time Ph.D. students received financial aid in the fall of 1975, and more than half of the full-time M.A. students received financial aid (Table 2). (The latter proportion is down somewhat from last year.) Women students at the Ph.D. level received financial aid approximately in proportion to their numbers, whereas women at the M.A. level received financial aid somewhat more often than proportional to their numbers.

[1] In 1975–76 for the fourth year, data related to supply of economists and academic demand for them are available from a survey of academic departments of economics. The data from the 1975–76 Universal Academic Questionnaires have been collected under the direction of C. Elton Hinshaw of *AEA*, and the data classified by sex are analyzed here. The questions asked in the 1975–76 survey are for the most part comparable to the data published in the *CSWEP* Report last year in the May *American Economic Review*. The number of departments which had reported in time for this analysis is 375 this year, but was only 311 last year. Not all of the departments who reported last year reported again this year. Thus, comparisons of absolute numbers must be made with care. Percentages are more comparable, although, of course, they are subject to sampling error.

[2] The data in the first two years related to students enrolled in the programs, while in the last two years the data refer to degrees received.

[a] Percentage not shown when fewer than 10 in cell.

This was particularly true in departments in the Chairman's Group in 1975. The increase in financial aid in the fall of 1975 to women students at the M.A. level should help perpetuate the increase in the proportion of women receiving M.A.s from 1973–74 to 1974–75 noted above.

Hopefully, next year, the increase in women receiving Ph.D.s will also continue to surpass the previous levels. However, the selected data available now do not suggest that this will occur. The proportion of women receiving M.A. degrees in 1973–74 who entered doctoral programs in 1974–75 was only 12 percent compared with 20 percent of the men (Table 3). In the previous year's survey the proportion of women with M.A. degrees from the year before who entered the Ph.D. program was 24 percent. This was nearly as high as the proportion among the men. Thus, the decrease in doctoral students entering from the M.A. level occurred for both sexes, but more often among women.

Women who received their Ph.D. degrees in economics in 1974–75 found jobs in academic institutions less often than was true for the class of the previous year. While 57 percent of the men Ph.D.s in the 1974–75 class found employment as economists in academia, only 33 percent of the women did.[3] In the previous year, 68 percent of the women with new Ph.D.s were employed in academic institutions. The decline in the academic market thus

[3] If the women whose current occupation was not reported are distributed, the proportion rises to over 40 percent.

hit the women Ph.D.s very hard. Over 20 percent of the women with new Ph.D.s found employment outside the United States.

As last year, fewer women with new Ph.D.s than men found employment in the federal government. In other respects, the employment patterns of men and women with new Ph.D.s were roughly similar. Five percent of the men and 6 percent of the women with new Ph.D.s were unemployed or out of the labor force. The differences between men and women in the proportions unemployed and in the proportions not in the labor force were small.

Considering all women economists employed in academic departments of eco-

TABLE 5—DISTRIBUTION OF DEPARTMENTS OF ECONOMICS BY NUMBER OF WOMEN FACULTY MEMBERS, 1975–76

(Departments reporting by December 10, 1975 on 1975–76 Universal Academic Questionnaire)

| Number of Women on Faculty | All Departments | Chairman's Group |
|---|---|---|
| Number of departments reporting one or more full-time faculty | 378 | 38 |
| Percent distribution by number of women full-time faculty | 100.0 | 100.0 |
| All male | 63.0 | 23.7 |
| 1 woman | 27.4 | 55.3 |
| 2 women | 6.1 | 13.1 |
| 3 or more women | 3.5 | 7.9 |
| Total number departments | 392 | 38 |
| Percent distribution of departments by number women part-time faculty | 100.0 | 100.0 |
| No part-time faculty | 50.5 | 36.8 |
| 1 or more part-time faculty | 49.5 | 63.2 |
| All male | 35.8 | 44.8 |
| 1 woman | 11.7 | 18.4 |
| 2 women | 1.0 | 0 |
| 3 or more women | 1.0 | 0 |
| Total number of faculty | 3,963 | 1,132 |
| Full-time | 3,409 | 1,028 |
| Percent women | 5.9 | 4.4 |
| Part-time | 554 | 104 |
| Percent women | 12.5 | 6.7 |

nomics, women comprised only 6 percent of all full-time faculty appointments in tenure-track positions—3 percent of the full professors, nearly 6 percent of the associate professors, 9 percent of the assistant professors, and 14 percent of the instructors (Table 4). This is an increase over last year's report, particularly at the instructor and assistant professor level. Departments in the Chairman's Group have improved their proportion of women at the assistant professor level (10 percent this year compared with 7 percent last year) and at the associate professor level (nearly 3 percent this year compared with 1 percent last year). Although the differences are small, the direction of the movement is important.

Overall, considering all levels of faculty appointments, the 6 percent of the full-time faculty positions held by women (Table 5) was the same as last year. The proportion of women among those holding part-time faculty appointments fell to 12 percent this year. (Last year it was 18 percent.) The number of economics departments with all male full-time faculty has increased. In 1975–76, the proportion was 63 percent. Last year 59 percent of the departments had only male full-time faculty. This is an unfortunate regression. On the other hand, among departments in the Chairman's Group, the proportion with all male full-time faculty dropped to 24 percent. Last year it was 30 percent.

Among the 378 departments reporting in the 1975–76 survey, there were 3,409 full-time faculty positions and 554 part-time faculty positions as economists. The number of new faculty hired in 1975–76 exceeded the number of faculty released at the end of 1974–75 by only 36 full-time positions and 85 part-time (Table 6). This represented only a 1 percent increase in full-time positions and an 18 percent increase in part-time positions. In last year's survey only a 2 percent increase in full-time positions was reported and a 19 percent increase in part-time positions. Of the 38 net increase in the number of full-time positions this year, 8 were women. Of the new hires, 9 percent were women. Of those released, 8 percent were women. This is a tight market. Women at least held their small relative position. In last year's survey the net increase in the number of full-time faculty positions was 86, and 13 were women.

Among departments in the Chairman's Group, the net increase in the number of women with full-time faculty positions increased by 5 at the same time the total number of positions decreased by 4. The increases for women were at the lower faculty ranks. For men, the changes were

TABLE 6—NET CHANGE IN FACULTY POSITIONS FROM END OF 1974–75 TO 1975–76, BY SEX, ALL DEPARTMENTS AND CHAIRMAN'S GROUP

net decreases at the professor and associate professor level, and net increases at the lower faculty ranks. The number of women with part-time faculty positions decreased by 3 at the same time the total number of part-time faculty positions in departments in the Chairman's Group increased by 11. For both men and women these changes were primarily at the lower ranks.

Considering all the departments of economics, the women faculty employed as new hires this year tended to come less from business than did men (Table 7). This was also true last year. However, this year there was a small reversal in the previous pattern in that a slightly higher proportion of women than men came from other faculties and a slightly lower proportion of women than men came from graduate school. Among departments in the Chairman's Group, more of the women among the new hires came from government and business this year than did men,

and a lower proportion of the women than of men were selected from graduate students.

Of the women faculty released, 8 percent were unemployed compared with only 1 percent of the men. Fewer of the women released found employment on the faculty at another university than did men.

This year as last, the persons reporting for the economics departments were asked to rank women full-time faculty by whether their salaries were above or below the departmental median for the particular rank and whether their length of service in that rank was above or below the median time at that rank for departmental faculty. Such estimates ignore how much the woman's salary is above or below the median. From other evidence we know that with increases in experience, women's salaries tend to lag behind men's. For all departments, 31 percent of the women had salaries more than $250 below the medians for their ranks (Table 8). When time in rank is considered, 8 percent of the women had salaries more than $250 below the median even though their time in rank was at or above the median length of experience for that rank in the department. It must be remembered that

TABLE 8—RELATIVE SALARIES FOR RANK AND TIME IN RANK OF FEMALE FULL-TIME ECONOMISTS, 1975–76, BY TYPE OF DEPARTMENT

(Departments reporting by December 10, 1975 on 1975–76 Universal Academic Questionnaire)

more than two-thirds of the women faculty members in economics covered in the 1975–76 survey reported here are at the assistant professor or lower ranks. In general, entrance level faculty positions in universities have little or no difference between men and women in salary.

Women received 9 percent of the promotions for 1975–76 (19 of the 214), whereas as noted above they comprised 6 percent of the faculty (Table 9). Of the 19 promotions for women, 5 were to full professor, 7 were to associate professor, and 7 were to assistant professor. None of the promotions of women to full professor included awarding of tenure. This may well be because the women already had tenure as associate professors. Six women were awarded tenure at the associate professor level (compared with 7 promotions to this rank). Only 1 promotion and 1 tenure award to women in the professor and associate professor level were among departments in the Chairman's Group.

Many factors affect the workings of the academic labor market and positive improvements in the opportunities opened to women economists. Critical to achieving improvements are actions by men of good will and sensitivity who help change traditionally narrow views of women's role potential and help open opportunities so women can have better educational and employment opportunities. Many of the improvements needed to combat role prejudice and sex discrimination in universities involve opening the informal network to women colleagues and greater investment in on-job training opportunities

for women. *CSWEP* will continue to work on behalf of the total Association to improve the operation of the total market for economists, including the academic market, and to improve the quality of education for women students in economics. Central to the latter goal is an increase in opportunities for women faculty at higher levels in the university so as to better utilize the capabilities of women educators.

BARBARA B. REAGAN, *Chairperson*

# REPORT OF REPRESENTATIVE TO THE INTERNATIONAL ECONOMIC ASSOCIATION

During the calendar year 1975, the International Economic Association held two conferences and one symposium.

The research conference in S'Agaro, Spain, April 21–26, 1975 was on "The Microeconomic Foundations of Macroeconomic Theory." It was prepared by a Program Committee chaired by Geoffrey C. Harcourt (Australia), with Sir John Hicks (United Kingdom), T. Negishi (Japan), Luigi Spaventa (Italy), Erich Streissler (Austria), and James Tobin (United States) as members. Three Americans presented papers: Robert E. Hall, Tjalling C. Koopmans, and Axel Leijonhufvud; another three acted as discussants: Paul Davidson, Martin Shubik, and Joseph Stiglitz.

The symposium, held in Kiel (Federal Republic of Germany), July 7–12, 1975, was on "The Organization and Retrieval of Economic Knowledge." It was prepared by Herbert Giersch (F. R. Germany) and Mark Perlman (United States) as co-chairmen of a Program Committee which included also Mark Blaug (United Kingdom), J. Meyriat (France), and Vladimir A. Vinogradov (*USSR*). Papers were given by economists as well as librarians and information-systems analysts. Participants from the United States included, besides Mark Perlman, Martin Bronfenbrenner, Ronald Coase, Otto Eckstein, Glyn Evans, Michael Gort, Harry G. Johnson, Charles Kindleberger, James Morgan, Naomi Perlman, Anna Schwartz, Carl Shoup, Joseph Spengler, and William G. Tyler.

A conference at Saltsjőbaden (Sweden), August 28–September 3, 1975, was held on "Inflation Theory and Anti-Inflation Policy." The Program Committee was chaired by Erik Lundberg and included Bela Csikos-Nagy (Hungary), Giorgio Fua (Italy), Robert J. Gordon (United States), Richard Lipsey (Canada), Michael Parkin (United Kingdom), Don Patinkin (Israel), and P. de Wolff (Netherlands). Economists from the United States, delivering or discussing papers, included William Branson, Martin Bronfenbrenner, James Duesenberry, Stanley Fischer, Marcus Fleming, Robert J. Gordon, Dwight Jaffee, and Fritz Machlup.

For the calendar year 1976 three research conferences are being prepared. The first, on "Economic Relationships between Different Economic Systems (East and West)," will be held in Dresden (German Democratic Republic), June 28–July 3, 1976. The Program Committee is chaired by Oleg Bogomolov (*USSR*) and includes Abram Bergson (United States), Michael Kaser (United Kingdom), Gunther Kohlmey (German Democratic Republic), Franz Nemschak (Austria), and Josef Pajestka (Poland) as members.

The second conference will be held in Urbino (Italy) from September 1 to 8, 1976 on "Econometric Contributions to Public Policy." The Program Committee, under the chairmanship of Richard Stone (United Kingdom), includes Emilio Fontela (Spain), Lev V. Kantorovitch (*USSR*), Janos Kornai (Hungary), Jauko J. Paunio (Finland), and Richard E. Quandt (United States).

The third conference is scheduled to be held in Teheran (Iran) September 18 to 23 on "Economic Choice of Technologies for Developing Countries." A Program Committee is being formed with K. N. Raj (India) as Chairman.

In 1977 the Fifth World Conference

will be held in Tokyo (Japan) from August 29–September 4, 1977. The topic will be "Economic Growth and Resources." The Program Committee is chaired by Edmond Malinvaud (France).

Two volumes of proceedings were published during 1975 (although the imprint states 1976 as the year of publication): *Methods of Long-Term Planning and Forecasting*, edited by Tigran S. Khachaturov; and *Economic Factors in Population Growth*, edited by Ansley J. Coale. Two other volumes are scheduled for publication in the first half of 1976: *The Economics of Public Services*, edited by Martin S. Feldstein, and *Economic Integration: Worldwide, Regional, Sectoral*, edited by Fritz Machlup. All these volumes are published in London by Macmillan and in New York by The Halsted Press.

FRITZ MACHLUP, *Chairperson*

# REPORT OF COMMITTEE ON ECONOMIC EDUCATION

In 1975, this Committee continued the implementation of a broad program laid out in its 1972 agenda for improving the teaching of economics (published in the *American Economic Review* in May, 1973). This year, special emphasis has been placed on the following:

1. The project outlined in the 1972 agenda to help university economics departments provide more effective training for Ph.D.s has been further extended. It is now in successful use at seven universities training a large number of potential teachers. Information on these experiences, on teaching materials available, and on teaching techniques has been organized into a special set of materials which the committee hopes will be useful to a wide variety of universities training future teachers. Further information can be obtained by writing Dr. Arthur Welsh, Joint Council on Economic Education, 1212 Avenue of the Americas, New York, New York 10036.

2. *Recent Advances In Economics,* edited by Rendigs Fels and John Siegfried of Vanderbilt University, under the general policy guidance of this Committee, has appeared as the first of the new *Readings* series designed to help teachers at small institutions keep up-to-date on central areas of economic theory and policy. This volume contains 25 articles chosen to provide information on recent advances in economics. They are selected to be of special help to teachers of economics at community and junior colleges and at other smaller colleges and universities where faculty members often find it difficult to keep up with new theory and policy developments and do an adequate job teaching a wide variety of courses. The volume is available (in paperback) from Richard D. Irwin, Inc., which has published it in cooperation with this Committee. Future volumes will be prepared and published if this one seems to serve a useful purpose.

3. The Committee has completed a review of experience with the *Journal of Economic Education,* published by the Joint Council on Economic Education with the cooperation of this Committee. The Journal has, in our judgment, been very successful. It now has a paid subscription list of some 2,600 persons, mainly college and university teachers at the undergraduate level. It is now in its seventh year, and has published a wide-ranging set of articles, mainly reporting research results evaluating different teaching approaches for undergraduate courses in economics. It has become the main source of information to members of the profession on such teaching developments and experiments. Professor Henry Villard, editor of the *Journal,* plans to broaden out somewhat the types of articles published, including a number of commissioned pieces on major developments of special interest to undergraduate teachers. We commend the *Journal* to economists who have special interests in undergraduate teaching.

4. The Joint Council on Economic Education is publishing reports on a series of six special projects, at as many universities, to develop experimental courses in elementary economics which might be transferable to smaller colleges which, because of limited manpower or time, have difficulty in developing elementary courses of particular usefulness to their own students. A small volume is being published on the course developed at each of the

cooperating institutions (Colorado, Florida State, Harvard, Indiana, University of Nebraska, and Vanderbilt). The courses developed at the different institutions vary widely. Copies of the booklets are available from the Joint Council on Economic Education, 1212 Avenue of the Americas, New York, New York.

5. This Committee has cooperated with *Change* Magazine, under a grant from the Fund for Post-Secondary Education, in a project to publish detailed information on interesting examples of innovative undergraduate teaching in a number of fields of knowledge. The purpose of the program is to identify, with the cooperation of the various disciplinary associations, examples of some of the best efforts to improve undergraduate teaching. *Change* (and the *Journal of Economic Education*) will publish the studies of each of the programs chosen for special attention. Choices of the programs to be included will be made by the officials of the project. These studies should be published over the period 1976–78, and, tentatively, will include several economics courses.

G. L. BACH, *Chairperson*

# REPORT OF THE COMMITTEE ON U.S.-SOVIET EXCHANGES

It may be desirable for the record to begin this report with an account of the early discussions leading to the visit of the Soviet delegation in April 1975.

### Preliminary Talks and Letters

The first suggestion for this undertaking came from Academician Nikolay P. Fedorenko, Director of the Central Economical Mathematical Institute of the Academy of Sciences of the *USSR*. He made the suggestion at a small party he gave for Fritz Machlup and others in Moscow in December 1972 on the occasion of a conference of the International Economic Association. Machlup acknowledged Fedorenko's "suggestion of annual symposia of the *USSR* and the U.S.A." in his letter of December 22 and promised further explorations with the Ford Foundation about the possibilities of financing such a project. A week later at the Executive Committee of the American Economic Association (*AEA*), Machlup reported the discussions with Fedorenko and was asked to continue his explorations with the Ford Foundation. He and Abram Bergson met with officers of the Ford Foundation. On March 15, Machlup wrote to Fedorenko that the Executive Committee of the *AEA* and the officials of the Ford Foundation expressed considerable interest in the project. Fedorenko replied on April 10 and promised to make concrete proposals after consulting his colleagues of the Academy of Sciences of the *USSR*. Machlup wrote to Fedorenko on May 8, 1973, but received no reply.

In August 1973, on the occasion of another visit of Machlup in Moscow, Academician Tigran S. Khachaturov repeated the proposal for annual symposia (apparently without earlier discussion with Fedorenko). He suggested that an official invitation be sent by the President of the American Economic Association, addressed to President Mystislav Keldish of the Moscow Academy, with carbon copies to Fedorenko and Khachaturov. Machlup told Khachaturov that we would first have to secure the funds and then obtain the definite concurrence of the Executive Committee of the *AEA*.

In October 1973, Machlup wrote to Craufurd Goodwin of the Ford Foundation, requesting some assurance of Foundation help before the proposal could be brought to the Executive Committee. On December 12, 1973, in a meeting at the Ford Foundation, it was agreed that *IREX* would provide the funds needed by the *AEA* to host twelve economists from the *USSR* for two weeks in the United States. At the December meetings Machlup reported again to the Executive Committee of the *AEA*, which responded favorably, and in a letter of January 6, 1974, he briefed President Walter Heller on the course of events.

In February 1974, President Heller applied to Allen Kassof of *IREX* for a grant of $7,000 to finance the proposed visit. After a concurring vote by the Executive Committee in its March meeting, Heller appointed a committee to plan for the visit of the *USSR* economists, the committee to consist of Abram Bergson, John R. Meyer, and Fritz Machlup (as Chairman). On May 10, Heller dispatched an invitation to President Keldish of the *USSR* Academy, with carbon copies to Fedorenko and Khachaturov, and (through Kassof of *IREX*) to Fedoseëv in Moscow. He also asked Burkhardt of

the American Council of Learned Societies (*ACLS*) in Washington to endorse the invitation in accordance with the agreement with the *ACLS* under the provisions of the General Agreement between the two governments concerning contacts, exchanges, and cooperation, signed on June 13, 1973.

No official reply was received for several months. In August Machlup saw Fedorenko and Khachaturov at the Budapest Congress of the International Economic Association. Khachaturov asked whether February or March 1975 would be acceptable dates for a visit of a Russian delegation. On October 20, 1974, Khachaturov sent to Heller an official acceptance of the invitation. This was confirmed by Heller in his letter of November 8.

At the Executive Committee in December 1974 it was agreed to propose scheduling the Symposium for April 1975. Machlup cabled to Khachaturov and received confirmation on January 6, 1975. At last the preliminaries had been completed and the actual planning for the first Symposium could get under way.

### Planning the First Symposium

In a letter of January 20, 1975, Khachaturov proposed six topics. All of these topics were accepted. Khachaturov was asked to send a list of the members of the Russian participants and to send copies of the papers as soon as possible. A list of twelve economists was given by Khachaturov in a letter postmarked March 14 and again in a telegram of March 25. The name of a Mr. Smirnov, included in the first list, was omitted in the telegram; upon our inquiry we were told by telegram on April 1 that Smirnov had withdrawn. The arrival was set for Friday, April 11, at Dulles Airport, Washington.

Only four papers had been received, two of them too late for distribution to prospective participants. Here is a list of the four papers:

(1) T. S. Khachaturov, "Dynamics of Capital Investments and Their Efficiency;"
(2) S. Nikitin, "Capital Investments, Fixed Productive Assets, and Their Efficiency: A Comparative Study;"
(3) A. Tolkachev, "Methods of the Long-Term Forecasting of the Volume and Effectiveness of Investments in the National Economy;" and
(4) O. Bogomolov, "Experience in Improving Economic Management in the European Socialist Countries."

Only ten of the eleven announced members of the *USSR* delegation actually came. The eleventh man, Victor Petrovich Krasovsky, Department Chief, Institute of Economics, did not arrive; he evidently failed to receive the necessary exit visa.

John Meyer appointed Gary Fromm of the National Bureau of Economic Research (*NBER*) as coordinator of the program and itinerary. The program provided for meeting the Russian visitors at their arrival at Dulles Airport, on Friday, April 11; an agenda meeting and general discussions on the morning of Saturday, April 12; a reception by the *NBER* in Washington on Sunday, April 13 in the afternoon; and six half-day sessions for papers and discussions; Sunday morning, Monday morning, Tuesday morning and afternoon, Wednesday morning and Thursday morning, all held in the State Department in Washington. For the subsequent seven days it provided for a visit to Columbia University on Friday, April 18, followed by two free days in New York City; a visit to Princeton University on Monday, April 21; to the Wharton School of the University of Pennsylvania on Tuesday, April 22; to Harvard University and the *NBER* in Cambridge on Wednesday, April 23; to Massachusetts

Institute of Technology and Data Resources Inc. on Thursday, April 24. Departure from Washington was set for Friday, April 25.

### The Symposium

The following topics were discussed in the six sessions of the symposium:

(1) "Methods of Determining the Efficiency of Investments and the Choice of Variants and Alternatives"
(2) "Methods of Forecasting Capital Investments"
(3) "Experience in Improving Economic Management in European Socialist Countries"
(4) "Effectiveness of Capital Investment in Public Service Sectors"
(5) "Comparisons of the Efficiency or Productivity of Investments in Different Countries"
(6) "Prospects for Soviet-American Economic Relations"

The composition of what might be called the American delegation proved to be a serious problem. The main difficulty was that, of the large number of persons invited from places other than Washington, only a few could find the time to attend at all and practically none could attend for more than two days. Only economists residing in Washington could be counted on to attend regularly, but a number of those approached were also unable to participate. As a result, the participation by American economists was totally inadequate, especially after the first meeting. Some of our colleagues from Philadelphia, particularly Lawrence Klein and Irving Kravis saved the day by coming to one additional session. Several economists from the Washington region did the best they could to keep up the appearance of a symposium in some of the remaining sessions.

No one is to be blamed for this poor showing on our part. We were evidently too optimistic regarding the length of time for which our colleagues could get away from their regular duties to attend a meeting of which they had received very short notice. With hindsight one may say that we should have relied more on our colleagues residing in the Washington area and should have invited them much earlier than we did.

Some of our Russian guests remarked that papers should have been prepared also by the American participants. This, however, would have been impossible because of the short notice. Even if all Russian papers had arrived in time for distribution four or five weeks before the symposium, one could not have expected any of the American economists to prepare discussion papers in a hurry and have them available for the Russian visitors.

### The Visits to East Coast Institutions

If the formal sessions of the symposium proved less than successful, the visits to various institutions can be regarded as highly satisfactory. Initially our guests were somewhat disappointed when they were told that a visit to the West Coast could not be arranged; there was neither enough time nor enough money available for such a long trip. However, they found the visits to the eastern institutions very successful from several points of view; they were glad to see some of the sights, to meet many economists, to listen to lectures and briefings, and to engage in informal discussions on topics of their interests.

In New York, the visitors spent the morning with the Economics Department at Columbia University. In the afternoon they attended a seminar at the National Bureau of Economic Research. There

were no planned activities for Saturday and Sunday, so that the visitors could make their own plans for these free days.

In Princeton, our guests attended two lectures in the Department of Economics, were shown the Computer Center and the Woodrow Wilson School of Public and International Affairs, and, finally, the Institute for Advanced Study.

In Philadelphia, they received briefings at the Wharton Econometric Forecasting Associates Inc. and attended a seminar at the Economics Department of the University of Pennsylvania.

In Cambridge, the visitors had a briefing at the National Bureau of Economic Research and a discussion comparing American and Soviet methodologies and findings. They were also shown the *NBER* Computer Research Center, especially their *SESAME, TROLL,* and *XMP* systems. In addition, there were visits at Data Resources Inc., Harvard University and Massachusetts Institute of Technology.

### Acknowledgments

The American Economic Association should express its gratitude to *IREX* for financing the entire undertaking. Although originally only $7,000 had been granted, Mr. Kassof and Mr. Matuszewski of *IREX* increased the funds at our disposal to a total of $13,000. This was highly necessary, especially as our visitors had to be wined and dined in the company of American colleagues selected to meet them at various places.

The officials and the staff of the *NBER* deserve high praise and sincere gratitude for making all the arrangements in Washington and elsewhere, including the arrangements for interpreters, guides, hotel accommodations, restaurants, travel, etc. A special vote of gratitude is owed to Gary Fromm of the Washington Office of the *NBER,* who personally attended to many of the organizational details.

### Recommendations

Khachaturov proposed that the next symposium be held in Moscow in the second half of June 1976. The timing may suit many American economists, since it will be well after commencement here and before some other conferences in Europe. (We know of at least two European conferences that begin on June 28, 1976.)

Khachaturov listed a number of preferred subjects for the symposium. Bergson suggested, and the rest of the committee agrees, that we should not embark on a wide array of topics, but choose one that in itself is broad enough to elicit interested response from a number of specialists. The topic most appropriate from this point of view would be "The Economics of Technological Progress."

This broad subject would allow discussions of such aspects as the meaning and nature of technological progress; the institutional framework, including the organization of research and development, patenting, etc.; trends in the volume of *R&D* activities; the measurement of technological progress; the diffusion of new technologies; and the international transfer of technological information.

We believe that a good group of American economists, knowledgeable in several aspects of this topic, could be selected and invited to the symposium. As to the number of participants, we think of ten to twelve. A large number would not only make travel expenses too high but might reduce the intensity of involvement in the discussions.

Khachaturov wants us to submit papers in advance. We fear that such a requirement would reduce the chances of our best possible candidates accepting our in-

vitation. Hence we propose that American participants be asked to submit only brief outlines, which they would then elaborate orally at the symposium in Moscow.

Fromm suggested that we try to obtain funding of the travel expenses from the U.S. Department of State. We propose that this be explored. If it proves impossible, we can still fall back on *IREX* as the financial sponsor of the undertaking.

We finally propose that a committee be appointed without much delay, charged with the task of selecting the American participants and assigning the topics on which they ought to prepare outlines for the symposium. We ought to inform Khachaturov before the summer is over.

FRITZ MACHLUP, *Chairperson*

# The London *Economist* urges this book for the "earnest citizen." Why not for your good and earnest students?

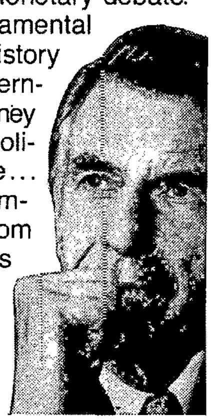
# Money

## WHENCE IT CAME, WHERE IT WENT

■ "If an earnest citizen, stirred to interest in monetarism... determines to try to get to the bottom of the subject, his instinct is absolutely sound. No area of public policy is likely to affect his future prospects more directly than the ability of the economy to cope with inflation or deflation or the modern malady of contriving to have both at once.

"Yet if the instinct is sound, the pursuit of information is perplexing in the extreme...

"But he might not... [find it] so if he could be persuaded to pick up Professor Galbraith's light-hearted yet profoundly serious gallop through the history of money which, beginning with the Kings of Lydia and ending with the slumpflation of 1975, might give him, as a general reader, some sense of the simplicities, ironies and deceptions of the world's long monetary debate. There he will learn a fundamental point — that throughout history what can be done by governments or bankers about money supply is fundamentally a political, not an economic issue... The conclusion will not commend the book to those whom Professor Galbraith defines as the conventionally wise. That is hardly his intention. But **the interested citizen will find himself enlightened and, which is even more unlikely, continuously amused."**



—*The Economist,* London, October 25, 1975

■ "MONEY is an application of Galbraith's analysis of power to the economic history of the West. Who wins and who loses is always clear in this highly readable account of the evolution of banking, the rise of paper money, the role of war in inflation, the mechanics of the great swindles from John Law to our own Bernard Cornfield, the rise of Keynesian fiscal theory, and the mystique and muddle which accompany the activities of the Federal Reserve and other central banks.

**"Galbraith performs the valuable service of draining the mystery out of banking... As ever, his prose, however gloomy its message, is a literary tonic."**

—ROBERT LEKACHMAN, *The Washington Post,* September 7, 1975

# The American Economic Review

## ARTICLES

JUNE 1976

# THE AMERICAN ECONOMIC ASSOCIATION

Founded in 1885

• Published at George Banta Co., Inc., Menasha, Wisconsin.

• THE AMERICAN ECONOMIC REVIEW, including four quarterly numbers, the *Proceedings* of the annual meetings, the *Directory*, and Supplements, is published by the American Economic Association and is sent to all members five times a year, in March, May, June, September, and December.

Association membership dues for 1976, which include a subscription to both The *American Economic Review* and the *Journal of Economic Literature*, are as follows:

$25.00 for regular members with rank of assistant professor or lower, or with annual income of $12,000 or less;

$30.00 for regular members with rank of associate professor, or with annual income of $12,000 to $20,000;

$35.00 for regular members with rank of full professor, or with annual income above $20,000;

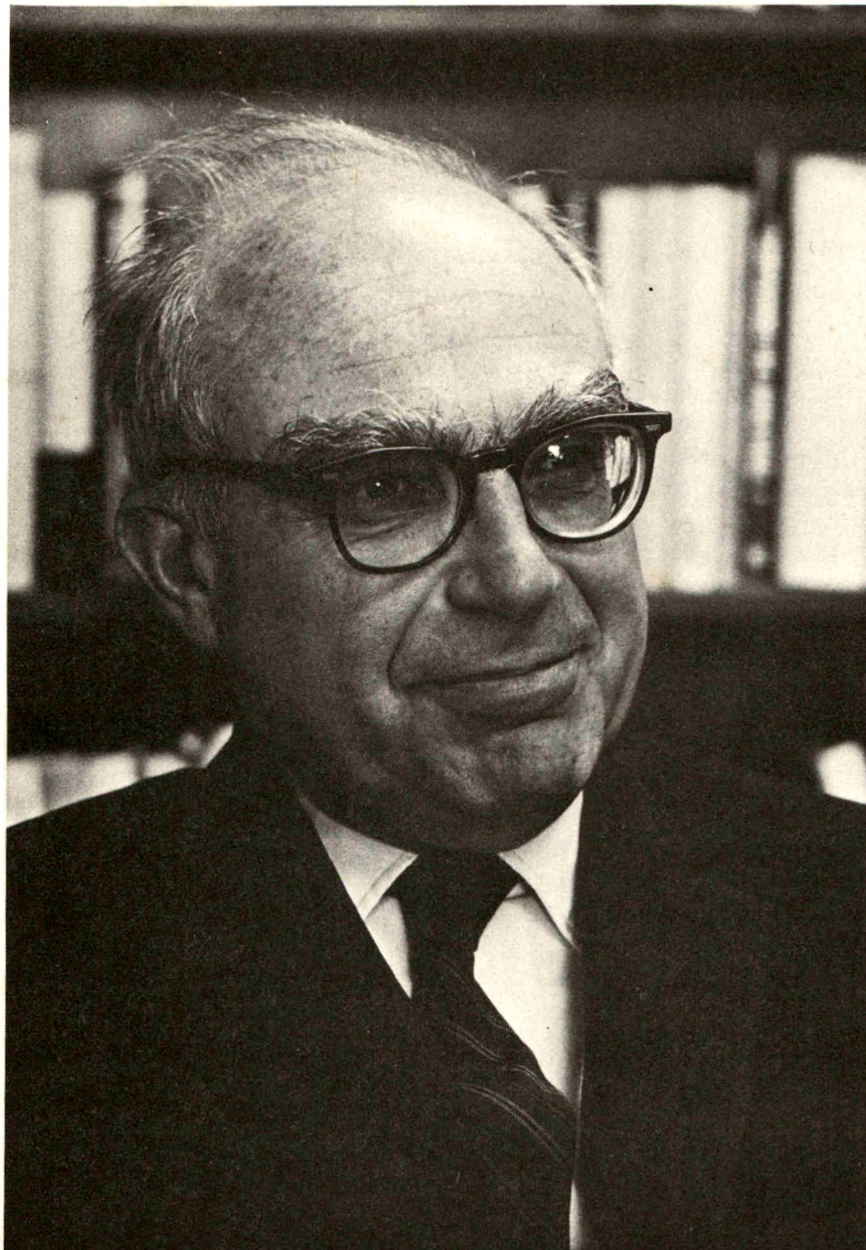
$12.50 for junior members (registered students). Certification must be submitted yearly.

Subscriptions (libraries, institutions, or firms) are $37.50 a year. Only subscriptions to both publications will be accepted. Single copies of either journal may be purchased from the Secretary's office, Nashville, Tennessee.

For foreign postage, add: PUAS countries, $3.20; all other countries and Canada, $3.75.

• Correspondence relating to the *Papers and Proceedings*, the *Directory*, advertising, permission to quote, business matters, subscriptions, membership and changes of address should be sent to the Secretary, C. Elton Hinshaw, 1313 21st Avenue South, Nashville, Tennessee 37212. Change of address must reach the Secretary at least six (6) weeks prior to the month of publication. The Association's publications are mailed second class.

• Second-class postage paid at Nashville, Tennessee and at additional mailing offices. Printed in U.S.A.



Moses Abramovitz

# MOSES ABRAMOVITZ

## Distinguished Fellow

## 1976

Moses Abramovitz is an economist for all seasons. Insight, perseverance, and modesty are a rare combination; and they have made him into a rare economist. His scholarly temperament made him shun the economic fashions; but thanks to his sense of the important, his work usually became the forerunner of fashions. While others imported analytic tools into economic history, he brought an historian's painstaking thoroughness and respect for evidence to economic analysis; and we owe to him much of what we know about our economy's growth and its ups and downs.

His dissertation was a forerunner of modern dynamic analysis. Among the first to make use of measures of total factor productivity growth, he identified the residual as a measure of our ignorance, and, as a means of reducing that ignorance, he urged recognition of health, education, training, and research as costly inputs contributing to long-term growth.

If his insight gave him the first word on much that has since become the economist's standard equipment, his perseverance also gave him the last word on many topics. He was the one definitely to establish inventory adjustment as the major component of cyclical instability; and the theory of long swings, the second major component, is also largely his work, based on his meticulous study of construction activity over a hundred years. We are pleased to recognize his distinction.

THE AMERICAN ECONOMIC REVIEW

June 1976

VOLUME 66, NUMBER 3

• Manuscripts and editorial correspondence relating to the regular quarterly issue of this REVIEW should be addressed to George H. # Flexible Exchange Rates, Forward Markets, and the Level of Trade

*By* David P. Baron*

One of the arguments made against a system of flexible exchange rates for regulating the balance of payments of countries is that the uncertainty posed by exchange rate variation will reduce the level of trade. Proponents of such a system have argued that traders are able to hedge their exchange risks by using forward exchange contracts or similar covering arrangements, and thus, traders can behave as if the exchange rates were certain. While there are numerous other arguments for and against a system of flexible exchange rates, the direct effect of exchange rate uncertainty on trade is central to the choice between the systems. The purpose of this paper is to investigate in the context of a simple model the effect of uncertain exchange rates on the output and exports of firms, and to determine the role of forward markets in planning output and trade. The model is based upon recent work concerning incomplete capital markets by Peter Diamond, Steinar Ekern and Robert Wilson, Ekern (1974, 1975), Hayne E. Leland (1973, 1974), Roy Radner, and Joseph Stiglitz.

It will be shown that in equilibrium all investors are indifferent to the covering decisions of firms, and hence, that the values of all firms are independent of the covering of any firm. In addition, all firms are able to plan their production and exports on the basis of the forward exchange rates and will behave as a multiproduct, "profit" maximizing firm using the fully covered marginal profit as a "planning-equivalent" even though the firm may not fully cover its exchange risks. The level of trade with a flexible exchange rate system will thus be identical to that which would exist with fixed exchange rates equal to the forward rates, so this uncertainty regarding exchange rates has no effect on trade.

To be able to plan its output levels, a firm does not need any information regarding the preferences or probability assessments of its shareholders, yet all shareholders will unanimously prefer the production levels that maximize the fully covered profit. A voting process may be constructed that will lead to the equilibrium outputs, but such a process is not necessary, since a firm can investigate the preferences for various output levels by considering a hypothetical shareholder. The analysis for the hypothetical shareholder indicates unanimity on the part of all actual shareholders thus permitting the planning of outputs and exports.

The separation of control and ownership of firms creates the possibility of alternative criteria for choices of output levels with those criteria reflecting the preferences of managers or the managers' perception of what would be in the best interests of its shareholders. Managers may believe, for example, that they have more accurate expectations regarding future exchange rates than have shareholders, and the managers may then wish to use their

* Professor of managerial economics and decision sciences, Graduate School of Management, Northwestern University. This research was undertaken while I was professeur associé, Institut d'Administration des Entreprises, Université de Droit, d'Economie et des Sciences, Aix-en-Provence, France.

probability assessments and maximize, for example, the expected utility of profits for some utility function and their expectations. The output levels resulting with this criterion will be shown to be identical to those resulting from maximizing fully covered profit, and thus managers of firms who use their own expectations and preferences for profit will be acting in the best interests of the shareholders of the firm. The separation of ownership and control thus does not affect trade if the managers maximize the expected utility of profit and are able to cover their exchange risks.

Central to these results is the existence of a forward exchange market or its equivalent for the currency of each country to which the firm exports. If investors are able to borrow and lend foreign currencies, the existence of forward markets is not necessary, since the interest rate-parity theorem of arbitrage is essentially a statement of the redundancy of forward exchange markets when foreign currency borrowing and lending is possible. If forward exchange markets or their equivalents do not exist, the indifference and unanimity results may not hold.

The model and the investor equilibrium are presented in Section I, and the production planning of firms and the resulting levels of trade are considered in Section II. The role of forward markets is investigated in Section III, and conclusions are offered in the final section.

## I. The Model and an Investor Equilibrium

### A. *The Capital and Foreign Exchange Markets*

Individual investors will be assumed to have the opportunity to trade in both foreign exchange markets and capital asset markets for the shares of firms. To simplify the notation, it will be assumed that there is only one firm in each country with its shares traded only in the capital asset market in that country. Investors will initially be permitted to purchase shares in any of the capital asset markets, all of which are assumed to be competitive in that the market participants do not believe that their portfolio decisions will affect share prices. The capital asset markets are assumed to be incomplete in the sense that the firm through its production decisions may offer to investors patterns of returns that are not found elsewhere in the markets and cannot be created independently by investors. Transactions costs are taken to be zero and short sales are permitted.

In addition to investing in shares, individuals may trade in the foreign exchange markets as may firms that wish to hedge their accounts receivable in the forward exchange market. A two-period model will be utilized, so three exchange rates are involved. The period-1 spot exchange rate between country $n$ and $j$ is denoted by $r_{nj}$ and is measured in units of currency $n$ per unit of currency $j$. Firms and investors may also sign contracts to exchange one currency for another in period 2 at the forward exchange rate $\rho_{nj}$.[1] The future spot exchange rate in period 2 is uncertain and is denoted by $\rho_{nj}(\theta)$, where $\theta$ is a state of nature reflecting the actions of other traders, such as tourists and governments, long-term capital movements, and exogenous events. The model analyzed here does not provide an explanation of the determination of the future spot rates (see H. G. Grubel), since not all determinants of the balance of payments are considered here. The model will, however, indicate the relationship between spot and forward rates.

Forward exchange markets are assumed to exist for every pair of currencies, and the exchange rates for a country with itself equals one ($\rho_{nn}(\theta)=\rho_{nn}=r_{nn}=1$ for all $\theta$

[1] Other forms of forward exchange transactions such as swaps will not be considered, since they simply duplicate the forward exchange markets.

and $n$). Two assumptions regarding the foreign exchange markets will be made. First, arbitrage opportunities within a market yield a zero return, so that $r_{nj}=1/r_{jn}$ and $r_{nj}=r_{nl}r_{lj}$ for all $n$, $j$, and $l$, and the same is true for the forward rates and the future spot rates in every state $\theta$. Investors are able to borrow and lend in foreign currencies, so arbitrage between spot and forward markets is permitted. Second, the foreign exchange markets are assumed to be competitive in the sense that investors do not believe that their foreign currency trading or the actions of any firm will affect the exchange rates.

## B. *Firms*

In order to focus on the effects of exchange rate uncertainty, the revenue and cost functions of firms are assumed to be deterministic and known to all market participants. The firm located[2] in country $n$ is taken to sell both in its home country and in a set of foreign countries with the firm's decisions being made in period 1 and the proceeds from its production and financial decisions being realized in the second period. Let there be $n=1, \ldots, N$ countries and assume that all foreign sales are exports from the home country that are invoiced in the currency of the importing country.[3] The quantity of goods sold in country $j$ by the firm located in country $n$ is denoted by $q_{nj}$, and the price in that country is given by an inverse demand function $p_{nj}(q_{nj})$. The quantity $q_{nj}$ is assumed to be sold on a line-of-credit basis with payment to be received in period 2.[4] The total currency $j$ revenue $R_{nj}$ is thus $R_{nj}=p_{nj}(q_{nj})q_{nj}$, and that amount is exposed to uncertainty regarding the spot exchange rate that will obtain at the time at which the firm receives payment for its exports. The firm may hedge its foreign currency risk by selling currency $j$ against its home currency at the forward exchange rate $\rho_{nj}$. Letting $A_{nj}$ be the forward sale ($A_{nj}>0$) or purchase ($A_{nj}<0$) of currency $j$ against $n$, where $A_{nj}$ is measured in currency $j$, the net exposure in currency $j$ is $(R_{nj}-A_{nj})$. The total revenue $TR_n(\theta)$ collected in period 2 in the firm's home currency is the net exposure converted at the future spot exchange rate plus the proceeds from the forward transactions for each country or

$$(1)\quad TR_n(\theta) = \sum_j \left[\rho_{nj}(\theta)(R_{nj} - A_{nj}) + \rho_{nj}A_{nj}\right]$$

where $A_{nn}\equiv 0$.[5] The total home currency revenue is thus the uncovered revenue plus the return on speculation $(\rho_{nj}-\rho_{nj}(\theta))A_{nj}$. To simplify the analysis, all production will be assumed to take place in the home country and all factor inputs are assumed to be purchased in the currency of the home country. The cost of production will be represented by a cost function $C_n(q_n)$, where $q_n=(q_{n1}, \ldots, q_{nN})$, with payment to the factors of production made in period 2.[6] The profit $\pi_n(\theta)$ realized in period 2 in state $\theta$ is thus

$$(2)\qquad \pi_n(\theta) = TR_n(\theta) - C_n(q_n)$$

[2] The term "located" is intended to indicate that the firm converts its revenue into the currency of that country and distributes its profits to its investors in that currency.

[3] The majority of exports are invoiced in the currency of the exporting currency although the practice varies considerably among countries and across industries as indicated by Sven Grassman. Instead of representing each firm as invoicing certain exports in its home currency and others in foreign currencies as well as importing factor inputs invoiced in a variety of currencies, the common assumption will be made that all exports are invoiced in the currency of the importing country.

[4] Grassman found that the average payment period for Swedish exports was 91 days in 1968.

[5] Firms will not be considered to conduct arbitrage operations or to deal in the forward markets not involving their country. Firms are also assumed not to borrow and lend in foreign currencies. The significance of this assumption will be considered in Section IV.

[6] The model may be generalized readily to the case in which a firm has production units in a foreign country. For example, if firm $n$ has a production unit in a

The profit function is assumed to be strictly concave and continuously differentiable in every state.

### C. *Investors*

Investors are assumed to maximize subject to a budget constraint their expected utility of return from investments in the shares of firms and from their foreign currency transactions. An investor[7] in country $m$ has an initial endowment consisting of shares of the equity of firms in each country and savings (or borrowing) in each currency. The investor's initial share of the equity of the firm in country $n$ will be denoted by $\bar{z}_{mn}$, and the market value of that firm in currency $n$ will be denoted by $V_n$. The investor's initial endowment of currency $n$ will be denoted by $\bar{y}_{mn}$ which has a current value in the home currency of $r_{mn}\bar{y}_{mn}$ with $\bar{y}_{mn}>(<)0$ representing savings (borrowing). The investor may also have been endowed with a contract for a proportion $\bar{t}_{mnj}$ of the forward sales of currency $j$ against currency $n$ where $\bar{t}_{mnj}A_{nj}>(<)0$ represents a forward purchase (sale) of currency $j$ against $n$. The forward purchase commits the investor to supply $\sum_j \bar{t}_{mnj}\rho_{nj}A_{nj}$ of currency $n$ in period 2. For $j=n$, $A_{nn}\equiv 0$, so $\bar{t}_{mnn}$ is not a decision variable. No margin requirement on forward contracts is assumed to be required, but the inclusion of such a requirement is straightforward and causes no changes in the results.[8]

The initial wealth $W_m^0$ of the investor is thus composed of the current value of the share holdings plus the savings (borrowing), or

$$(3) \quad W_m^0 = \sum_n \bar{z}_{mn} r_{mn} V_n + \sum_n \bar{y}_{mn} r_{mn}$$

Given this initial wealth, the investor reallocates his portfolio by choosing new ownership proportions $z_{mn}$ and new foreign currency holdings $(t_{mnj}, y_{mn})$ subject to the budget constraint

$$(4) \quad W_m^0 = \sum_n z_{mn} r_{mn} V_n + \sum_n y_{mn} r_{mn}$$

The forward commitments do not enter the budget constraint because no margin requirement is incorporated into the model.

The total return on the investor's portfolio is his share of the profits of firms, his lending and borrowing return, and his gain or loss on forward transactions all converted to the home currency in period 2. His share of the profit of a firm is converted to the home currency at the future spot exchange rate for a value of $\sum_n z_{mn}\rho_{mn}(\theta)\pi_n(\theta)$. The value of the savings (borrowing) in currency $n$ is $y_{mn}i_n$, where $i_n$ is the gross borrowing-lending rate in currency $n$, and this will be converted at the future spot rate for a total value of $\sum_n \rho_{mn}(\theta)y_{mn}i_n$. The home currency value of the forward purchases $\sum_n t_{mnj}A_{nj}$ of currency $j$ is $\rho_{mj}(\theta)\sum_n t_{mnj}A_{nj}$, and the total value of all forward purchases is $\sum_j \rho_{mj}(\theta)\sum_n t_{mnj}A_{nj}$. The cost in currency $n$ of the forward purchases of $j$ against $n$ is $\rho_{nj}t_{mnj}A_{nj}$, and the total obligations in currency $n$ are $\sum_j \rho_{nj}t_{mnj}A_{nj}$. This amount of currency $n$ must be purchased at the future spot exchange rate $\rho_{mn}(\theta)$ for a total currency $m$ cost of $\sum_n \rho_{mn}(\theta)\sum_j \rho_{nj}t_{mnj}A_{nj}$. The net gain $S_m(\theta)$ on speculation via forward transactions is thus

$$(5) \quad S_m(\theta) = \sum_n \rho_{mn}(\theta) \sum_j (\rho_{nj}(\theta) - \rho_{nj})t_{mnj}A_{nj}$$

---

country $j$ and $C_{nj}(q_{nj})$ is the cost for that unit, then the profit from country $j$ in terms of the currency of the home country is

$$\rho_{nj}(\theta)(R_{nj} - C_{nj}(q_{nj}) - A_{nj}) + \rho_{nj}A_{nj}$$

The results presented below also hold for this case.

[7] To simplify the indexing notation, individual investors in each country are not identified.

[8] If a fraction $\beta_{mnj}$ of the forward commitment is required as margin, let $\beta_{mnj}\in[0, 1]([-1, 0])$ if $\bar{t}_{mnj}\rho_{nj}A_{nj}\geq(<)0$. Then, if the margin deposit is made in the home currency of the investor, the total margin deposit is $\sum_n r_{mn}\sum_j \beta_{mnj}\bar{t}_{mnj}\rho_{nj}A_{nj}$. If this margin deposit earns the risk-free rate of interest, the margin is simply another form of saving in the home currency, and none of the results are affected.

where $(\rho_{nj}(\theta)-\rho_{nj})$ is the gain to speculation on each unit of currency $j$ purchased forward against $n$. The total portfolio return $X_m(\theta)$ in currency $m$ is then

$$(6)\quad X_m(\theta) = \sum_n z_{mn}\rho_{mn}(\theta)\pi_n(\theta) + \sum_n \rho_{mn}(\theta)y_{mn}i_n + S_m(\theta)$$

Each investor is assumed to have preferences for period 2 return that are represented by a measurable utility function $U_m(X_m(\theta))$ that is increasing, strictly concave, and continuously differentiable in $X_m(\theta)$.[9] Each individual is assumed to assess a probability distribution on $\theta$, and expectation with respect to that assessed probability distribution will be denoted by $E_m$. Investors may have different assessed distributions of the states of nature, but all are assumed to agree that there is no default risk on forward contracts or on borrowing commitments. The investor thus seeks to maximize

$$E_mU_m(X_m(\theta))$$

with respect to the $z_{mn}$, $t_{mnj}$, and $y_{mn}$ subject to the budget constraint implied by (3) and (4). In equilibrium the decisions for all investors are restricted by the constraints

$$(7)\quad \sum_m z_{mn} = 1, \quad n = 1,\dots,N$$
$$\sum_m t_{mnj} = 1,$$
$$j = 1,\dots,N,\ n = 1,\dots,N,\ n \neq j$$

### D. *Investor Equilibrium*

To develop the portfolio optimality conditions for an investor, solve the budget constraint in (4) for the savings $y_{mm}$ in the home currency and substitute into $X_m(\theta)$ in (6) to obtain the net return

$$(8)\quad X_m(\theta) = \sum_n z_{mn}[\rho_{mn}(\theta)\pi_n(\theta) - r_{mn}i_mV_n] + \sum_n y_{mn}[i_n\rho_{mn}(\theta) - i_mr_{mn}] + S_m(\theta) + \sum_n \bar{z}_{mn}r_{mn}V_n + \sum_n \bar{y}_{mn}r_{mn}$$

The first term in brackets in (8) is the net return on the shares of the firm in country $n$ less the opportunity cost of purchasing shares in lieu of saving in the home country. The second term in brackets is the home currency value of a unit of savings in country $n$ less the opportunity cost of saving in country $n$ instead of the home country. The third term is the gain or loss due to speculation using forward transactions.

The necessary optimality conditions for the investor are[10]

$$(9)\quad \frac{\partial E_mU_m}{\partial z_{mn}} = E_m\{U_m'\cdot(\rho_{mn}(\theta)\pi_n(\theta) - r_{mn}i_nV_n)\} = 0, \quad n = 1,\dots,N$$

$$(10)\quad \frac{\partial E_mU_m}{\partial t_{mnj}} = E_m\{U_m'\cdot(\rho_{mn}(\theta)(\rho_{nj}(\theta) - \rho_{nj})A_{nj})\} = 0, \quad n = 1,\dots,N,\ j = 1,\dots,N,\ j \neq n$$

$$(11)\quad \frac{\partial E_mU_m}{\partial y_{mn}} = E_m\{U_m'\cdot(i_n\rho_{mn}(\theta) - i_mr_{mn})\} = 0, \quad n = 1,\dots,N,\ n \neq m$$

where $U_m'$ denotes the first derivative with respect to $X_m(\theta)$ and the arguments of $U_m$

[9] The utility function may be state dependent and may be an indirect utility function derived from optimal consumption decisions after $\theta$ has occurred in period 2. The model could also be formulated as a 2-period consumption model as in Ekern (1974).

[10] The existence of an equilibrium is assumed here. Oliver Hart and Dimitri Bertsekas have presented necessary and sufficient conditions for the existence of an equilibrium in a capital market model.

and $U'_m$ are understood.[11] An investor equilibrium for a given set of decisions by firms is characterized by the conditions in (9), (10), and (11), and by the market clearing conditions in (7).

### E. *Arbitrage between Spot and Forward Markets*

The interest rate parity theorem may be verified by rewriting $\rho_{mn}(\theta)\rho_{nj}(\theta)$ in (10) as $\rho_{mj}(\theta)$, solving (11) for $E_m(U'_m \cdot \rho_{mj}(\theta))$, and by substituting into (10) to obtain

$$E_m\{U'_m \cdot (r_{mj}(i_m/i_j) - \rho_{mn}(\theta)\rho_{nj})A_{nj}\} = 0$$

Then solving (11) for $E_m(U'_m \cdot \rho_{mn}(\theta))$ and substituting above, yields

$$E_m\{U'_m \cdot [r_{mj}(i_m/i_j) - \rho_{nj}r_{mn}(i_m/i_n)]A_{nj}\} = 0$$

The term in brackets does not involve $\theta$ and marginal utility is positive, so in equilibrium the term in brackets must equal zero. That term may be rewritten as

$$\rho_{nj} = r_{nj}i_n/i_j \tag{12}$$

since $r_{mj}/r_{mn} = r_{nj}$. The interest rate-parity theorem is thus verified and all gains due to arbitrage between spot and forward markets will be eliminated at an investor equilibrium. The arbitrage mechanism has not been introduced explicitly in this model but instead the two components of that form of arbitrage, borrowing or saving in a foreign currency and a matching forward contract, have been utilized. The significance of the interest rate-parity theorem will be considered in Section IV.

## II. Firm Production and Covering

### A. *Processes for Firm Decision Making*

The process by which firms make production and covering decisions has yet to be specified, and that process is subject to debate with firms being hypothesized to maximize their market value, to maximize the expected utility of their shareholders, or to maximize the preferences of their managers, for example. Leland (1974), Stiglitz, and Ekern and Wilson have demonstrated that in an incomplete capital market, value maximization does not in general result in Pareto optimal resource allocations so attention will be focused on the latter two processes.[12] The maximization of the expected utility of shareholders is certainly the most reasonable criterion for a firm, but firms do not in general know the preferences, probability assessments, and portfolio holdings of their shareholders. Although a firm does not know the characteristics of its shareholders, it can consider a hypothetical shareholder. Such a shareholder will necessarily have portfolio holdings that satisfy the conditions in (9), (10), and (11) for some utility function, some probability assessments, and some initial wealth. The firm may then determine how its decisions affect the optimal expected utility of a shareholder at his optimal portfolio holdings.

In order to investigate an investor's preference for the forward covering by the firm, consider a change $\Delta A_{nj}$ in covering at an investor equilibrium where the optimal decisions are denoted by a ($\hat{}$). The resulting change in the investor's return in (6) is

$$\rho_{mn}(\theta)(\rho_{nj}(\theta) - \rho_{nj})\Delta A_{nj}(\hat{t}_{mnj} - \hat{z}_{mn}) \tag{13}$$

Given such a change in covering by the firm, suppose that each investor alters his foreign currency holdings as follows:

$$\begin{aligned} \Delta y_{mj} &= (\hat{z}_{mn} - \hat{t}_{mnj})\Delta A_{nj}/i_j \\ \Delta y_{mn} &= -(\hat{z}_{mn} - \hat{t}_{mnj})\Delta A_{nj}\rho_{nj}/i_n \end{aligned} \tag{14}$$

[11] The condition in (10) for $t_{mnj}$ is equivalent to that for $t_{mjn}$, since $\rho_{nj} = 1/\rho_{jn}$ implies $\rho_{mn}(\theta)(\rho_{nj}(\theta) - \rho_{nj}) = \rho_{mj}(\theta)(\rho_{jn} - \rho_{jn}(\theta))/\rho_{jn}$. Consequently, an optimal solution can be taken to have $\hat{t}_{mnj} - \hat{t}_{mjn}$ as the investor's share of the net forward sales of currency $j$ against $n$.

[12] The criterion of value maximization also does not lead to optimal output levels that are independent of investor characteristics as do the other two criteria.

$$\begin{aligned}(15)\quad \frac{\partial E_m U_m}{\partial q_{nj}} = E_m \Bigg\{ U'_m \cdot \Bigg[ &\sum_k (\bar{z}_{mk} - \hat{z}_{mk}) i_m r_{mk} \frac{\partial V_k}{\partial q_{nj}} \\ + &\sum_k (\pi_k(\theta)\rho_{mk}(\theta) - i_m r_{mk} V_k) \frac{\partial \hat{z}_{mk}}{\partial q_{nj}} \\ + &\sum_{\substack{l \\ l \neq k}} \sum_k \rho_{ml}(\theta)(\rho_{lk}(\theta) - \rho_{lk}) A_{lk} \frac{\partial \hat{l}_{mlk}}{\partial q_{nj}} \\ + &\sum_k (i_k \rho_{mk}(\theta) - i_m r_{mk}) \frac{\partial \hat{y}_{mk}}{\partial q_{nj}} \\ + &\rho_{mn}(\theta)(\rho_{nj}(\theta) MR_{nj} - MC_{nj}) \hat{z}_{mn} \Bigg] \Bigg\}\end{aligned}$$

Adding the returns from (13) and (14) indicates that the return $X_m(\theta)$ in (6) in each state $\theta$ is then unchanged by the change in the firm's covering, since the change in the return on forward contracts plus profits is exactly offset by the change in the return on foreign currency borrowing and lending. If the investor's alterations in his currency purchases are feasible, the distribution of return optimal before the change can be duplicated after the change in covering. Then no investor has an incentive to alter his shareholding or his share of the forward contracts, so the value of the firm (and all other firms) must remain the same. To show that the investor's alterations in his currency purchases are feasible, determine the net change in the home currency cost of the purchases in (14) which is

$$r_{mj}\Delta y_{mj} + r_{mn}\Delta y_{mn} = (\hat{z}_{mn} - \hat{l}_{mnj})\Delta A_{nj}(r_{mj}/i_j - \rho_{nj} r_{mn}/i_n)$$

The arbitrage relationship $\rho_{nj} = r_{nj} i_n / i_j$ in (12) then implies that this term is zero. This holds for all investors at any output levels for firms, so the investor is able to exactly offset or duplicate the covering of any firm. Consequently, the value of a firm is independent of its covering, and all investors are indifferent to the covering of any firm. This homemade covering result is stated as Proposition 1.

PROPOSITION 1: *At an investor equilibrium for given output levels of firms, all investors are indifferent to the covering decisions of any firm, and hence the value of a firm is independent of the covering by any firm.*[13]

In an incomplete capital market, an investor is not able to duplicate the return possibilities generated by the productive activities of firms, and hence, investors are not globally indifferent to the production levels of firms. The preferences of an investor for the exports $q_{nj}$ may be determined by differentiating his optimal expected utility with respect to $q_{nj}$ to obtain[14] equation (15). The marginal revenue in currency $j$ is:

$$MR_{nj} = p'_{nj}(q_{nj})q_{nj} + p_{nj}(q_{nj})$$

[13] The same result obtains for firm borrowing and lending in foreign currencies, which justifies leaving such possibilities out of the model. Since the firm has no guide as to its covering decisions, the values of $A_{nj}$ will be taken as nonzero in the following analysis.

[14] The output of firm $n$ is assumed not to affect the profit of any other firm, so that there are no industry effects. Such industry effects are considered by Ekern (1975).

The marginal cost in currency $n$ is

$$MC_{nj} = \partial C_n(q_n)/\partial q_{nj}$$

and the value of the firm is assumed to be differentiable with respect to $q_{nj}$. The second, third, and fourth terms of (15) are zero at an investor equilibrium from (9), (10), and (11).

The analysis of the firm's decisions will be conducted at an *ex post* equilibrium in which investors already hold optimal portfolios given the decisions of firms.[15] Investors may be thought of as having gone through a series of portfolio revisions until arriving at the portfolio holdings ($\bar{z}_{mn}$, $\bar{y}_{mn}$, $\bar{l}_{mnj}$) that are optimal, and then the investor does not wish any further revision. Thus $\hat{z}_{mn}=\bar{z}_{mn}$, $\hat{y}_{mn}=\bar{y}_{mn}$, and $\hat{l}_{mnj}=\bar{l}_{mnj}$. The first term in (15) is then equal to zero, and the investor's preference for a (local) change in $q_{nj}$ is given by

$$(16) \quad \frac{\partial E_m U_m}{\partial q_{nj}} = E_m\{U'_m \cdot \rho_{mn}(\theta)(\rho_{nj}(\theta)MR_{nj} - MC_{nj})\}\hat{z}_{mn}$$

As expressed in (16) the preferences of an investor for changes in output depend on the investor's utility function, probability assessments, and portfolio holdings. The investor equilibrium, however, reflects these investor characteristics and establishes prices for the risks that are traded in the foreign exchange markets. For example, scaling expected marginal utility $E_m U'_m$ in (11) to equal one and using (12) yields

$$(17) \quad E_m\{U'_m \cdot \rho_{mn}(\theta)\} = \rho_{mn}$$

This holds for all investors, so $\rho_{mn}$ may be interpreted as the market price for a claim to one unit of currency $n$ in period 2. The role of the forward market in taking into account divergent investor characteristics may be seen by writing (17) as

$$E_m(\rho_{mn}(\theta)) - \rho_{mn} = -\,cov_m(U'_m, \rho_{mn}(\theta))$$

where $cov_m$ is the covariance of $U'_m$ and $\rho_{mn}(\theta)$. The left side is the difference between the expected future spot rate and the forward rate. If the investor believes that the expected future spot rate will be greater (less) than the forward rate, the investor will adjust his portfolio so that the covariance between marginal utility and the future spot rate will be negative (positive). For example, if the left side is positive, the investor will choose a portfolio that has positive net claims to currency $j$ through share ownership, savings, and forward sales. A similar interpretation may be given to the condition in (10).

This market price may be used to further analyze investor preferences in (16). Substituting $E_m\{U'_m \cdot \rho_{mn}(\theta)\}$ from (11) and similarly $E_m\{U'_m \cdot \rho_{mj}(\theta)\}$ from (11) into (16) yields

$$(18) \quad \frac{\partial E_m U_m}{\partial q_{nj}} = E_m\{U'_m\}\rho_{mn}(\rho_{nj}MR_{nj} - MC_{nj})\hat{z}_{mn}$$

Since expected marginal utility is positive as is $\rho_{mn}$, the sign of the expression in (18) depends on the marginal "fully covered profit" ($\rho_{nj}MR_{nj}-MC_{nj}$) on the firm's exports to country $j$ and the sign of $\hat{z}_{mn}$. This is true for all investors, so all shareholders ($\hat{z}_{mn}>0$) will unanimously prefer a (local) increase (decrease) in the exports to country $j$ if and only if the marginal fully covered profit is positive (negative). Shareholders will prefer no change in the outputs of a firm when

$$(19) \quad \rho_{nj}MR_{nj} - MC_{nj} = 0, \quad j = 1, \ldots, N$$

The firm may thus serve the interests of its shareholders by acting as a multiproduct firm using the forward exchange rates as planning equivalents. This establishes the

[15] Leland (1974) and Ekern (1974) have also used *ex post* equilibrium analysis. Radner has considered *ex ante* equilibrium analysis.

following shareholder unanimity and production planning proposition.

PROPOSITION 2: *All shareholders have unanimous preferences for (small) changes in the output levels of firms, and the firm may maximize the expected utility of its shareholders by acting as a multiproduct, profit-maximizing firm using the forward exchange rates as planning equivalents.*[16] *The export levels that equate fully covered marginal revenue to marginal cost are Pareto optimal.*[17]

The production levels are thus independent of the characteristics of investors except to the extent that those characteristics establish the forward exchange rates. This result obtains because investors are able to offset any exchange rate risk created by the exports of the firms by trading in forward exchange markets and/or by borrowing and lending in foreign currencies. For example, if the firm has export revenue $R_{nj}$ in currency $j$, the investor can offset that exchange rate risk by borrowing a quantity $R_{nj}\hat{z}_{mn}/i_j$ of currency $j$ to cover the exchange rate risk generated by exports. In period 2 the investor's share of the firm's exports will effectively cover the loan obligation. Proposition 1 reflects this homemade covering effect which implies that the firm can ignore the exchange rate uncertainty in planning its operations and may use the forward rate as a "planning equivalent."

Another implication of the homemade covering result of Proposition 1 is that production may be planned independently of any capital market considerations. The results of Leland (1974) and Ekern (1974), for example, indicate that production will in general be a function of the value of the firm. In the model considered here, the production levels are independent of the value of the firm (except in that the forward exchange rates and firm values are determined simultaneously in equilibrium) because the existence of the forward exchange markets permits investors to efficiently price the exchange risks.

The process by which the firm determines its optimal output levels may be thought of as a voting process in which the firm submits its planned output levels to its shareholders for ratification. Given any output plan, shareholders will be unanimous with respect to their preferences for small changes in the plan, and the process will terminate when (19) is satisfied. Such a voting process is not necessary however because a firm can consider any hypothetical shareholder and can predict the response of that shareholder and hence the responses of all shareholders. To do so, the firm need not know anything about shareholders except that they maximize the expected utility of their portfolio return. The

[16] Proposition 2 is an *ex post* unanimity result (see Leland 1973, 1974, Ekern and Wilson, Ekern 1974, and Radner) that obtains because for each state $\theta$ the marginal returns with respect to a firm's decisions may be expressed as a linear combination of the returns on foreign currency holdings. The unanimity result is *ex post* in the sense that it holds at the optimal portfolio for investors. Proposition 1 is stronger than Proposition 2 because the existence of a forward market or the opportunity for foreign currency borrowing and lending allows the investor to create the same opportunities that a firm can create through its covering. Investors are not assumed to be able to create the same pattern of return as can be generated by the output decisions of firms. If the stronger assumption is made that investors can duplicate those patterns of return, unanimity results may be obtained for *ex ante* shareholders. The same production planning result obtains under these assumptions.

[17] To demonstrate that the output levels are Pareto optimal, consider the problem of maximizing the expected utility of one investor subject to constrained levels of expected utility for other investors. Thus, for investor $m$ the program is max $E_mU_m(X_m(\theta))$ subject to $E_lU_l(X_l(\theta))=U_l^0$, $l=1,\ldots,N$, $l\neq m$, where $U_l^0$ is a fixed level of expected utility. The necessary condition for Pareto optimality for $q_{nj}$, for example, is

$$E_m\left\{U_m'\cdot\frac{\partial X_m(\theta)}{\partial q_{nj}}\right\}-\sum_{l\neq m}\lambda_{ml}E_l\left\{U_l'\cdot\frac{\partial X_l(\theta)}{\partial q_{nj}}\right\}=0$$

where $\lambda_{ml}$ is a multiplier associated with the constrained expected utility of investor $l$. From (9), (10), (11), (18), and the analysis of (13) and (14), this condition is satisfied for every investor, at an *ex post* equilibrium.

determination of the optimal output levels thus is an efficient process that respects the privacy of investors.

An alternative method of determining output levels would be to explicitly recognize the separation between the owners and the managers of firms. The managers of firms may have profit objectives reflecting their own preferences and probability assessments, and even if they do wish to act in the best interests of shareholders, the management may seek to do so by accepting a criterion such as maximizing the expected utility of profit. The criterion of maximizing the expected utility of profit for some utility function and some probability assessments has been frequently used in the literature[18] as a surrogate for the maximization of the expected utility of investors' return, and if firms are not assumed to have performed the previous analysis, such a criterion might seem reasonable. Furthermore, the management of a firm might believe that it has more accurate knowledge of the likelihood of various exchange rate levels obtaining, for example, and thus might use its own probability assessments in making its decisions.

Suppose that firm $n$ has chosen a strictly concave, measurable utility function $\mathcal{U}_n$ and a probability distribution over the states of nature with expectation denoted by $\mathcal{E}_n$ and seeks to maximize

$$\mathcal{E}_n \mathcal{U}_n(\pi_n(\theta))$$

with respect to $(q_{nj}, A_{nj})$, $j = 1, \ldots, N$. The necessary optimality conditions are

$$(20) \quad \frac{\partial \mathcal{E}_n \mathcal{U}_n}{\partial q_{nj}} = \mathcal{E}_n\{\mathcal{U}_n' \cdot (\rho_{nj}(\theta) MR_{nj} - MC_{nj})\} = 0, \quad j = 1, \ldots, N$$

$$(21) \quad \frac{\partial \mathcal{E}_n \mathcal{U}_n}{\partial A_{nj}} = \mathcal{E}_n\{\mathcal{U}_n' \cdot (\rho_{nj} - \rho_{nj}(\theta))\} = 0, \quad j = 1, \ldots, N, j \neq n$$

[18] See the author and Leland (1972), for example.

Solving (21) for $\mathcal{E}_n\{\mathcal{U}_n' \cdot \rho_{nj}(\theta)\}$ and substituting into (20) yields

$$\mathcal{E}_n\{\mathcal{U}_n'\} \cdot (\rho_{nj} \cdot MR_{nj} - MC_{nj}) = 0, \quad j = 1, \ldots, N$$

Since expected marginal utility is positive, the term in parentheses must be zero and is thus identical to (19).[19] Consequently, a firm that maximizes the expected utility of profit for any utility function and probability assessments will produce such that all shareholders prefer those production levels. This is again a form of a homemade covering result, since the firm may compensate for the exchange rate risk created by exportation by selling (or buying) foreign currencies forward. The amount of such forward transactions will depend on the expectations and the utility function used, but since investors are indifferent to the forward exchange transactions of firms, the dependence of the covering decisions on the expectations and preferences of management does not affect investors' expected utility.

Consequently, the firm may act as a maximizer of expected utility of profit or equivalently may act to directly maximize the expected utility of a shareholder, and the resulting output levels will be Pareto optimal and will maximize the expected utility of all shareholders. Both of these processes are efficient in the sense that they require no communication between firms and investors, and both respect the privacy of investors. The equivalence of the two processes in terms of the output levels of firms obtains because of the opportunity to trade foreign currency risks in a market. While the level of such covering by firms may differ for the two processes, the value of a firm will be identical, since that value depends on the real pro-

[19] This result has also been obtained by Wilfred Ethier. The existence of positive output levels satisfying (20) and (21) is assumed.

ductive decision of the firm and not on the covering of the exchange rate risks as indicated in Proposition 1.

### B. *Firm Valuation*

While the firm will use the forward exchange rate as a planning equivalent, the firm's profit will be uncertain unless the firm fully covers its exchange risk. The value of the firm may be determined by eliminating the future spot rates from (9) by using (10) and (11) to obtain

$$(22)\quad E_m\{U'_m\}\left[\rho_{mn}\left(\sum_j \rho_{nj}R_{nj} - C_n(\hat{q}_n)\right) - i_m r_{mn} V_n\right] = 0$$

where $\hat{q}_n$ is the vector of outputs satisfying (19). The term in brackets does not involve $\theta$, so the value of the firm is

$$(23)\quad V_n = \left(\sum_j \rho_{nj}R_{nj} - C_n(\hat{q}_n)\right) \Big/ i_n$$

which is the fully covered profit of the firm discounted at the risk-free rate of interest. The value is independent of the level of covering as previously indicated, but the value of the firm depends on the forward exchange rates as do the output levels. The production planning condition in (19) may be used to eliminate the forward exchange rates from (23) yielding

$$(24)\quad V_n = \sum_j (R_{nj}(MC_{nj}/MR_{nj}) - C_n(\hat{q}_n))/i_n$$

The value of the firm is thus determined completely by its revenue and cost functions. The term $(MC_{nj}/MR_{nj})$ converts the currency $j$ revenue $R_{nj}$ to currency $n$, and the equivalence between this conversion and the usual conditions for a multiproduct firm is evident by noting that for a firm that does not export $(j=n)$, $MC_{nn}=MR_{nn}$. The profit is thus just the difference between revenue and cost. If firm $n$, for example, sells in only country $j$ and the market in that country is competitive $(R_{nj}/MR_{nj}=\hat{q}_{nj})$, the value of the firm is

$$V_n = \hat{q}_{nj}(MC_{nj} - AC_n)/i_n$$

where $AC_n=C_n(\hat{q}_{nj})/\hat{q}_{nj}$ is average cost. The value of the firm will be positive if the marginal cost exceeds average cost at the optimal output, which is the usual valuation rule for a competitive firm producing an output such that price equals marginal cost.

### C. *Comparative Statics of Trade Policies*

Within the context of the model a variety of governmental policies can be analyzed. For example, a tariff $T_j$ imposed by country $j$ on imports reduces the revenue of an exporter to $(p_{nj}(q_{nj})-T_j)q_{nj}$ and the marginal revenue to $(MR_{nj}-T_j)$. Such a tariff will reduce the imports of that country in the same manner as in a deterministic model. Such a tariff can, of course, be offset by the exporting country with a per unit subsidy of $\tau_j\rho_{nj}=T_j$ from country $n$. A lump sum subsidy or import license fee does not affect the quantity of imports or exports directly but does reduce the value of the firm by the amount of the fee, and if the cost of the import license is great enough, a firm will not export. Similarly, the exports of a firm are independent of the profits tax rate in the firm's home country. Further analysis will be left to the reader.

## III. The Role of Forward Markets

With the results of Proposition 2, one can compare fixed and flexible exchange rate systems. A fixed exchange rate system may be considered as a special case of a flexible exchange rate system in which all market participants have degenerate probability assessments with $\rho_{mn}(\theta)=\rho_{mn}=r_{mn}(i_m/i_n)$ for all $\theta$, $m$, and $n$. The outputs resulting with a fixed exchange rate system will be those obtaining with a flexible ex-

change rate system as specified in (19), so the two systems may be considered to be equivalent in the context of this model. This equivalence is insured by the existence of forward markets or by the opportunity to borrow and lend in foreign currencies. Either permits the firm to adopt one of the processes in Section II and hence to use the forward rate for planning purposes.

If forward exchange markets do not exist and investors are prohibited from borrowing and lending in foreign currencies, the level of trade will be the same as that given in Section II if there exists a firm in each country with a nonzero value that sells only in that country. That firm faces no uncertainty, and the necessary portfolio optimality conditions for such firms for an investor in country $m$ are from (9)

$$(25)\quad E_m\{U'_m\cdot(\rho_{mn}(\theta)(R^k_{nn}-C^k_n) - r_{mn}i_mV^k_n)\} = 0, \qquad n = 1,\ldots,N$$

where the superscript $k$ denotes the riskless firm. Solving this for $E_m\{U'_m\cdot\rho_{mn}(\theta)\}$ and $E_m\{U'_m\cdot\rho_{mj}(\theta)\}$ and substituting into (16) yields

$$(26)\quad \frac{\partial E_mU_m}{\partial q_{nj}} = [E_mU'_m]\left(MR_{nj}\frac{r_{mj}i_mV^k_j}{R^k_{jj}-C^k_j} - MC_{nj}\frac{r_{mn}i_mV^k_n}{R^k_{nn}-C^k_n}\right)\hat{z}_{mn}$$

For an investor in country $n$ the condition in (25) implies that the value of the riskless firm is the present value of profits or $V^k_n=(R^k_{nn}-C^k_n)/i_n$. Using this condition for $n$ and $j$ in (26) yields

$$(27)\quad \frac{\partial E_mU_m}{\partial q_{nj}} = [E_mU'_m](MR_{nj}r_{mj}i_m/i_j - MC_{nj})(r_{mn}i_m/i_n)\hat{z}_{mn}$$

Since $(r_{mj}i_m/i_j)$ would equal the forward exchange rate if it existed, the preferences of all shareholders for changes in $q_{nj}$ are the same as those given in (18). Consequently, the opportunity to trade in the shares of a riskless firm in each country provide sufficient patterns of returns for unanimity to result and for firms to use the equivalent forward rate for the planning of exports.

The opportunity to trade in the securities of a riskless firm in each country provides the same patterns of returns in the economy as may be created by borrowing and lending in the currency of that country. Consequently, if there is no riskless firm in a country, but borrowing and lending in that country are permitted, the same results as those with a forward market obtain. The forward exchange market, the borrowing and lending markets in foreign currencies, and securities trading of the shares of riskless firms are thus redundant in the sense that if only one existed, the resulting equilibrium would be the same. The interest rate-parity theorem is essentially a statement of this redundancy.

Even if none of these three market opportunities is available to investors, unanimity may result regarding the levels of a firm's exports. As an example, suppose that there is a firm in country $m$ that exports only to one country, $j$. The conditions in (9) and (18) for an investor in country $m$ who may not make forward transactions, foreign borrowing or lending, or purchase shares of riskless foreign firms are

$$(9a)\quad E_m\{U'_m\cdot[\rho_{mj}(\theta)R_{mj} - C_m - i_mV_m]\} = 0$$

$$(18a)\quad \frac{\partial E_mU_m}{\partial q_{mj}} = E_m\{U'_m\}[(MR_{mj}/R_{mj})\cdot(C_m+i_mV_m) - MC_{mj}]\hat{z}_{mm}$$

The term in brackets in (18a) is independent of $\theta$, and all shareholders in country $m$ prefer an increase (decrease) in $q_{mj}$ if that term is positive (negative). All such

investors are unanimous with respect to their output preferences, but the preferred output level will be different from that in (19). The output level in this case will depend on the value of the firm.[20,21]

In reality, there are investors who invest in securities of firms but who do not consider trading in foreign currencies. The indifference and unanimity results still obtain for the shareholders in the former group but not those in the latter group. For the latter group the sign of the term in (16), for example, depends on the preferences and probability assessments of that investor, and hence production planning is complicated by the same issues that arise with public goods.

With this type of market segmentation shareholder unanimity may still result for certain firms. Consider the above example of the firm in country $m$ that exports only to country $j$. If there are some investors in country $m$ who do trade in a forward exchange market or its equivalent, shareholders in this second group will prefer an increase in output if and only if $\rho_{mj}MR_{mj} - MC_{mj} > 0$ from (18). From (23) the value of the firm will be $V_m = (\rho_{mj}R_{mj} - C_m)/i_m$ which implies in (18a) that shareholders in the first group will be in agreement with the shareholders in the second group. If the output satisfying (19) is produced, then (18a) is zero, and all shareholders will achieve their optimal expected utility.

Another type of market segmentation will exist if investors in one country do not consider trading in the security markets in other countries, so that the investor equilibrium conditions in (9) hold only for $n = m$. If those investors trade in a forward market or its equivalent, all investors are again indifferent to the covering decisions of firms, and shareholders in a firm are unanimous with respect to their preferences for changes in output. The value of the firms and the forward exchange rates are also unchanged. The only essential effect of such segmentation is that these results must be developed by examining the capital market in each country instead of a single market. If the investors also do not trade in the forward exchange market or its equivalent, then the unanimity and indifference results may not obtain, in general.[22]

## IV. Conclusions

Forward exchange markets or their equivalents permit investors to perform their own covering of the uncertain returns from share ownership, and consequently, firms are able to plan their outputs using the forward exchange rate as a planning equivalent. The output levels determined by equating fully covered marginal revenue and marginal cost will be unanimously supported by all shareholders and will maximize their expected utility. These output levels may be achieved without the firm knowing any characteristics of its shareholders, and thus, the planning process respects the privacy of shareholders. The resulting value of the firm will be the present value of its fully covered profit, which is independent of the covering of the firm because all investors are indifferent to that forward covering. These results must be qualified to the extent to which there are imperfections in the capital or foreign exchange markets or if there are additional forms of uncertainty that cannot be efficiently allocated in competitive markets.

[20] This result is analogous to that obtained by Leland (1974) and Ekern (1974).

[21] This example may be generalized for firms that may export to any number of foreign countries. If the system of equations in (9) may be solved for $E_m[U'_m\rho_{mn}(\theta)]$, $n=1, \ldots, N$, for each investor, unanimity will result, but in general the output of a firm will depend on the revenues, costs, and values of all firms. With one firm in each country a necessary and sufficient condition for this is that the inverse exist for the $N \times N$ matrix with elements $R_{ij}$, $j=1, \ldots, N$, $i=1, \ldots, N$, $j \neq i$, and $R_{ij} - C_i$ for $i=j$.

[22] Unanimity may still result if, for example, the condition in fn. 21 is satisfied.

In the absence of such imperfections the forward exchange markets duplicate the borrowing and lending markets as indicated by the interest rate-parity theorem. The presence of a riskless firm in each country also provides equivalent market opportunities to guarantee unanimity. To achieve unanimity, it is not necessary that investors trade in foreign capital markets if they trade in the forward exchange market or its equivalent. Even if investors do not trade in forward markets or their equivalents, unanimity may result although the output levels may be different as demonstrated in the previous section.

# Related Market Conditions and Interindustrial Mergers

*By* M. L. Greenhut and H. Ohta*

William Baumol and David Bradford once introduced a paper in this *Review* by suggesting that its subtitle could be: *The Purloined Proposition or The Mystery of the Mislaid Maxim.* They proposed that the results contained in their paper had already appeared often in the literature, but that these results would still surprise many readers who tend to consider them at variance with ideas they had long accepted. The same caveat applies in many ways to the present paper. However, the literature which contends (as we do below) that important benefits stem from vertical integration has been predicated essentially on analysis of bilateral monopoly. It was, perhaps, this condition that prompted Fritz Machlup and Martha Taber to conclude their review of the literature by, in effect, rejecting the *Maxim* in question. Possibly this *Maxim*, even as repeated by S. Y. Wu, has been and continues to be *Mislaid* because proofs have been sketchy, chiefly diagrammatic, and the subject joined with that of bilateral monopoly. The upshot has been that a vital part of the *Maxim* has been lost, namely that the benefits stemming from vertical merger of successive monopolies dovetail with the effects of having perfect competition on the higher stage of production rather than monopoly. This particular identification, perhaps even more so than the generality of our proofs, nurtures our hope that the *Maxim* in question will not be permanently mislaid. We consider this *Maxim*, as set forth below, to be especially vital in this period of energy shortage and attacks on big business.

Our paper considers two types of related firms: producers of goods who have no monopsony power over input suppliers, and a monopolist input supplier.[1] The two theorems which will be deduced here are (I) *the price charged by the monopolistic supplier of an input is not affected by the market structure in the market for the final good, be it perfectly competitive, monopolistic, etc.*, and (II) *merger or collusion between the input supplier and the final good producer brings about lower prices, greater output and sales, and greater profits to the merged or colluding firms—a welfare gain.*[2]

In Section I we present our theorems for

* Professor, Texas A&M University, and associate professor, Aoyama Gakuin University, respectively. We wish to thank Ming-jeng Hwang for critiques and suggestions and Martin Bronfenbrenner who pointed out the intimate relation of the present work to that of Augustin Cournot. This paper is based in part on research funded by the National Science Foundation.

[1] Our analysis relates to all connected stages of production, e.g., raw materials to intermediate products to final products, consignor to consignee, inputs of labor in producing goods, etc. Simplicity in reference is gained, however, by conceiving generally in this paper of two particular connected stages of production: A) production of final goods, and B) production of the raw materials used as inputs in producing the final goods.

[2] In a sense, this second theorem is related to Cournot's theorem on production with joint inputs. However, some significant differences in analytical framework exist between the two. To begin with Cournot assumes that $n$ kinds of raw materials, e.g. copper and zinc, are *jointly* used to produce a commodity, e.g. brass. His problem was to analyze the impact on price and quantity produced of a *horizontal* merger or collusion between the producers of the raw materials when the final commodity is sold under conditions of perfect competition. In contrast, our model will include among others the case where all producers are monopolistic, and our problem is to investigate the impact of *vertical* collusion between firms in different stages of production and/or distribution.

the two polar cases—perfect competition and monopoly—in the final good market structure. Section II extends our theorems to a Cournot-oligopoly final good market structure. Section III establishes the basic welfare results for varying as well as constant marginal cost situations and demonstrates the generality of our results by illustrating their applicability to such inputs as transportation services. Section IV concludes the paper with a discussion of some antitrust implications of the theory.

## I

Consider a final good market demand function $f$ of the form:

$$(1)\quad p=f(q),\quad f'=\frac{df(q)}{dq}<0,\quad f(0)<\infty$$

where $q$ stands for the quantity demanded at whatever price $p$ is charged in that market. The correspondent to $f(q)$ may then be defined as:[3]

$$(2)\quad g(q)=f(q)+f'q,\qquad f'=\frac{df(q)}{dq}$$

$$=f(q)\left(1-\frac{1}{e_f}\right),\quad e_f=-\frac{dq}{df(q)}\frac{f(q)}{q}$$

The graphs of $f(q)$, $g(q)$, and $h(q)$, i.e., the correspondent to $g(q)$, are drawn respectively in Figure 1a, which assumes *for simplicity* a linear demand. Our analysis, however, is not restricted to this linearity assumption, as will shortly be demonstrated.

Three situations warrant analysis initially, namely (i) where perfect competition prevails in the final good (commodity) market and the input supplier is a simple monopolist; (ii) simple monopoly prevails in each market; and (iii) the monopolists in the two related industries collude. Later, in Section II, we shall examine as well the market where the final good is sold under imperfectly competitive conditions.

CASE (i): Consider first the case where the producer of the final good, firm $A$, is a perfect competitor. His profit maximizing calculus requires

$$(3)\qquad p=MC=c+r$$

where $c$ relates to the original factor inputs used by firm $A$ (say, labor) and $r$ to the quantity of raw materials purchased from the input supplier, firm $B$, per unit of output $q$. Without loss of generality, $c$ and $r$ are assumed to be constant for the time being, an assumption relaxed later in Section II of the paper. Firm $A$'s cost $r$ constitutes firm $B$'s revenue. Combining (1) with (3) provides the revenue function of $B$ per unit output $q$ on sales to $A$, i.e.:

$$(4)\qquad r=f(q)-c$$

Defined as such, (4) represents the average revenue of firm $B$ in terms of $q$, *not* the average revenue (or price) it receives *per unit of raw materials* sold to firm $A$ (and to other atomistic firms in the final good industry).[4] The marginal revenue for firm $B$, $MR_B$, is then:

$$(5)\qquad MR_B=g(q)-c$$

$$=f(q)\left(1-\frac{1}{e_f}\right)-c$$

[3] The correspondent $g(q)$ is, in effect, the marginal revenue function of the final good producer if and only if monopoly prevails in that market. However, if perfect competition prevails in that market, the correspondent $g(q)$ constitutes the marginal revenue function for the monopolistic input supplier, indirectly and in part, but of course not for the competitive producer of the final good (see equation (3)). Incidentally, the concept of *correspondent* used herein should not be confused with Joan Robinson's correspondent which relates to a tangent to an average revenue function.

[4] Let the input material supplied by firm $B$ be represented by $M$ and the price of $M$ by $p_M$. Then the average revenue of a unit of $M$ can be specified as $p_M=(f(q)-c)q/M$. The average revenue per unit of $q$, specified in the text, is then readily derived as $r=(p_MM)/q=f(q)-c$. Note further that a constant $r$ requires constant proportions between $M$ and $q$ for any $p_M$ parametrically given to firm $A$; as noted above in the text, this fixed relation will be relaxed later in the paper.

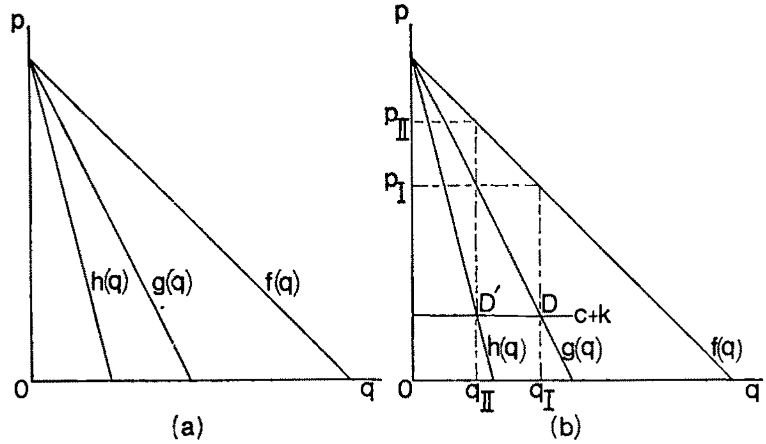

FIGURE 1

where the marginal revenue relates to an extra unit of output $q$, not input.

Profit maximization by firm $B$ requires equating $MR_B$ with its marginal cost of production $k$, also assumed to be constant for the moment. Thus:

$$(6) \qquad f(q)\left(1 - \frac{1}{e_f}\right) - c = k$$

or

$$g(q) = c + k$$

Associated with this equilibrium is output $q = q_I$ depicted in Figure 1b, which is produced under conditions of perfect competition in the commodity market and monopoly in the raw material market.[5] Correspondingly, the price of the final good is $p = p_I$ in Figure 1b, the average revenue per unit of $q$ earned by firm $B$ is $r = p_I - c$, so the input supplier's profit on his production for firm $A$ is $\pi_B = [p_I - (c+k)]q_I$, while firm $A$ is covering costs with $\pi_A = 0$. Total profits in Case (i) are $\pi = \pi_B + \pi_A = [p_I - (c+k)]q_I$, an area easily observed in Figure 1b.

A mathematical summary of the preceding analysis helps shed light on certain important relationships. In particular, note that Case (i) consists of three fundamental equations, (1), (3), and (6), in three unknowns, $p$, $q$, and $r$. Equation (1), recall, represents the commodity market demand function, equation (3) the equilibrium condition for the competitive producers in that market, and equation (6) the equilibrium condition in the market of the monopolistic supplier of input materials. These equations may be solved simultaneously for $p$, $q$, and $r$ at the equilibrium point $D$, as depicted in Figure 1b.

CASE (ii): Consider now a *monopolist* final good producer who is subject to the demand function given as (1). His profit maximizing calculus, i.e. $MR_A = MC_A$, provides:

$$(7) \qquad g(q) = c + r$$

which is the counterpart equilibrium condition to (3). Equation (7), however, also establishes the average revenue function of the monopolistic input supplier firm $B$ in the form:

$$(8) \qquad r = g(q) - c$$

Firm $B$'s profit maximizing condition $MR_B = MC_B$ may, in turn, be obtained from (8) as:

$$(9) \quad g(q)\left(1 - \frac{1}{e_g}\right) - c = k, \; e_g = -\frac{dq}{dg}\frac{g(q)}{q}$$

[5] The amount $q = q_I$ is the aggregate supply by the $n$ competitive producers of the final product.

or $$h(q) = c + k$$

where $h(q)$ represents the correspondent to $g(q)$.[6] (And see the curve $h(q)$ in Figure 1.)

Equation (9) defines the equilibrium condition for firm $B$ stemming from a monopolized commodity market. This equilibrium is represented by point $D'$ in Figure 1b. Accordingly, the equilibrium output is $q=q_{II}$, the equilibrium price of the raw material package is $r=p_I-c$, firm $B$'s profit is $\pi_B=[p_I-(c+k)]q_{II}$, the price the final good producer (firm $A$) charges his buyers is $p=p_{II}$, and his profit is $\pi_A=(p_{II}-p_I)q_{II}$. The sum of the two independent monopolists' profits amounts to $\pi=\pi_B+\pi_A=[p_I-(c+k)]q_{II}$.

Figure 1b shows that output produced under the conditions of Case (i) is greater than that of Case (ii), i.e., $q_I>q_{II}$, and profits are also greater in Case (i) than Case (ii). Moreover, Figure 1b implies that the equilibrium input price is the same, i.e., $r=p_I-c$ in each case. *The input price charged by the monopolistic supplier is, therefore, invariant to the final good market structure*, be it either monopolistic or perfectly competitive. Moreover, it will be shown that the same conclusion holds also for imperfectly competitive final good markets. Section II will formally establish these relationships.

Though the equation system for Case (ii) has the same three unknowns, $p$, $q$, and $r$, it contrasts sharply from that of Case (i) by consisting of equations (1), (7), and (9) rather than (1), (3), and (6). As before, equation (1) sets forth the demand function, and equations (7) and (9) serve as counterparts to (3) and (6), respectively providing the average revenue and profit maximizing conditions for the input supplier, firm $B$.

CASE (iii): The greater profits available under Case (i) conditions compared to those of Case (ii) would induce the monopolistic supplier of inputs, firm $B$, to collude with the monopolistic producer of products, firm $A$. The demand function given by equation (1) would then become the relevant average revenue function for the integrated monopolist, and hence (2) provides the corresponding marginal revenue (alternatively $g(q)$ in Figure 1). This $MR$ would then be equated directly with the relevant marginal costs of producing the final product (which are related to the value-added of the final good and that of its input), i.e., $c+k$. Equilibrium price and output therefore apparently dovetail with that of Case (i); i.e., $q=q_I$ in Figure 1. The pooled profits $\pi$ for the integrated monopolist are, in turn, $\pi=\pi_B+\pi_A=[p_I-(c+k)]q_I$, with the profit resulting from collusion being the same as in Case (i).[7] Since profit in Case (i) exceeds that of Case (ii), it follows that profit in Case (iii) is also greater than that of Case (ii). Collusion pays from the standpoint of firms operating in related markets. Collusion also offers advantages to society since the final commodity price is lower and the output produced greater than otherwise. But the relations sketched above are based on the linear demand assumption; need exists for formal proof of these relations to include the more general case of non-linear demand.

A proof is available which requires two basic constraints on $f$ in addition to the requirements that $f'$, $g'$, $h'<0$ and $f(0)>0$: namely, 1) the demand function $f$ is limited to yield a correspondent $g$ such that the horizontal lengths of the two curves are in fixed proportion, as is the case when $f$ is of the algebraic form given later in footnote

[6] Equation (9) reveals the equality between the correspondent $h(q)$ minus the marginal cost of producing the final product and its raw material component.

[7] It should be stressed that the entire profit $\pi=[p_I-(c+k)]q_I$ is received by the monopolistic input supplier in Case (i) whereas the distribution of total profits in Case (iii) must be negotiated by the colluding firms, the lower limit for firm $B$ being set by $[p_I-(c+k)]q_{II}$.

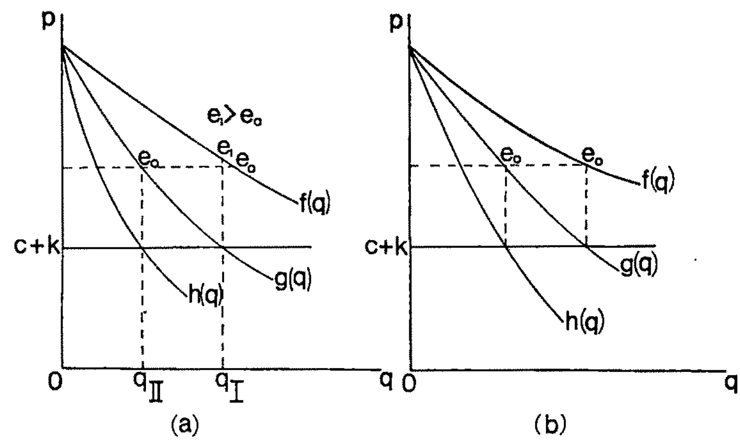

FIGURE 2

10; and 2) the elasticity of demand decreases with price, i.e., $de_f/dp>0$.[8]

To see the implication of proviso 1), consider arbitrarily two quantities $q_I$ and $q_{II}$ such that $f(q_I)=g(q_{II})$. It readily follows under proviso 1) that $e_f(q_I)=e_g(q_{II})$.[9] Combined with proviso 2), the present condition can be extended to the relations:

$$(10) \qquad e_f(q_I) \gtreqless e_g(q_{II})$$

$$\text{if and only if} \quad f(q_I) \gtreqless g(q_{II})$$

We are, accordingly, now in position to prove the generality of our first theorem.

[8] Neither of these specifications is required when $f$ is assumed to be of the specific algebraic form given in fn. 10. It warrants mention, however, in connection with the second constraint, that demand curves of constant or increasing elasticity are typically ruled out in the space economy since they generate the unlikely practice of discriminating against distant buyers, and this opens up the possibility of repackaging and resale by nearer buyers. For example, see Edgar Hoover, Arthur Smithies, and Greenhut, M. J. Hwang and Ohta. From the standpoint of spatial economics, therefore, the subject constraint is quite meaningful. Nevertheless, in fn. 10 below we shall include instances of increasing and constant elasticity that yield the same results.

[9] For proof consider the condition of $f(q_I)=g(q_{II})$. Then:

$$\frac{df}{dq_I}\frac{q_I}{f} = \frac{dg}{dq_{II}}\frac{q_{II}}{g}\frac{dq_{II}}{dq_I}\frac{q_I}{q_{II}}$$

$$\therefore\ e_f(q_I) = e_g(q_{II}) \quad \text{if } \frac{dq_{II}}{dq_I}\frac{q_I}{q_{II}} = 1 \text{ or } \frac{q_I}{q_{II}} = \text{constant}$$

To recall, Theorem I holds that the two alternative equilibrium conditions (6) and (9), i.e., $g(q_I)=c+k$ and $h(q_{II})=c+k$, generally imply $f(q_I)=g(q_{II})$, under well-defined demand functions given by the conditions specified above. Consider in this context the null hypothesis that $h(q_{II})=g(q_I)$ implies $f(q_I) \gtrless g(q_{II})$; via (10), this relation in turn implies $e_f \gtrless e_g$, as illustrated in Figure 2a. But this condition is impossible since combining (6) and (9) establishes:

$$(11) \quad f(q)\left(1-\frac{1}{e_f}\right) = g(q)\left(1-\frac{1}{e_g}\right), \qquad e_f,\ e_g > 1$$

$$\therefore\ e_f(q) \lesseqgtr e_g(q)$$

$$\text{if and only if} \qquad f(q) \gtreqless g(q)$$

In particular, note that $f(q) \gtrless g(q)$ implies $e_f \lesseqgtr e_g$, which contradicts the elasticity requirement derived from the null hypothesis and must therefore be rejected. The relations $g(q)=h(q)=c+k$ necessarily imply the remaining condition $f(q)=g(q)$, which condition alone consistently yields $e_f=e_g$ in (10) and (11). *Except for* the equality parts of the relations in (10) and (11), which alone are consistent, these equations reveal contradictory conditions derived from the equilibrium conditions

$g(q)=h(q)=c+k$. Under the defined demand function $f$ subject to the aforementioned constraints, the equilibrium conditions $g(q_I)=h(q_{II})=c+k$ yield not only $f(q_I)=g(q_{II})$ but also implies $e_g(q_I)=e_f(q_{II})$, as illustrated in Figure 2b.[10]

The second theorem can be readily established with the aid of the first theorem. Observe from the first theorem that the value of the equilibrium marginal revenue $g(q_{II})$ of the monopolist firm $A$ is the same under Case (ii) conditions as the price $f(q_I)$ set by the colluding monopolists of Case (iii). Since the price $f(q_{II})$ is in general higher than the corresponding marginal revenue $g(q_{II})$, it follows that $f(q_{II}) > f(q_I)=g(q_{II})$. This relation establishes formally the proposition that Case (iii) and Case (i) as well provide a lower equilibrium price than does Case (ii). Since $f$ is assumed to be a monotonically decreasing function of $q$, it further follows that $q_I > q_{II}$; i.e., the output produced under Cases (i) or (iii) is greater than that under Case (ii).

[10] A proof which utilizes the algebraic function $f(q)=a-bq^\alpha$ with varying combinations of the parameters $a$, $b$, and $\alpha$ is set forth below. Significantly, the combinations allowed include $a, b, \alpha>0$; $a, b<0$, $-1<\alpha<0$ (decreasing elasticity situations); and, in addition, $a=0$, $b<0$, $-1<\alpha<0$ as well as $a>0$, $b<0$, $-1<\alpha<0$, combinations which respectively establish economically stable equilibrium situations under conditions of constant and increasing demand elasticities as price decreases. Pursuant to the constraints set forth above on the function $f(q)=a-bq^\alpha$, the correspondents $g(q)$ and $h(q)$ are given by:

$$\text{(a)}\qquad g(q) = a - b(\alpha+1)q^\alpha$$

$$\text{(b)}\qquad h(q) = a - b(\alpha+1)^2q^\alpha$$

Let $g(q_I)=h(q_{II})=c+k$ to obtain the specific values $q_I$ and $q_{II}$:

$$\text{(c)}\qquad q_I = \left(\frac{a-c-k}{b(\alpha+1)}\right)^{1/\alpha}$$

$$\text{(d)}\qquad q_{II} = \left(\frac{a-c-k}{b(\alpha+1)^2}\right)^{1/\alpha}$$

Substituting $q_I$ of (c) in $q$ of the demand function $f(q)$ and $q_{II}$ of (d) in $q$ of the correspondent $g(q)$ yields:

$$\text{(e)}\qquad f(q_I) = a - \frac{a-c-k}{\alpha+1} = g(q_{II})$$

## II

The thesis presented in Section I applied to a perfectly competitive or perfectly monopolized final good market. However, what about relationships where the final good market is neither perfectly competitive nor perfectly monopolized? To evaluate this possibility, assume an oligopolistically competitive market of the Cournot type where each firm considers its rival's supply to be fixed. Profit maximization for the representative firm requires:

$$\text{(12)}\qquad \frac{\partial(pq_i)}{\partial q_i} = f(q) + f'\frac{\partial q}{\partial q_i}q_i = f(q) + f'(q)q_i = c_i + r_i \qquad i = 1, 2, \ldots, m$$

where $q_i$ stands for the $i$th firm's supply, $c_i$ for the $i$th firm's marginal production cost in using original input factors, and $r_i$ for the marginal cost of using the raw material input; alternatively, $r_i$ provides (in terms of $q$) the price charged the $i$th firm by the monopolistic input supplier. Note that the unit value applies to $\partial q/\partial q_i$ in (12) because market demand equals the aggregate supply of the $m$ oligopolistic firms, i.e.,

$$\text{(13)}\qquad q = \sum^m q_i$$

and any change in $q_i$ is assumed under Cournot's framework not to elicit a change in supply by rival firms. Summing both sides of (12) over all $i$, dividing by $m$, and utilizing (13) establishes:

$$\text{(14)}\qquad f(q) + \frac{f'(q)}{m}q = c + r$$

where $c = \dfrac{1}{m}\sum c_i \qquad r = \dfrac{1}{m}\sum r_i$

For the purpose of this paper, $c_i$ and $r_i$ must be assumed to be the same as they would be under conditions of perfect competition or monopoly, i.e., the same as $c$

and $r$ previously. Equation (14) may then be rewritten as:

$$(14') \qquad r = f(q) + \frac{f'(q)q}{m} - c$$
$$= f(q)\left(1 - \frac{1}{me_f}\right) - c$$

Equation (14′) represents the monopolistic input supplier's average revenue function in terms of $q$ under the specified Cournot conditions. When $m=1$, (14′) is equivalent to (8), the case of monopoly in the final good market. As $m$ increases, i.e., as more and more firms enter the final good market, the adjusted elasticity of demand $e_f^* = me_f$ increases by the multiplier $m$. And when $m$ approaches $\infty$, (14′) approaches (4) in reflection of perfect competition.[11]

To obtain the equilibrium price $r$ per unit of raw material input for all in-between market conditions (i.e., where $m$ is a finite number greater than one), some concrete form of the demand function $f$ must be assumed, such as the $f(q) = a - bq^\alpha$ evaluated previously in footnote 10. That function represents a general form as it generates not only convex, linear, or concave demands, but curves of either constant, decreasing, or increasing elasticities of demand depending on the alternative combinations of parameters $a$, $b$, and $\alpha$ that are applied. (See fn. 10.) Equation (14′) can then be particularized to:

$$(14'') \quad r = (a - c) - \left(\frac{m + \alpha}{m}\right) bq^\alpha$$

The profit maximizing condition for the monopolist firm $B$ is:

$$(15) \quad (a - c) - \left(\frac{m + \alpha}{m}\right) b(\alpha + 1)q^\alpha = k$$

where the left-hand side of (15) represents the raw material supplier's marginal revenue while the right-hand side, i.e., $k$, stands for his marginal cost of producing the raw materials. Substituting in (14″) the equilibrium $q$ obtainable from (15) yields:

$$(16) \qquad r = \frac{\alpha(a - c) + k}{\alpha + 1}$$

Remarkably enough, $r$ does not depend on the number of producers in the final good market; viz., the raw materials price $r$ charged the final good producer by the monopolistic input supplier is the same for any final good market type, whether it be simple monopoly (when $m=1$), duopoly ($m=2$), etc.[12] An invariance theorem on raw material inputs prevails regardless of selling conditions in the final good market under the specified Cournot behavioral assumption and the technical assumption on the form of the demand function.

A two-fold question remains with respect to oligopolistic competition in the final good market: 1) would horizontal merger between final good producers lower the market price of their good; and 2) would vertical merger between final good producers and the monopolistic supplier of raw materials lower the price of the final good? Answer to question 1) simply requires conceiving of a constant raw material price $r$ (in addition to $c$). Differentiating (14) or (14′) with respect to the number of competitive producers of the final good, yields—in conformance with (16)—the equation:

$$(17) \quad \frac{dp}{dm} = \frac{-(r + c)\left(e_f + m\dfrac{de_f}{dp}\dfrac{dp}{dm}\right)}{(me_f - 1)^2}$$

This equation demonstrates that under the

[11] See John Greenhut and M. L. Greenhut for a development along this line which isolates the impacts on delivered price schedules of the location of rivals and the intensity of their competition at alternative points.

[12] Manifestly we are not in a bilateral monopoly situation since our final good producer is not a monopsonist but simply an oligopolist or, as in Section I of the paper, a monopolist or perfect competitor.

normality assumption of decreasing elasticity with price, the equilibrium price $p$ must fall as the number of firms increases. It follows, accordingly, that horizontal merger, i.e., a decrease in $m$, raises the equilibrium commodity price $p$.

An asymmetric result obtains with respect to the vertical rationalization proposed under question 2). More specifically, profit maximization for any and all independent final goods producers is given by (12). But if these oligopolists, or just some of them, merge with the monopolistic supplier of the needed raw materials, the new profit maximization requires:

$$f(q) + f'(q)q_i = c_i + k_i, \quad i = 1, 2, \ldots, j \leq m \tag{18}$$

where (18) assumes that $(m-j)$ firms do *not* merge with the monopolistic supplier of raw materials, and hence equation (12) applies to these $(m-j)$ firms. Of course, the marginal cost $k_i$ of producing the raw material is lower than the comparable marginal cost (price) $r_i$ in (12). Summing (18) and (12) over their relevant ranges then gives:

$$mf(q) + f'(q)q = \sum_{i=1}^{m} c_i + \sum_{i=1}^{j} k_i + \sum_{i=j+1}^{m} r_i \tag{19}$$

where $$q = \sum_{i=1}^{j} q_i + \sum_{i=j+1}^{m} q_i$$

Dividing both sides of (19) by $m$ establishes:

$$f(q)\left(1 - \frac{1}{me_f}\right) = c + \frac{j}{m}k + \frac{m-j}{m}r = c + r - (r-k)j/m < c + r \tag{19'}$$

provided that $r > k$, i.e., the average price charged per package of raw materials by the monopolist supplier is greater than the average marginal cost of supplying that package. Thus the *average* marginal costs, viz.,

$$\left(\sum^{m} c_i + \sum k_i + \sum^{m} r_{j+i}\right) \Big/ m$$

decrease as more and more firms collude (merge) with the firm that supplies the raw materials. Given the market demand function $f(q)$ and the fixed total number $m$ of firms producing the final good, the same adjusted $MR$ curve $f(q)[1-1/me_f]$ that was derived from the original $MR = f(q) \cdot (1-1/e_f)$ obtains. Thus equilibrium price $f(q)$ *falls* as average $MC$ falls. Vertical merger lowers commodity price and increases the quantity demanded and the output produced.

## III

We have thus far assumed fixed proportions of inputs to output. The basic welfare results scored above remain unaffected, however, by variation in marginal costs. In demonstrating this condition, two concepts of variable marginal costs are required, as we shall extend our previous analysis to include spatial price relations.

Consider a monopolistic producer who ships his commodity to spatially separated market points. Let the demand function (1) apply now to any one local market point. If a transportation service is provided by a monopolistic carrier, the carrier's average revenue function would be given by (8), where $r$ would represent the freight rate applicable to the market point under consideration. The equilibrium condition for an independent monopoly situation between the carrier and shipper of goods is then given by (9), where $c$ now represents the marginal cost of production while $k$ provides the marginal cost of transportation. Note that $k$ and $c$ are specified differently in:

$$k = \phi(q) \tag{20}$$

$$c = \psi(Q), \qquad Q = \sum q \tag{21}$$

where the summation applies to all relevant market points. Thus $k$ is a direct function of $q$, but $c$ is not so related since a change in the particular supply $q_1$ may be carried out by an offsetting change in the supply $q_2$; the consequence would be that the total output produced $Q$ and the related cost $c$ are unchanged. For this reason, marginal production cost $c$ does not vary with a change in supply $q$ to a particular market point. We assume, however, that $c$ does increase if (and only if) *aggregate* $q$ (i.e., $Q$) increases.

The relation between $c$ and $k$ with respect to a change in $q$ is illustrated in Figure 3. Marginal cost $k$ of shipping goods is assumed in the figure to be a decreasing function of $q$; i.e., economies derive from using larger input quantities, with the effect $c+k$ decreases as $q$ increases.[13] Suppose equilibrium prevails initially at $D$ in a particular market, and that the input supplier (carrier) and his customer are independent monopolists. The question of impacts of collusion may, accordingly, be raised again.

Any change in equilibrium from, say, $D$ to $D'$ implies an increase in a particular market's supply as price is lowered. Collusion must, however, change the equilibrium price-quantity set *for all submarkets*. The consequence is that total output and cost of production increase (compare $c$ with $c'$ in Figure 3); correspondingly, the $MC$ curve shifts from $c+k$ to $c'+k$, with final equilibrium taking place at point $D''$. This new position guarantees a greater output than that obtainable when the monopolists are independent. But the question arises as to whether or not an increase in $c$ which results from collusion might occasionally be so great as to generate a smaller equilibrium output. To resolve this particular question, note initially that $c$ rises only if *equilibrium* output increases; in

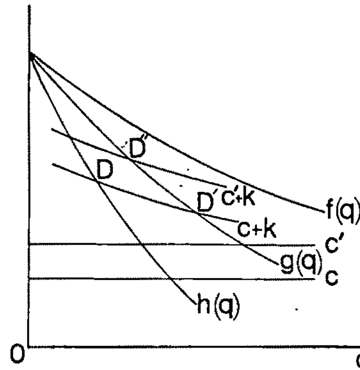

FIGURE 3

other words, marginal production cost $c$ increases only if the *equilibrium* output produced under Case (iii) conditions increases. If the equilibrium output does not increase, neither does the related marginal production cost. It further follows that the rightward placement of $g(q)$ compared to $h(q)$ cannot be offset by a change in $c$ to $c'$, and accordingly output must increase. This requirement fully establishes the generality of our proposition that output is greater and price lower for Case (iii) than Case (ii).

## IV

The comparative profitability of merged firms with that of individual monopolists is thus completely given by the demand condition $f(q)$. Maximum profits obtain if and only if marginal revenue $g(q)$ is equated with the lowest obtainable marginal cost, i.e., $c+k$ distinct from $c+r$. Any deviation from this equilibrium, such as in Case (ii), necessarily implies a decrease in profits.

The results obtained above apply to any particular market in which sales are made. Aggregate outputs and profits increase and prices are lower when vertical merger or some other rationalization process takes place between an input supplier and the user(s) of his product whenever the succes-

[13] Decreasing marginal cost $k$ is not a required assumption for our proof.

sive stages of production involve independent monopolistic powers. The surprising implication of these relationships is that excess capacity may be eliminated to a considerable extent by rationalization in related industries. Moreover, greater efficiency in production derives from the integration process described in this paper under imperfect market conditions.

The last contention is a sweeping one which is underscored by the fact that production generally requires the input of raw materials, intermediate goods, and services. Given a demand function for a good, one may deduce a derived demand function for, let us say, the intermediate good or service, such as transportation. This function would yield, in turn, another derived demand function, for example, for the tires used by the carrier, and so forth. Successively shrinking *correspondents* to derived demand functions thus obtain, as the smallest correspondent is equated with the relevant marginal cost to provide the equilibrium applicable under the case of independent monopolistic firms. This smallest correspondent obviously shrinks toward the origin as more and more related industries are subjected to independent monopoly powers. And the converse principle holds, as the smallest *correspondent* would be twisted upward by integration of firms in related industries. Equilibrium output increases as a result, except for the unlikely *and unstable* cost situation of rapidly decreasing $MC$ in the region of the equality of marginal values that prevailed before the integration of firms.

In a related context to this paper, Donald Dewey contended that rationalization of firms increases efficiency in imperfectly competitive markets. This effect was said to arise since the merged firms can utilize one plant more efficiently in producing a small high-cost output than can two firms which would otherwise produce at very inefficient small output points. Only over a narrow range of outputs, where each plant must be utilized, would the costs of the unified firm necessarily involve the sum of the costs of *each* of the individual firms. In fact, Dewey argued that *even in such case* the unified firm would operate the single firm's plant(s) more efficiently at greater profit than that which would eventuate under a Cournot competitive equilibrium. The Dewey merger model unfortunately involves smaller output than the competitive model, and in this respect can be criticized by welfare theorists.

Our paper, similar to Dewey's, has *also* advocated merger as a source of increased efficiency in imperfectly competitive markets. But even closer to Wu's, it proposes vertical rationalization only for firms in related industries. We contend that merger of firms in related industries generates a greater output than the sum of the individual outputs of nonintegrated firms. In effect, this present paper has, therefore, illustrated *and* proved two theorems which were *implicitly* assumed by the present authors and Hwang in this *Review* on the type of (and direction of) discrimination practiced by motor carriers. That paper, in particular, anticipated the advantages to carriers and shippers of vertical integration in noting that freight rates were unaffected by the market structure in the shipper's industry (compare Josephine Olson). The roots of the present paper based as they are on successive stages of production thus include the distribution process as well as the production process. Indeed, one can readily conceive of freight rates covering certain specified places that converge in time under Commission regulations to the derived $r_i$ values that were described above. By permitting shippers of goods the ownership of their own carriers (or permitting them vertical integration with existing contract or common carriers), cost $k_i$ replaces $r_i$ and in the process generates greater outputs and lower prices.

Other policy implications of our theorems should be manifest. For example, objections being expressed against the possible "take-over" of the retailing function by the larger oil companies under deregulation of "old oil prices" appear ill-founded as greater output and lower prices should result from that integration. Excluded from our analysis of related markets is only the possibility of bilateral monopoly, since our higher stage producer is not conceived to have monopsony buying power over the lower stage producer. All other related market situations fall within our analysis. Possibly most important of all are the antitrust implications of our findings which, to say the least, will prove shocking to many.[14] At the same moment, these implications will clearly warrant study.

[14] Consider a standard case before our courts involving vertical merger, such as United States v. Yellow Cab. Concern in that case was with a monopolistic buying firm (e.g. Yellow Cab or our firm $A$) which would exclude other input suppliers from certain markets if it merged vertically with a particular supplier of the needed input. In opposite situations, elimination of competition on the final good market level might appear questionable to many. However, strict interpretation of our theorems must yield an interesting difference in conclusions. A less rigid interpretation from a long-run perspective can be found in Greenhut, p. 366.

# The Effect of Rate of Return Regulation is Highly Sensitive to the Nature of the Uncertainty

*By* YORAM C. PELES AND JEROME L. STEIN*

The fundamental conclusion derived from the theory of the monopoly firm seeking to maximize profits subject to a regulatory constraint is that: the optimum *ex ante* scale of plant chosen by the firm will increase as the regulated rate of return ($s$) declines towards the cost of capital ($i$). This proposition and its implications, known as the Averch-Johnson (A-J) effects,[1] have been the focus of numerous articles on rate of return regulation.

There is a serious danger that public policy concerning public utility regulation will be based upon an uncritical acceptance of the A-J effects. Although uncertainty of the state of nature characterizes the investment decisions, the A-J theorems have been based upon a model which ignores uncertainty. In the present paper we prove that the fundamental A-J conclusion is not robust to the type of uncertainty faced by the firm.

Decisions made by the firm are dichotomized into *ex ante* decisions (controls) made before the state of nature ($u$) is known and *ex post* decisions (controls) made after the state of nature is known. The scale of plant ($K$) is an *ex ante* control. The quantities of the variable inputs and the price charged by the firm are *ex post* controls. Uncertainty is introduced into the maximal quasi-rents function $R(K, u)$, which is defined as the total quasi rents that will be earned when the firm with capital stock $K$ selects the *optimum ex post* controls, and the state of nature is $u$. The risk-neutral firm selects the scale of plant to maximize expected profits $E[R(K, u)] - iK$, where $E$ is the expectations operator.

If the uncertainty concerning the state of nature is additive so that $R(K, u) = R(K)+u$, and $u$ is independent of scale $K$, the conventional A-J results are obtained. The imposition of an effective regulatory constraint will either drive the firm out of business if the spread $s-i$ is not sufficiently large, or it will lead the firm to select *ex ante* a scale of plant larger than that chosen by the unregulated monopolist. When the uncertainty is multiplicative, $R(K, u) = R(K)(1+u)$, the conventional A-J effect is completely reversed. Assume that the regulatory constraint does not drive the firm out of business. Then the closer the regulated rate of return is to the cost of capital (but $s>i$), the *smaller* will be the optimum *ex ante* scale of plant relative to that chosen by the unregulated monopolist. Call this the "Anti A-J Theorem."

The effects of rate of return regulation are highly sensitive to the characterization of the uncertainty. For this reason, public policy towards public utilities should not be formulated on the basis of the A-J effect until there is evidence that the uncertainty is not of the multiplicative type. Otherwise, tightening the regulatory con-

straint may lead to a decrease in output as well as to production inefficiency. No regulation would then be socially preferable to this sort of regulation.

## I. The Scale of Plant is the *Ex Ante* Control and the Variable Inputs are the *Ex Post* Controls

### A. *The Maximal Quasi-Rents Function*

When the firm decides upon its optimal scale of plant, the total revenue function expected to prevail when the plant is in operation is not known with certainty. A firm does not know precisely what will be the growth of demand, the geographic location of its customers, or the development of rival technologies by firms which produce substitute products. If the proposed plant scale involves the introduction of a new technology, then the firm is not even sure what will be the rate of output associated with a given vector of inputs. Uncertainty in this context refers to the state of nature, described by variable $u$, that prevails when the plant is in operation.

A firm which seeks to maximize profits from a given plant when the state of nature is revealed selects the quantities of variable inputs—referred to under the generic name of labor—to maximize *quasi rents* $Z$. The labor input is an *ex post* control.

Quasi rents $Z$ earned by a firm are total revenue $pQ$ (where $p$ is price and $Q$ is quantity sold) less total variable costs $WL$, where $L$ is the quantity of the labor input and $W$ is the exogenously given price of labor. Price $p$ depends upon $Q$ and the state of nature: $p=f(Q, u)$. Quantity sold is assumed to equal quantity produced, where the latter depends upon the inputs of labor and capital (i.e., scale of plant) $K$. For these reasons, total revenue can be written as a function $H(K, L; u)$ of the inputs and the state of nature. Function $H$ is strictly concave in the inputs and reaches a maximum. Quasi rents are then described by equation (1).

$$Z = H(K, L; u) - WL \tag{1}$$

*Ex post* control $L$ is chosen to maximize quasi rents $Z$, given *ex ante* control $K$ and the state of nature $u$. Under these conditions, the marginal revenue product of labor $H_L(K, L; u)$ is set equal to the nominal wage $W$ as described by equation (2).

$$H_L(K, L; u) = W \tag{2}$$

Solve equation (2) for the optimal quantity of labor and derive equation (3). The optimum quantity of labor (*ex post* control) is a function of the scale of plant (*ex ante* control), the nominal wage, and the revealed state of nature. Since the nominal wage is a constant, it will not always be written explicitly. We assume that an increase in $K$ always raises the marginal revenue product of labor in the relevant range: $H_{LK}>0$.

$$L = l(K; u, W); \qquad l_K = \frac{H_{LK}}{-H_{LL}} > 0, \tag{3}$$
$$l_u = \frac{H_{Lu}}{-H_{LL}} > 0, \quad l_W = \frac{1}{H_{LL}} < 0$$

Substitute the optimal quantity of labor into equation (1) and derive equation (4). The latter represents the *maximum* quasi rents that can be obtained by a firm with a scale of plant $K$ when the state of nature is $u$.

$$\begin{aligned} R &= H[K, l(K; u, W); u] \\ &\quad - Wl(K; u, W) \\ &= R(K; u, W) = R(K, u) \end{aligned} \tag{4}$$

Again, remember that $R$ is also a function of $W$. The $R(K, u)$ function is graphed in Figure 1 as $OFMBR$. The slope of this function is the marginal revenue product of capital:

$$R_K(K, u) = H_K(K, L; u) \tag{4'}$$

and it is strictly concave because

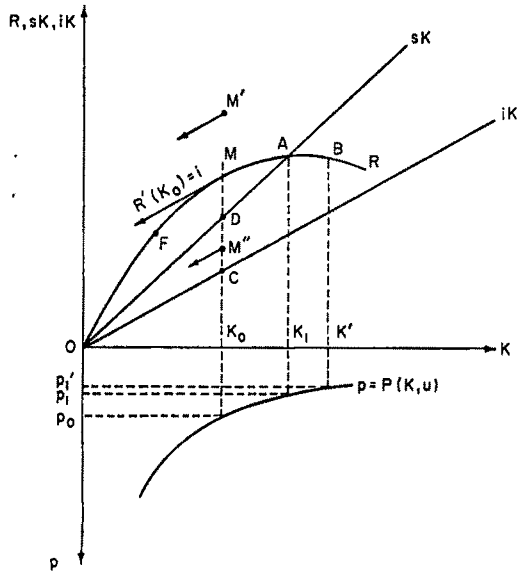

FIGURE 1. CURVE $OMR$ REPRESENTS MAXIMAL QUASI RENTS. RAY $OsK$ REPRESENTS TOTAL PERMISSIBLE PROFITS AT RATE OF RETURN $s$. RAY $OiK$ REPRESENTS TOTAL CAPITAL COSTS. CURVE $p=p(K, u)$ DETERMINES THE OPTIMAL PRICE. THE UNREGULATED MONOPOLIST EMPLOYS CAPITAL STOCK $K_0$. THE A-J POINT IS $K_1$.

$$(4'') \quad R_{KK}(K, u) = H_{KK}(K, L; u) - \frac{H_{KL}^2}{H_{LL}}(\ ) < 0$$

The optimal price $p$ charged by the firm is described by equation (5), which is drawn in Figure 1 (lower part). It corresponds to the point on the demand curve above the intersection of the marginal revenue curve (associated with state of nature $u$) with the short-run marginal cost curve (associated with scale of plant $K$).

$$(5) \quad p = P(K; u, W); \qquad P_K(\ ) < 0$$

Function $P_K$ is negative because a rise in the scale of plant shifts the short-run marginal cost curve to the right, and it intersects the marginal revenue curve at a higher level of output. Since the demand curve is negatively sloped, the price declines as the optimum output increases.

## B. *Alternative Characterizations of the Uncertainty*

There is a considerable literature concerning the theory of the firm facing an uncertain demand. One conclusion is that: if the firm's *ex ante* control is quantity produced and offered for sale, then the risk-neutral firm would select the same optimum quantity as it would if it were certain of the state of nature.[2] In our analysis, the scale of plant is the *ex ante* control, and the resulting state of nature determines the total revenue function. To stay as close to A-J as we can, assume that the firm is risk neutral.[3] Uncertainty would not affect the *ex ante* scale of plant selected by the *unregulated* firm. Nevertheless, we prove that uncertainty concerning the state of nature may induce the *regulated* firm to select a smaller scale of plant than would be chosen if there were no uncertainty concerning the state of nature.

There are several ways to characterize the uncertainty concerning the state of nature that will prevail when the plant is in operation. Our main theme is that the nature of the uncertainty will profoundly affect the response of the firm to a rate of return constraint.

In equation (6), uncertainty is characterized as a percentage deviation of the maximal quasi-rents function $R(K, u)$ from its expected value $E[R(K, u)]$. The coefficient of variation, defined as the ratio of the standard deviation to the mean, is a constant independent of $K$.

$$(6) \quad R(K, u) = R(K)(1 + u)$$

$$(6') \quad E[u] = 0$$

$$(6'') \quad E[u^2] = \int u^2 f(u)du > 0$$

$$(6''') \quad \underset{u}{E}[R(K, u)] = R(K)$$

[2] See Agnar Sandmo, and Hayne Leland, p. 283.
[3] The assumption of risk aversion would bias the results away from Averch-Johnson.

Multiplicative deviation $u$ is a random variable with a zero mean, positive variance, and a probability density function $f(u)$. Consequently, the expected value of the maximal quasi rents is $R(K)$.

Alternatively, the uncertainty could be additive and independent of $K$ as described by equation (7). Again, let the expected value of the disturbance be equal to zero with a positive variance and a probability density function $g(u)$. The coefficient of variation in this case is a declining function of $R$.

$$R(K, u) = R(K) + u \tag{7}$$

$$E[u] = 0 \tag{7'}$$

$$E[u^2] = \int u^2 g(u) du > 0 \tag{7''}$$

$$\underset{u}{E}[R(K, u)] = R(K) \tag{7'''}$$

If the *unregulated* firm were risk neutral, the *ex ante* control $K$ would be chosen to maximize expected profits $\pi_0(K)$, the difference between the expected maximal quasi rents $E[R(K, u)]$ and total capital costs $iK$, where $i$ is the cost of capital. The zero subscript denotes the absence of regulation.

$$\begin{aligned} \underset{K}{\text{Max}}\, \pi_0(K) &= \underset{K}{\text{Max}}\, \underset{u}{E}[R(K, u)] - iK \\ &= \underset{K}{\text{Max}}\, R(K) - iK \end{aligned} \tag{8}$$

Since the expected quasi rents $E[R(K, u)]$ equal $R(K)$ in both the additive and the multiplicative cases, the *ex ante* scale of plant chosen will be the same as would be chosen if there were no uncertainty. The expected marginal product of capital $(d/dK)E[R(K, u)] = E(d/dK)R(K, u) = R'(K)$ in both the additive and the multiplicative cases. An unregulated risk-neutral firm will select $K_0$ (in Figure 1) as the optimum *ex ante* control, where the expected marginal revenue product of capital $R'(K_0)$ is equal to the cost of capital $i$, provided that $\pi_0(K_0) \geqq 0$.

$$R'(K_0) = i \tag{9}$$

This point is described by point $M$ in Figure 1. Total profits are maximal and positive at point $M$, and the monopolist will charge price $p_0$. The ratio of quasi rents to the optimal capital stock is $K_0M/OK_0$. The nature of the uncertainty is irrelevant for the risk-neutral unregulated monopolist.

## II. The Regulatory Constraint and the Expected Maximal Quasi-Rents Function

When a regulatory constraint is imposed the firm is not allowed to earn more than $sK$ of quasi rents. To be effective, the regulated rate of return $s$ must be less than what was earned by the unregulated monopolist, but it must exceed the cost of capital $i$. In terms of Figure 1, $K_0M/OK_0 > s > i$.

The expected maximal quasi rents consists of two parts. Define $S$ as the set of states of nature $u$ where the maximal quasi rents $R(K, u)$ are less than $sK$. Define $T$ as the complement of that set.

$$S \equiv [u \mid R(K, u) < sK] \tag{10a}$$

$$T \equiv [u \mid R(K, u) \geqq sK] \tag{10b}$$

$$Pr[u \in S] + Pr[u \in T] = 1 \tag{10c}$$

Suppose that the firm selected a scale of plant $K'$ and the state of nature that occurred when the plant came into operation yielded maximal quasi-rents curve $OFMBR$ in Figure 1. The state of nature is in set $S$ because maximal quasi rents $K'B$ are less than $sK'$. At that scale of plant and given the state of nature, profits would be maximized by charging price $p'$. Nevertheless, the ratio of quasi rents to the stock of capital would be below $s$, the regulated rate. There is nothing that the regulatory authorities can do to help the firm earn $sK'$ because $K'B < sK'$ represents the maximal quasi rents that can be generated from this plant. By raising the price above $p'$, the firm would be generating less than the

maximum profits associated with this scale of plant and state of nature: i.e., it would be operating below point $B$ in Figure 1.

Had the firm selected scale of plant $K_0$, when the state of nature is in set $T$ yielding maximal quasi rents $K_0M$, then it would be earning a rate of return in excess of $s$. The maximum profit price charged by the firm would be $p_0$. During the period of the regulatory lag, the firm would be earning a rate of return greater than the "fair rate." Sooner or later, the regulatory authority would catch up with the firm and require it to lower its price below $p_0$.[4] At the lower price, the quantity demanded would rise. The regulated monopolist is required to meet the demand. To produce the greater quantity demanded, more variable inputs (labor) would have to be employed with scale of plant $K_0$. At point $M$ on the maximal quasi-rents curve, the marginal revenue product of labor is equal to the wage: equation (2). When employment increases to satisfy the greater quantity demanded at the lower price, the marginal revenue product of labor is driven down below the wage. The regulatory authority will require the firm to lower its price and meet the quantity demanded until total quasi rents fall to $K_0D=sK_0$, which are below the maximal quasi rents $K_0M$.

The expected quasi rents, denoted by $E[R]$, are described by equation (11). When state of nature $u$ is in set $S$, then the firm earns the maximal quasi rents $R(K, u) < sK$. When the state of nature is in set $T$ then, after the regulatory lag, the firm earns $sK \leqq R(K, u)$ of quasi rents. The second integral in equation (11) is the probability that state of nature $u$ is in set $T$.

$$(11) \quad E[R] = \int_{u\in S} R(K, u)f(u)du + sK\int_{u\in T} f(u)du \leqq sK$$

Suppose that set $S$ is not empty. Then for $u$ in set $S$, the maximal quasi rents $R(K, u)$ are less than $sK$.

$$(11') \quad E[R] = \int_{u\in S} R(K, u)f(u)du + sK\, Pr[u \in T] < sK$$

It follows that the expected quasi rents earned by a regulated monopolist are less than $sK$, the maximum permissible quasi rents.[5]

## III. Uncertainty and the Regulated Monopolist

### A. *When the Uncertainty is Additive, Conventional Results are Obtained*

If the disturbance term is additive and independent of $K$, the conventional A-J results are obtained. The imposition of an effective regulatory constraint will either drive the firm out of business or will lead it to select *ex ante* a scale of plant larger than $K_0$ chosen by the unregulated monopolist.

Equation (12) describes the expected quasi rents earned by a regulated firm when the disturbance term is additive. The first integral in equation (12) describes the maximal quasi rents when $R(K)+u$ is less than $sK$, i.e., when $u$ is in set $S$. The second integral in equation (12) describes the situation when the quasi rents are at least as great as $sK$, i.e., $u$ is in set $T$.

$$(12) \quad E[R(K) + u] = \int_{u\in S} [R(K) + u]g(u)du + sK\int_{u\in T} g(u)du$$

Equation (12′) is a useful way of writing (12). The integral $\int_{u\in S} ug(u)du$ is the expected value of $u$ such that $R(K)+u$ is

[4] It is assumed that the regulatory lag is short relative to the life of the plant. For this reason, the regulatory lag is disregarded here.

[5] This is the essence of corollary 2 in the paper by Stylianos Perrakis, appearing elsewhere in this issue.

less than $sK$, and can be written as $E[u|u \in S]$.

$$(12') \quad E[R(K)+u] = R(K)\, Pr[u \in S] + \int_{u \in S} ug(u)du + sK\, Pr[u \in T]$$

Total expected profits denoted by $\pi_1(K)$ are expected quasi rents minus total capital costs $iK$, as described by equations (13) and (13′). Subscript 1 denotes the profits of the regulated firm when the uncertainty is additive.

$$(13) \quad \pi_1(K) = E_1[R(K)+u] - iK = R(K)\, Pr[u \in S] + E[u|u \in S] + sK\, Pr[u \in T] - iK$$

Since the state of nature must be either in set $S$ or set $T$, equation (13) may be written as:

$$(13') \quad \pi_1(K) = [R(K) - sK]\, Pr[u \in S] + (s-i)K + E[u|u \in S]$$

Now it is easy to prove that the optimal *ex ante* scale of plant chosen by the regulated monopolist will exceed $K_0$, the scale selected by the unregulated monopolist provided that the regulation does not drive the firm out of business completely.

Differentiate $\pi_1(K)$ with respect to $K$. Term $\phi_1(K)$ involves the derivatives of $Pr[u \in S]$ and $E[u|u \in S]$, and will generally be ignored.

$$(14) \quad \pi_1'(K) = [R'(K) - s]\, Pr[u \in S] + (s-i) + \phi_1(K)$$

The firm will go out of business if Max $\pi_1(K)$ is negative. Assume that $(s-i)$ is sufficiently large that the maximum expected profits are positive at the unregulated point $\pi_1(K_0) > 0$, so that this possibility will not occur.

Evaluate equation (14) at the unregulated point $K_0$ where $R'(K_0) = i$ and derive:

$$(14') \quad \pi_1'(K_0) = (s-i)\, Pr[u \in T] > 0$$

It follows that total expected profits can be increased by selecting *ex ante* a scale of plant larger than that chosen by the unregulated monopolist.

In the conventional A-J case when there is no uncertainty, it is certain that the firm will earn more than $sK_0$ when it selects scale $K_0$. Point $M$ is above ray $OsK$ in Figure 1 with probability 1; $Pr[u \in T] = 1$ at that point. Consequently, $\pi_1'(K_0) = (s-i) > 0$, and the firm selects a larger scale of plant than it did when it was not regulated. The well-known A-J effect may be considered as a special case of inequality (14′) above.

### B. *When the Uncertainty is Multiplicative, an Anti A-J Theorem is Derived*

When the uncertainty is multiplicative, the conventional A-J effect is completely reversed. The closer the regulated rate of return is to the cost of capital, the *smaller* will be the optimum *ex ante* scale of plant. Call this the anti A-J theorem.

Total expected profits of the regulated firm are $\pi_2(K)$, where subscript 2 denotes the regulated firm facing a multiplicative disturbance.

$$(15) \quad \pi_2(K) = E[R(K)(1+u)] - iK$$

Expected maximal quasi rents are described by equation (16). The first integral describes the situation where the maximal quasi rents $R(K)(1+u)$ are less than $sK$: i.e., the state of nature $u$ is in set $S$. The second integral refers to the situation where the firm is able to earn at least the regulated rate of return: i.e., $u$ is in set $T$, but would have to lower its price to satisfy the regulatory constraint.

$$(16) \quad E_2[R(K)(1+u)] = \int_{u \in S} R(K)(1+u)f(u)du +$$

$$sK \int_{u \in T} f(u)du < sK$$

Equation (16′) is another way of writing equation (16). Certainly for scales of plant between 0 and $K_1$ in Figure 1, the expected value of $u$ which will make $R(K)(1+u) < sK$ is negative. Integral $\int_{u \in S} uf(u)du \equiv E[u|u \in S]$ is denoted by $-\gamma$ in equation (16″).

$$(16') \quad E_2[R(K)(1+u)] = R(K)\,Pr[u \in S] + R(K)E[u \mid u \in S] + sK[1 - Pr[u \in S]]$$

$$(16'') \quad E[u \mid u \in S] = -\gamma < 0$$

Total profits expected by the regulated monopolist when the uncertainty is multiplicative are given by equation (17), derived from equations (15) and (16).

$$(17) \quad \pi_2(K) = (R(K) - sK)\,Pr[u \in S] + (s - i)K - \gamma R(K)$$

Differentiate equation (17) with respect to $K$. Term $\phi_2(K)$ involves the derivatives of $Pr[u \in S]$ and $\gamma$. As a rule, it will be ignored.

$$(18) \quad \pi_2'(K) = (R'(K) - s)\,Pr[u \in S] + (s - i) - \gamma R'(K) + \phi_2(K)$$

Evaluate this expression at the unregulated point $K_0$ where $R'(K_0) = i$. Equation (19) is obtained by setting $R'(K_0) = i$ and $Pr[u \in T] = 1 - Pr[u \in S]$.

$$(19) \quad \pi_2'(K_0) = (s - i)\,Pr[u \in T] - \gamma i$$

At scale of plant $K_0$, the expected value of the maximal quasi rents $R(K_0)$ exceeds $sK$. Point $M$ in Figure 1 is above ray $OsK$. Consequently at point $K_0$, the expected value of $u$ such that $u$ is in set $S$ is negative. Variable $\gamma$ is positive.

Equation (19) describes the slope of the expected profits function at the unregulated optimum scale of plant. As the regulated rate of return decreases, $\pi_2'(K_0)$ will become negative; and the optimum *ex ante* scale of plant selected by a regulated firm will be less than that chosen by the unregulated monopolist. This is an anti A-J theorem.

The conventional A-J effect can be considered as a special case of our analysis. When there is certainty that point $M$ lies above ray $OsK$ then $Pr[u \in T] = 1$ and $\gamma = 0$ at scale of plant $K_0$. Then $\pi_2'(K_0) = (s-i) > 0$ at the unregulated point. Total expected profits can be raised by selecting an *ex ante* scale of plant in excess of $K_0$, which is the A-J effect. Once multiplicative uncertainty is introduced, a sufficiently large gap $(s-i)/i > \gamma/Pr[u \in T]$ must exist between the regulated rate of return and the cost of capital to induce the firm to select *ex ante* a scale of plant in excess of the unregulated scale $K_0$.

### C. *Discussion and Interpretation of the Results*

Every theorem, once proved and understood, should be obvious. Our theorem was that the character of the uncertainty determines whether a decline in the regulated rate of return towards the cost of capital raises or lowers the optimum *ex ante* scale of plant relative to what would be chosen if there were no regulation. Conventional A-J results are derived when the uncertainty is additive and independent of the scale of plant in the maximal quasi rents function. If, however, the uncertainty is multiplicative in the maximal quasi-rents function, then a decline in the regulated rate of return towards the cost of capital will lower the optimum *ex ante* scale of plant relative to what would be chosen if there were no regulation. As far as we know, these points have not been recognized in the literature.

These results may not as yet be obvious, but they can better be understood on the basis of more specific examples. First, consider the additive case where the distur-

bance is independent of the scale. Let $R(K)$ be described by curve $OMR$ in Figure 1, where $R(K)$ exceeds $sK$ for values of $K$ in the open interval $(0, K_1)$. Let there be three possibilities.

| $R(K, u)$ | Probability |
|---|---|
| $sK < R(K) + u$ | $p/2$ |
| $sK = R(K)$ | $1 - p$ |
| $sK > R(K) - u$ | $p/2. = Pr[u \in S]$ |

Then the total expected profits function $\pi_1(K)$ can be written as equation (20) or (20′), and it is based upon equation (13).

$$\pi_1(K) = (1 - p/2)sK + [R(K) - u](p/2) - iK \tag{20}$$

or

$$\pi_1(K) = (1 - p/2)(s - i)K + [R(K) - u - iK](p/2) \tag{20'}$$

Maximal expected profits are a linear combination of $(s-i)K$ with probability $(1-p/2)$ and $[R(K)-u-iK]$ with probability $p/2$.

Marginal expected profits are:

$$\pi_1'(K) = [(1 - p/2)s + (p/2)R'(K)] - i \tag{21}$$

$$\pi_1'(K) = (1 - p/2)(s - i) + (p/2)[R'(K) - i] \tag{21'}$$

In terms of Figure 1, maximal quasi rents will be above curve $OMR$ with probability $p/2$, below that curve with probability $p/2$ and will be on the curve with probability $(1-p)$. If the maximal quasi-rents curve is $R(K)$ or $R(K)+u$, then the marginal quasi rents will be $sK$ due to regulation; and marginal profits will be $(s-i)$. If the maximal quasi-rents curve is $R(K)-u$, then the marginal rents will be $R'(K)$; and the marginal profits will be $R'(K)-i$. In the additive case, when $u$ is independent of the scale, the slope of the maximal quasi-rents curve is independent of the disturbance term. It just depends on the scale of plant. The expected marginal rents are:

$$[(1 - p/2)s + (p/2)R'(K)] \quad \text{independent of } u$$

At the unregulated optimum scale of plant $K_0$, the marginal quasi rents will be $s$ with probability $(1-p/2)$ if the state of nature puts the firm at point $M$ or $M'$ in Figure 1; and the marginal quasi rents will be $R'(K_0)=i$ with probability $p/2$ if the state of nature puts the firm at point $M''$. The weighted average of $s$ and $i$ exceeds $i$ at the unregulated point.

$$\pi_1'(K_0) = (1 - p/2)(s - i) = (s - i)\, Pr[u \in T] > 0 \tag{21''}$$

Since $\pi_1'(K_0)$ is positive, expected profits can be raised by selecting a scale of plant greater than $K_0$, the optimum *ex ante* scale of plant chosen by the unregulated monopolist. Uncertainty, however, may deter the firm from investing in this industry, unless there is a sufficiently large gap between $s$ and $i$. For example, suppose that the firm selected the A-J solution $K_1$ where $R(K_1)=sK_1$. Then total expected profits are:

$$\pi_1(K_1) = (s - i)K_1 - up/2 = (s - i)K_1 + E[u \mid u \in S] \tag{22}$$

In the certainty case, these profits will be positive. When there is uncertainty, the value of $(s-i)$ must be positively related to the riskiness of the venture if expected profits are to be positive. The greater $u(p/2)$, a reasonable measure of risk in this case, the greater must be the spread between the regulated rate of return and the cost of capital, in order to justify investment in this industry.

A very different situation prevails in the multiplicative case. Consider the following distribution of quasi rents. Suppose that $K_1 > K > 0$ in terms of Figure 1 below.

| $R(K, u)$ | Probability |
|---|---|
| $sK < R(K)(1+u)$ | $p/2$ |
| $sK = R(K)$ | $1-p$ |
| $sK > R(K)(1-u)$ | $p/2 = Pr[u \in S]$ |

When there is regulation, total expected profits are:

$$\pi_2(K) = sK(1-p/2) + R(K)(1-u)(p/2) - iK \tag{23}$$

Expected quasi rents will be $sK$ with probability $1-p/2$ due to the regulatory constraint and $R(K)(1-u)$ with probability $p/2$ in the unfavorable case. Marginal expected profits will be

$$\begin{aligned}\pi_1'(K) &= [s(1-p/2) + R'(K)(1-u)(p/2)] - i \\ &= (s-i)(1-p/2) + [R'(K)(1-u) - i](p/2)\end{aligned} \tag{24}$$

If the total maximal quasi-rents curve is above $sK$, then the marginal quasi rents will be $s$ with probability $(1-p/2)$. If the maximal quasi-rents curve is below $sK$, then the marginal quasi rents will be $R'(K)(1-u)$ with probability $p/2$. The greater the range of outcomes, the larger is $u$; consequently, the smaller will be the marginal returns $R'(K)(1-u)$ in the case when the maximal quasi-rents curve is below $sK$. Since the expected marginal rents are a weighted average of $s$ and $R'(K)(1-u)$, $\pi_2'(K)$ is negatively related to $u$. *This is what makes the multiplicative case so different from the additive case.*

At the unregulated scale of plant $K_0$, where $R'(K_0)=i$, the expected marginal returns are $s(1-p/2)$ plus $i(1-u)(p/2)$. Unlike the additive case, this is *less than* a linear combination of $s$ and $i$. Expected marginal profits are:

$$\begin{aligned}\pi_2'(K_0) &= [s(1-p/2)+i(1-u)p/2]-i \\ &= (s-i)(1-p/2)-iup/2\end{aligned} \tag{24'}$$

The regulated monopolist will select a scale of plant larger than the unregulated scale if[6]

$$\frac{(s-i)}{i} > \frac{up/2}{1-p/2} \tag{24''}$$

A sufficiently large spread must exist between $s$ and $i$ to make it profitable to select a capital stock in excess of $K_0$, the unregulated scale.

The quasi rents must cover interest plus depreciation if the firm is to recover its investment, therefore, $i$ is considerably above the interest rate. The ratio $s/i$ must exceed the quantity $1+u(p/2)/[1-(p/2)]$ if the firm is to be induced to select a scale of plant greater than that chosen by an unregulated firm. The table below gives the greatest lower bound of $s/i$, for selected values of $u$ and $p/2$, which would satisfy inequality (24'').

| | $u = .25$ | $u = .5$ |
|---|---|---|
| $p/2 = .25$ | 1.08 | 1.17 |
| .30 | 1.11 | 1.21 |
| .40 | 1.17 | 1.33 |

If the cost of capital were 20 percent per annum, resulting from an interest rate of 10 percent and a depreciation rate of 10 percent, then the regulated rate of return must exceed 23.4 percent when $u=.25$, $p/2=.40$ or $u=.5$, $p/2=.25$. It must exceed 26.6 percent when $u=.5$, $p/2=.4$.

It is natural to call $u(p/2)/(1-p/2)$ a measure of risk. Then, the spread $(s-i)/i$ must exceed this measure of risk if regulation is to induce a larger scale of plant than would be selected by the unregulated monopolist.[7]

[6] We also require that Max $\pi_2(K)$ in equation (23) be positive.

[7] It is worthwhile to compare Perrakis' conclusions with ours. His main theme is as follows:

The firm must satisfy *ex post* (i.e., after the value of the

random demand becomes known) both the rate of return constraint and the demand constraint. . . . At some 'states of nature,' it must increase its labor above a certain minimum in order to stay within the allowed rate of return. This, however, forces it to underutilize the invested capital in order to meet demand exactly. These states of nature will occur with a positive probability whenever the firm chooses *ex ante* the output price and capital stock by maximizing profit (or expected utility of profit. . . . Barring restrictive assumptions, therefore, there is very little that can be said about relative sizes of capital stock, price, expected output, etc. [p. 415].

An explanation of his results is as follows. His firm selects both the price and the scale of plant *ex ante*. It is then required to satisfy the quantity demanded at the given price and also the rate of return constraint. Let the quantity demanded be $D(p, x)$ where $x$ is the stochastic variable. Production is $F(VK, L)$ where $V$ is the rate of utilization. The rate of return constraint is

$$sK = pD(p, x) - WL \tag{a}$$

Since the firm must also meet the demand at the price set *ex ante*,

$$F(VK, L) = D(p, x) \tag{b}$$

It follows that

$$sK = pF(VK, L) - WL \tag{c}$$

*Ex ante* controls are $p$ and $K$, and the wage is exogenous. In our analysis, only the scale of plant $K$ is an *ex ante* control; and price and labor inputs are *ex post* controls.

Demand shifts, in his analysis, are reflected by changes in $x$. When $x$ rises, total employment must rise to satisfy the rate of return constraint (a). This means that $dL/dx$ is positive. To determine the effect upon the utilization rate $V$, differentiate (c) with respect to $x$ and derive

$$(W - pF_L)\frac{dL}{dx} = pF_1K\frac{dV}{dx} \tag{d}$$

The regulated firm is a monopolist, so at the unregulated point the wage is *less than* the value of the marginal product of labor $pF_L$. The wage is equal to the marginal revenue product of labor $MR \cdot F_L < pF_L$, where $MR$ is marginal revenue. This means that $(W - pF_L)$ is negative. Consequently $dV/dx$ is negative. When $x$ rises, the employment rises and the utilization rate declines. This is how we interpret his results. Our utilization rate is constant but price is an *ex post* control. Whereas our main focus is upon the optimum *ex ante* scale of plant, he did not solve for the effect of a change in the regulated rate of return upon the optimum *ex ante* scale of plant.

## III. Social Welfare Implications of Rate of Return Regulation

Suppose that the economy were divided into two sectors: a competitive sector $X$ and a monopoly sector $Y$. Long-run equilibrium would be at point $A$ in Figure 2.

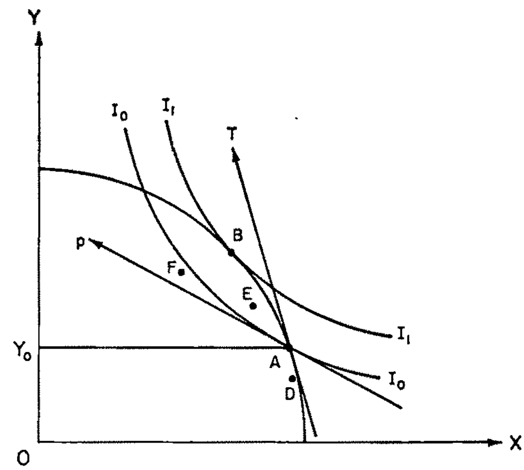

FIGURE 2. WHEN THERE IS NO REGULATION, THE ECONOMY IS AT POINT $A$. IN THE CONVENTIONAL CASES, REGULATION WILL DRIVE THE ECONOMY TO POINT $E$, AND IF IT IS TOO STRINGENT, TO POINT $F$. WHEN THE DISTURBANCE IS MULTIPLICATIVE AND THE SPREAD $(s-i)/i$ IS TOO LOW, BUT POSITIVE, REGULATION MAY DRIVE THE ECONOMY TO POINT $D$.

Within the competitive sector, price $p_X$ would be equal to both short- ($SMC_X$) and long-run ($LMC_X$) marginal cost. In the monopoly sector, the rate of output would be $Y_0$. Capital stock $K_0$ would be employed so that long-run ($LMC$) and short-run marginal cost $SMC(K_0)$ would equal marginal revenue $MR$ at that rate of output (Figure 3).

The economy would be operating on its production possibility curve because, in each sector, the rate of output is produced in the cheapest possible manner. Nevertheless, there is less than the optimal production of the monopoly output. The marginal rate of transformation in production $T = -dY/dX$ is the ratio of the long-run marginal cost of producing $X$ to that of producing $Y$. The marginal rate of substitution in consumption $p = -dY/dX$ is the ratio of the price of $X$ to the price of $Y$. In Figure 2, the marginal rate of transformation $T$ in production exceeds the marginal rate of substitution $p$ in consumption because the marginal revenue in

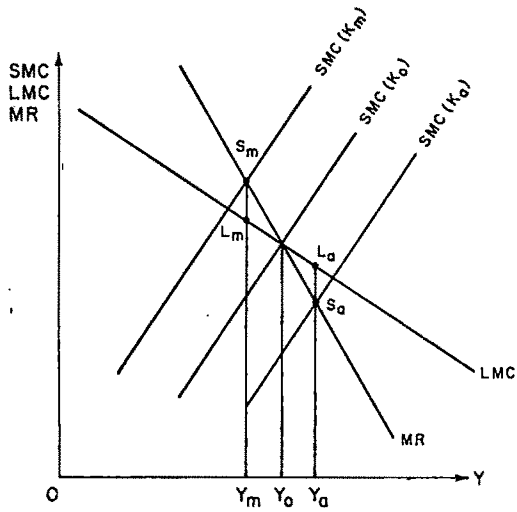

FIGURE 3. LONG-RUN MARGINAL COST IS $LMC$ AND MARGINAL REVENUE IS $MR$. THE UNREGULATED CAPITAL STOCK IS $K_0$. REGULATION MAY INDUCE THE FIRM TO SELECT CAPITAL STOCK $K_a$ OR $K_m$ DEPENDING UPON THE SPREAD $(s-i)/i$ RELATIVE TO THE RISKINESS OF THE INVESTMENT. THE CONVENTIONAL A-J EFFECT IMPLIES THAT $K_a$ IS CHOSEN. THE ANTI A-J THEOREM OPENS THE POSSIBILITY THAT $K_m$ IS CHOSEN.

sector $Y$ is less than the price: $MR_Y < P_Y$.

$$(25) \quad T = \frac{LMC_X}{LMC_Y} = \frac{P_X}{MR_Y} > \frac{P_X}{P_Y} = p$$

as described in Figure 2.

An expansion of production of sector $Y$ along the production possibility curve to point $B$ would raise social welfare to indifference curve $I_1$ from curve $I_0$.

Suppose that rate of return regulation were used to induce an expansion of the monopoly output. In the certainty case, or when inequality (21″) or (24″) is satisfied, the regulated monopolist would select a scale of plant $K_a$ in excess of $K_0$. See Figure 3. The short-run marginal cost curve associated with a capital stock $K_a$, denoted by $SMC(K_a)$ lies uniformly to the right of the short-run marginal cost curve $SMC(K_0)$ associated with the capital stock chosen by the unregulated monopolist. Consequently, the regulated monopolist would produce output $Y_a$. To be sure, there is a larger scale of output; however, production is no longer efficient. Output $Y_a$ is not being produced in the cheapest possible manner.[8] Long-run marginal cost $L_a$ exceeds short-run marginal cost $S_a$. This means that in producing output $Y_a$, the marginal capital cost $i/MPK$ (where $MPK$ is the marginal product of capital) exceeds the marginal labor cost $W/MPL$ (where $MPL$ is the marginal product of labor).

$$(26) \qquad \frac{i}{MPK} > \frac{W}{MPL}$$

Indeed the economy has been induced to produce more of the output of the monopolized sector, but it is no longer operating on its production possibility curve. In the neighborhood of the unregulated point $A$ (Figure 2), a slight decrease of $s$ below the unregulated rate $K_0M/OK_0$ in Figure 1 will drive the economy into the region between indifference curve $I_0$ and the production possibility curve[9] (say) to point $E$ (in Figure 2). The greater the degree of monopoly, the greater the gap between the marginal rate of transformation $T$ and the marginal rate of substitution $p$. Welfare will be increased by expanding the output of the monopoly sector, even though the higher rate of output is not being produced efficiently (i.e., the economy is operating inside the production possibility curve). For large deviations of $s$ from the unregulated rate of return, the economy could be driven to point $F$ where welfare is in fact reduced.

If the stochastic term were multiplicative, then the establishment of a "fair" rate of return $s$ where

$$(27) \qquad 0 < \frac{s-i}{i} < \frac{up/2}{1-p/2}$$

would violate inequality (24″). The monopolist would be induced to select *ex ante*

[8] See Stein and Borts.
[9] This is an explanation of Sheshinski's result.

a capital stock $K_m$ *below* $K_0$. The short-run marginal cost curve would be $SMC(K_m)$ in Figure 3; and the output produced would be $Y_m < Y_0$. Not only would such rate of return regulation lead to a decline in output, but the smaller output is not produced efficiently. Marginal labor cost $W/MPL$ would exceed marginal capital cost $i/MPK$. This is, of course, the reverse of the A-J effect. The net result is to drive the economy to point $D$ in Figure 2, where welfare is unambiguously lowered.

The moral of this story is that the nature of the uncertainty determines whether the A-J effect, or the anti A-J effect, occurs. Reasonable policy would aim to make the spread $(s-i)/i$ positively related to our measure of risk.

# The Benefits and Costs of Rate of Return Regulation

By JEFFREY CALLEN, G. FRANK MATHEWSON, AND HERBERT MOHRING*

The seminal article "Behavior of the Firm Under Regulation" by Harvey Averch and Leland Johnson has evoked extensive comment during the years since it appeared. Only in recent articles by Eytan Sheshinski and Alvin Klevorick, however, has the Averch-Johnson analytical framework been employed to deal with the question: If, for whatever reason, a rate of return constraint is the device that must be employed to control a monopolist's profits, at what level should the allowable rate of return be set? The answer to this question and pseudoempirical analysis of its implications are the subjects of this paper.

Specifically, Section I provides a simpler development of Sheshinski's and Klevorick's main formal conclusions than was contained in their papers.[1] Section II analyzes, as did Klevorick, the special case of constant elasticity demand and Cobb-Douglas production functions in a world in which income distribution considerations can be ignored and in which the regulatory process involves no resource costs. Expressions are derived and tabulated for the optimum allowable rate of return and for the effects on "social welfare" (i.e., the sum of consumers' and producers' surpluses), output, costs, and capital intensity of imposing a rate of return constraint on a formerly unregulated monopoly.

If this simple example sustains generalization, an allowable rate of return in excess of a monopoly's cost of capital would be desirable only if some combination prevails of a low demand elasticity, modest scale economies, and a small exponent on capital in the production function.[2] Furthermore, the gains from rate of return regulation (gross of the costs of the regulatory process) are substantial even if the allowed return differs considerably from its optimum value. Finally, at least for combinations of parameter values which reflect capital intensive production processes with substantial scale economies, rate of return regulation could capture a substantial share of the benefits derivable from setting price equal to average or (except when the elasticity of demand is large) even marginal cost.

## I. The Optimum Allowable Rate of Return

As preparation for dealing with the optimization problem involved in specifying the rate of return allowed a regulated monopoly, consider first the optimization problem faced by the monopoly itself. Its profits can be written:

$$(1) \qquad \Pi = R(Q) - wL(Q, K) - rK$$

where $R(Q)$ is the revenue derived from selling $Q$ units of product; $L(Q, K)$—obtained by inverting the production function—is the amount of variable input re-

Most of the work described in this paper was undertaken during 1973 while we were all associated with the University of Toronto's Faculty of Management Studies and department of political economy. We are indebted to Bela Balassa and Carl Christ for helpful suggestions.

[1] Albeit, in Sheshinski's case, at the expense of employing a less general social welfare function.

[2] Ignoring the motivational and indeterminacy problems that arise when the allowable rate of return is set equal to the cost of capital.

quired to produce $Q$ units of output if a capital stock valued at $K$ dollars is employed; $w$ is the wage rate of the variable input; and $r$ is the cost of capital. Depreciation expenses are assumed away.

The constraint that the monopoly is allowed to earn a rate of return $s$, which is less than the rate $s^*$ it would earn in the absence of regulation, can be written

$$(2) \qquad sK = R(Q) - wL(Q, K)$$

This constraint can be interpreted as specifying the required capital stock $K$ as an implicit function of the output level $Q$. Using this implicit function to eliminate $K$ in equation (1) reduces the set of decision variables to $Q$ alone. Proceeding in this fashion avoids the difficulties involved in interpreting auxiliary variables. Differentiating the amended equation (1) with respect to $Q$ yields

$$(3) \quad R' - w(L_Q + L_K K') - rK' = 0$$

where, from (2)

$$sK' = R' - w(L_Q + L_K K')$$

or:[3]

$$(4) \qquad K' = (R' - wL_Q)/(s + wL_K)$$

Substituting (4) into (3) and rearranging terms yields:

$$(5) \qquad (s - r)(R' - wL_Q) \doteq 0.$$

If $r$ is less than $s$, this reduces to:

$$(6) \qquad R'(Q) = wL_Q(Q, K)$$

As several writers have noted, if $s = r$, the behavior of the monopoly is indeterminate since each of the continuum of $K$ values which satisfies equation (2) would yield the same (zero) economic profit.

Equation (6) is the analogue for a regulated monopoly of the standard condition for profit maximization, marginal revenue equals marginal cost: $R'$ is marginal revenue while $wL_Q$ is regulated or pseudomarginal cost. That is, $wL_Q$ is the cost of the variable inputs required to produce an additional unit of output when $K$ is set at the level required to satisfy the rate of return constraint, equation (2). In the range $r < s < s^*$, using equation (2) to eliminate $K$ from equation (6) yields $Q^{**} = Q^{**}(s, w)$, the monopoly's profit-maximizing output as a function of the allowable rate of return and the wage rate of the variable input. Substituting $Q^{**}$ for $Q$ in equation (2) yields the profit-maximizing capital input level $K^{**} = K^{**}(s, w)$.

Turning to the regulatory authority's optimization problem, we assume, as did Klevorick, the social objective to be maximization of the sum of consumers' and producers' surpluses:

$$(7) \quad W = \int_0^{Q^{**}} P(q)dq - wL(Q^{**}, K^{**}) - rK^{**}$$

Differentiating with respect to $s$ yields:

$$(8) \qquad [P - wL_Q]Q_s^{**} = [r + wL_K]K_s^{**}$$

as the necessary condition for maximizing $W$. The left-hand side of this equation is the difference between price and (pseudo) marginal cost times the change in output resulting from a change in the allowable rate of return—the marginal net benefit of a change in $s$. The right-hand side of equation (8) is the change in capital employed by the monopoly as a result of a change in $s$ times the difference between the annual cost of a dollar's worth of capital plant and the reduction in variable input costs resulting from employment of that additional unit of capital. That is, the right-hand side of (8) equals the marginal

[3] Cost minimization would dictate employing that amount of capital for which $r + wL_K = 0$. If the monopolist is to stay in business, $s$ must be greater than or equal to $r$. As is well known from the Averch-Johnson literature, a rate of return constraint induces the employment of an inefficiently large amount of capital, i.e., a level for which $r + wL_K > 0$. The denominator on the right-hand side of (4) would therefore be positive.

net increase in costs resulting from the excessive substitution of capital for labor that rate of return regulation induces.

An unconstrained profit-maximizing monopoly would produce at minimum cost. Therefore, with $s=s^*$, $wL_Q$ would equal *the* marginal cost of its product while $r$ would equal $-wL_K$. This being the case, when evaluated at $s=s^*$, the left-hand side of (8) would be positive while the right-hand side would be zero. Reducing $s$ to a value less than $s^*$ could be expected to lower the difference between price and (pseudo) marginal cost. Also, by inducing the substitution of capital for labor, reducing $s$ would lead $-wL_K$ to fall short of $r$. These considerations suggest that if administration costs could be ignored, reducing $s$ below $s^*$ would increase our measure of social welfare. That is, they suggest that regardless of the specific natures of the production and demand functions involved, the optimum allowable rate of return is less than that which an unconstrained monopolist would earn. It also *seemed* plausible to conjecture that the optimum value of $s$ could be shown to lie in the range $r<s<s^*$. We were unable to demonstrate the general validity of this conjecture, however.[4] Indeed, the specific example described in the following section provides a counterexample to it, at least when increasing returns to scale are involved.

## II. The Benefits and Costs of Rate of Return Regulation: An Example

We suppose, as did Klevorick, that the monopoly is faced by a constant elasticity demand schedule and that its production function is Cobb-Douglas. Specifically, the demand function is:

$$P = AQ^{-\epsilon} \tag{9}$$

where $A$ is a constant and $1/\epsilon$ is the elasticity of demand. By appropriately specifying the units in which output is measured, the production function can be written without further loss of generality as

$$Q^{\beta} = K^{\alpha}L^{1-\alpha} \tag{10}$$

where $0<\alpha<1$, and $\beta\leq 1$ is the reciprocal of the order of homogeneity of $Q$. For notational convenience, it proves useful to define the following combinations of parameters:

$$\begin{aligned}
\gamma &\equiv \beta + \epsilon - 1 \\
\delta &\equiv w\beta/[A(1-\epsilon)(1-\alpha)] \\
\eta &\equiv \gamma + \alpha(1-\epsilon) \\
&\equiv \beta - (1-\epsilon)(1-\alpha)
\end{aligned}$$

In the absence of constraints, the monopoly's profit function would be

$$\Pi = AQ^{1-\epsilon} - wL - rK \tag{11}$$

Using (10) to eliminate $Q$ in equation (11) and differentiating with respect to $L$ and $K$ yields[5] the profit-maximizing values of these variables. Substituting the results into equation (10) yields the profit-maximizing output level:

$$Q^* = [A(1-\epsilon)(\alpha/r)^{\alpha}((1-\alpha)/w)^{1-\alpha}/\beta]^{1/\gamma} \tag{12}$$

The difference between the revenue derived from this output level and the cost $wL^*$ of the variable input used in producing it is the monopoly's accounting profit. This difference divided by its profit-maximizing capital stock yields the ratio of its rate of return on invested capital as conventionally measured to its cost of capital:

$$s^*/r = [\beta/(1-\epsilon) - (1-\alpha)]/\alpha \tag{13}$$

The profit-maximizing capital stock itself can be written:

$$K^* = [\alpha w/((1-\alpha)r)]^{1-\alpha}Q^{*\beta} \tag{14}$$

[4] Roger Sherman (pp. 390–93) presents a geometric analysis suggesting the validity of this conjecture when the monopoly operates under constant returns to scale.

[5] The algebra involved is straightforward if tedious. Only the final results and a sketchy outline of the steps involved will therefore be given.

Substituting $K^*$ and $L^*$ into $C=wL+rK$ yields the monopoly's total cost:

$$(15)\quad C^* = (r/\alpha)^{\alpha}(w/(1-\alpha))^{1-\alpha}Q^{*\beta}$$

Turning to the regulated monopoly, substituting the demand and production functions into equation (2) and using the result to eliminate $K$ in equation (6) yields its profit-maximizing output:

$$(16)\quad Q^{**} = [(A\delta - w)/(s\delta^{1/\alpha})]^{\alpha/\gamma}$$

Inserting (16) into equation (2) yields the profit-maximizing capital stock:

$$(17)\quad K^{**} = \delta^{(1-\alpha)/\alpha}Q^{**\eta/\alpha}$$

Introducing these last two equations into $L=L(Q, K)$ and the result into $C=wL+rK$ yields the constrained monopoly's total cost function:

$$(18)\quad C^{**} = wQ^{**1-\epsilon}/\delta + r\delta^{(1-\alpha)/\alpha}Q^{**\eta/\alpha}$$

For the Cobb-Douglas production function under examination, $L(Q, K)$ is:

$$(19)\quad L = (Q^{\beta}/K^{\alpha})^{1/(1-\alpha)}$$

Inserting equation (9), the derivatives of $L$ with respect to $K$ and $Q$, and the derivatives of equations (16) and (17) with respect to $s$ into equation (8) yields the optimum allowable rate of return $s^{opt}$ *if* a value of $s>r$ satisfies equation (8):

$$(20)\quad s^{opt} = \eta^2 r/[\alpha(\beta - (1-\alpha)(1-\epsilon)^2)]$$

If this equation is satisfied only for a value of $s \leq r$, welfare maximization would involve a corner solution. That is, it would require establishing an $s$ sufficiently in excess of $r$ to avoid the indeterminacy (see equation (5)) which arises when $s$ equals $r$ and the incentive to withdraw from production associated with an $s<r$. Note that the ratio $s^{opt}/r$ derivable from equation (20) depends only on parameters having straightforward economic interpretations: the elasticity of demand $(1/\epsilon)$, the exponent of capital in the production function $(\alpha)$, and the order of homogeneity of that function $(1/\beta)$.

Division of equation (16) by equation (12) gives the relative increase in output effected by establishing a ratio $r/s$ of the cost of capital to the allowable rate of return as a function of these same parameter values:

$$(21)\quad Q^{**}/Q^* = [(r/s)\eta/\alpha(1-\epsilon)]^{\alpha/\gamma}$$

Substitution of $Q^{**}$ for $Q^*$ in equation (14) yields the amount of capital that would be required for production of $Q^{**}$ at minimum cost. Division of the resulting expression into equation (17) then yields a measure of the extent to which rate of return regulation leads to excessive employment of capital:

$$(22)\quad K^{**}(Q^{**})/K^*(Q^{**}) = [(r/s)\eta/(\alpha(1-\epsilon))]^{1-\alpha}$$

A similar substitution in equation (15) and division into equation (18) yields a measure of the cost increasing effect of rate of return regulation:

$$(23)\quad C^{**}(Q^{**})/C^*(Q^{**}) = (1-\alpha)[(s/r)\alpha(1-\epsilon)/\eta]^{\alpha} + \alpha[(r/s)\eta/(\alpha(1-\epsilon))]^{1-\alpha}$$

Given the way the analysis has been set up, the logical measure of the social benefits attributable to rate of return regulation might seem to be $W^{**}/W^*$, "net social welfare" contributed by the monopoly's operations under regulation divided by that associated with its unregulated behavior. However, as the absolute value of the elasticity of demand approaches one from above, the area under a constant elasticity demand schedule approaches infinity. This being the case, the *percentage* gain in $W$ resulting from a given *absolute* gain in the sum of consumers' and producers' surpluses diminishes with reductions in the elasticity of demand. With low elasticity values, small percentage

*Note:* $\alpha\equiv$capital exponent; $\beta\equiv$scale economy coefficient; $1/\epsilon\equiv$demand elasticity; $s^*/r\equiv$monopoly rate of return $\div$ cost of capital; $s^{opt}/r\equiv$optimum allowable rate of return $\div$ cost of capital; $Q^{**}/Q^*\equiv$output ratio; $K^{**}/K^*\equiv$capital ratio; $C^{**}/C^*\equiv$cost ratio; $\Delta W^r/R^*\equiv$regulated welfare gain; $\Delta W^r/\Delta W^a\equiv$regulated welfare gain $\div$ average cost pricing welfare gain; $\Delta W^r/\Delta W^m\equiv$regulated welfare gain $\div$ marginal cost pricing welfare gain.

gains would result even from very large absolute gains. This being the case, the $W^{**}/W^*$ measure is less than ideal. An alternative measure is the change in net social welfare resulting from regulation $\Delta W^r \equiv W^{**} - W^*$, divided by the market value of the monopolist's output under unregulated conditions.

With a constant elasticity demand schedule, the net social welfare associated with $Q$ units of the monopolist's output can be written:

$$W = AQ^{1-\epsilon}/(1-\epsilon) - C(Q) \tag{24}$$

Substituting equations (12) and (15) into equation (24) yields $W^*$ while substitution of equations (16) and (18) yields $W^{**}$. Subtracting and dividing by $R(Q^*) = A(Q^*)^{1-\epsilon}$ results in:

$$\begin{aligned}\Delta W^r/R^* = {} & [1/(1-\epsilon) - (1-\epsilon)(1-\alpha)/\beta] \\ & \cdot (Q^{**}/Q^*)^{1-\epsilon} - 1/(1-\epsilon) \\ & + (1-\epsilon)/\beta - (r/s)^{\eta/\gamma}(\eta/\beta) \\ & \cdot [\eta/\alpha(1-\epsilon)]^{\alpha(1-\epsilon)/\gamma}\end{aligned} \tag{25}$$

Table 1 gives the ratios of $s^*$, the unconstrained monopoly rate of return, and $s^{opt}$, the optimum allowable rate of return (more accurately, the value of $s$ which satisfies equation (20)) to $r$ the cost of capital for alternative values of $\alpha$, $\beta$, and $\epsilon$ that yield stable equilibria.[6] In addition, it provides values of equations (21)–(23) and (25) with $s/r$ equal to $s^{opt}/r$ when $s^{opt} > r$ and $s/r$ equal to one when a value of $s \leq r$ satisfies equation (20). The equation values associated with $s/r = 1$ would not, of course, be observed in the real world. Still, it seems better to tabulate them than values associated with one plus some arbitrarily chosen increment.

[6] If $\beta + \epsilon < 1$, the demand schedule intersects the marginal cost schedule from below. Entries in this table therefore involve only $\beta + \epsilon$ values greater than one.

Perhaps the most important conclusion to be drawn from Table 1 is that the optimum allowable rate of return exceeds the cost of capital only when some combination of modest scale economies, an elasticity of demand close to one, and a small exponent of capital in the production function are in effect. If the $\Delta W^r/R^*$ benefit measure is accepted as reasonable, the potential gains (again, gross of administrative costs) from rate of return regulation are substantial. This form of regulation does produce substantial increases in capital inputs and, to a lesser extent, production costs. However, these cost increases are far more than offset by the additional consumers' plus producers' surpluses generated by the increased output. While the smallest value of the $\Delta W^r/R^*$ index tabulated (for $\alpha=0.33$, constant returns to scale, and a demand elasticity of four) is 11 percent, one index value in excess of 200 percent appears while values in excess of 100 percent are common.

Showing that rate of return regulation could make substantial contributions to social welfare given appropriate parameter combinations is not, of course, the end of the story. If raising subsidies involves no resource misallocation, the sum of consumers' and producers' surpluses would be maximized by establishing that output level for which price equals long-run marginal cost. If, for whatever reason, subsidies cannot be paid, the output level at which price equals long-run average cost is the best that can be hoped for. If the benefits derivable from rate of return regulation are close to those attainable with average or marginal cost pricing, the search for alternative regulatory procedures would be pointless.

To explore the potential benefits of alternative regulatory procedures, define the increases in net social welfare that would result from replacing unconstrained monopoly pricing by price equal to average and marginal cost, respectively, as $\Delta W^a = W^a - W^*$ and $\Delta W^m = W^m - W^*$ where $W^a$ and $W^m$ are the respective values of net social welfare resulting from setting price equal to marginal and to average cost. Using equations (9) and (15) to determine the output levels that would result from average and marginal cost pricing, making appropriate substitutions in equation (24), and dividing by $R^*$ yields:

$$(26)\quad \Delta W^m/R^* = (1-\epsilon)^{-\beta/\gamma} - (1-\epsilon)^{-(1-\epsilon)/\gamma} - \gamma$$

$$(27)\quad \Delta W^a/R^* = \beta^{(1-\epsilon)/\gamma}[\Delta W^m/R^* + \gamma] - \gamma$$

Dividing equations (26) and (27) into equation (25) yields $\Delta W^r/W^a$ and $\Delta W^r/\Delta W^m$—the ratios of benefits derivable from rate of return regulation to those associated with average and marginal cost pricing. These ratios are given in the final two columns of Table 1.

The values of these ratios differ considerably from one set of parameter values to another. The $\Delta W^r/\Delta W^a$ and $\Delta W^r/\Delta W^m$ measures range from respective lows of 0.32 and 0.07 to respective highs of 0.94 and 0.82. Both of these ratios increase with increases in the exponent of capital in the production function. Also, $\Delta W^r/\Delta W^a$ increases with increases in the elasticity of demand and in scale economies whereas $\Delta W^r/\Delta W^m$ exhibits an irregular pattern of change with increases in these variables.

It seems highly unlikely that any regulatory authority anywhere has the information at its disposal that would be necessary for precise determination of optimum allowable rates of return for the activities it controls. Indeed, with such complete data, rate of return regulation would be pointless. No less information is necessary to determine $s^{opt}$ than to dictate the inputs necessary to produce efficiently that output for which demand price equals average or marginal cost. That is, the information necessary to determine $s^{opt}$ would permit

TABLE 2— $\Delta W/R^*$ WELFARE GAIN RATIOS FOR ALTERNATIVE NONOPTIMAL RATIOS OF THE ALLOWABLE RATE OF RETURN TO THE COST OF CAPITAL

*Note:* $\alpha\equiv$ capital exponent; $\beta\equiv$ scale economy coefficient; $1/\epsilon\equiv$ demand elasticity; $s^{opt}/r\equiv$ optimum allowable rate of return ÷ cost of capital; $s/r\equiv$ allowable rate of return ÷ cost of capital; $a\equiv(s-r)/(s^*-r)\equiv$ deviation of allowable rate of return from cost of capital ÷ deviation of monopoly rate of return from cost of capital.

[a] $s/r>s^*/r$.

[b] Equation (20) satisfied for $s<r$.

complete elimination of Averch and Johnson-type distortions.

For this reason, it is of interest to determine how the benefits suggested by Table 1 would be affected by specification of a nonoptimum allowable rate of return. It is this issue to which Table 2 is addressed. It lists $\Delta W^r/R^*$ for values of $s/r$ different from the optimum. In the first group of columns, ratios are calculated for allowable rates of return equal, alternatively, to 1.1, 1.25, 1.5, and 2 times the cost of capital when these values do not exceed the rate of return an unconstrained monopolist would earn. In the second group of columns, ratios are calculated for $s/r$ values equivalent, alternatively, to $a\equiv(s-r)/(s^*-r)$ values of 0, 0.25, 0.5, and 0.75. The ratio $a$ is the amount by which the allowable rate of return exceeds the cost of capital divided by the amount by which the unconstrained monopoly rate of return exceeds the cost of capital.

Deviations from optimum allowable rates of return do lead to reduced benefits, of course. Reductions are particularly great when allowable rates are close to the cost of capital under circumstances in which $s^{opt}/r$ is substantially greater than one. But the benefits listed in Table 2 are positive and typically substantial even when there is a considerable difference between the allowable and the optimum rate of return. If—a very big if—generalization is warranted on the basis of these tables, regardless of the values of the technological and demand parameters under which it operates, subjecting a

formerly unregulated monopoly to the constraint that its rate of return on invested capital not exceed, say, 1.1 times its cost of capital would generate social gains substantially in excess of those which would accrue in the absence of regulation. Indeed, for some combinations of values of the scale economy, capital intensity, and demand elasticity variables, this form of regulation could yield benefits almost as great as those derivable from cost minimizing production coupled with average or even marginal cost pricing.

The literature contains a number of reports on attempts to fit Cobb-Douglas production functions to regulated utilities. Unfortunately, however, we have found only one such study which provides estimates of all three of the parameters that enter into our model. In this study, A. Rodney Dobell et al. derived estimates of our $\alpha$ and $\beta$ parameters equal to 0.36 and 0.90 respectively from an analysis of Bell Canada data for the period 1952–67. In addition, when evaluated for 1967 conditions, their demand relationship yields a long-run price elasticity of 2.01.

From equation (13), an unconstrained profit-maximizing monopolist subject to these conditions would earn a rate of return equal to 3.2 times its cost of capital. From equation (20), the optimum ratio of the allowable rate of return to the cost of capital would be 1.26. Imposing this constraint would generate a $\Delta W^r/R^*$ benefit (equation (25)) of 0.28. This benefit is 45 and 43 percent respectively of those that would result from average and marginal cost pricing (equations (26) and (27)). Setting the allowable rate of return equal to 1.1 times the cost of capital would only lower the $\Delta W^r/R^*$ benefit to 0.27, 43, and 41 percent respectively of the average and marginal cost pricing benefits. Even allowing a rate of return equal to twice the cost of capital would generate benefits equal to 30 and 29 percent respectively of those associated with average and marginal cost pricing.

# The Economics of Multiple Job Holding

*By* Robert Shishko and Bernard Rostker*

A person holding two or more jobs is said to be moonlighting, or participating in a secondary labor market.[1] This study investigates the determinants of the moonlighting supply function in terms of demographic and market factors and describes the relationship between primary and secondary employment.

Economic literature has treated moonlighting in two ways. First, there have been several attempts to extend traditional micro-economic theory to explain the individual moonlighter's supply curve.[2] Second, some researchers have presented demographic profiles of the typical moonlighter.[3] To our knowledge, no one has combined these two approaches to estimate a moonlighting supply curve. In this paper we attempt to estimate the moonlighting supply curve with data from the Income Dynamics Panel (*IDP*) using the Tobit technique for estimating relationships with limited dependent variables.

## I. The Economics of Moonlighting

Traditionally, an individual receives purchasing power, or income, as payment for work. Time spent to obtain this income can be viewed as forgone leisure. In Figure 1, which shows a representative set of indifference curves indicating equal-utility combinations of income and leisure, point $B$ represents the maximum amount of leisure available per period. The slope of the line $AB$ is the negative of the prevailing wage rate, i.e., the rate at which leisure can be traded for income in the labor market. If an individual is assumed to maximize utility, he will choose a contract such that the prevailing wage rate is equal to his marginal rate of substitution of leisure for income. Such a contract is point $P$, the point of tangency between the indifference curve $\Omega_2$ and the wage line $AB$. The locus of all such tangency points $SS'$, i.e., the price expansion path, can easily be translated into the individual supply curve.

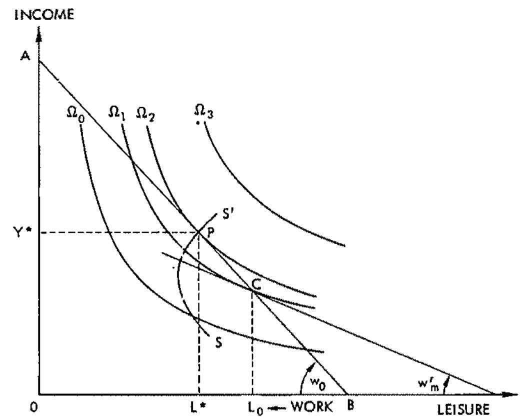

Figure 1. Utility Maximization in Income and Leisure with and without Restricting Hours Worked on Primary Job

### A. *Multiple Job Holding—A Geometric Treatment*

An individual's willingness to take a second job depends on whether he can

Robert Roll, Finis Welch, and our dedicated programmer, Laura Sammis. Views expressed in this paper are our own, and are not necessarily shared by Rand or its research sponsors.

[1] The term secondary employment has also been used in the literature to refer to employment by groups who enter and withdraw from the labor market at irregular intervals, e.g., married women. In this paper we refer to secondary employment as the holding of a job or jobs in addition to steady, full-time employment.

[2] For example, see Richard Perlman and Leon Moses.

[3] For example, see Harold Guthrie (1965, 1969), Harvey Hamel, and Allyson Grossman.

work enough hours at his prevailing primary wage rate to satisfy his income goals. Consider an individual whose primary job allows him to work only $L_0$ hours but who would like to work $L^* - L_0$ additional hours. This restriction forces the individual to indifference curve $\Omega_1$ at point $C$. Ignoring any additional costs of securing the second job, or any additional job-related costs (such as transportation), an individual will accept a second job as long as it pays a wage above the marginal rate of substitution of income for leisure at point $C$—the intersection of the primary wage line and the allowable hours on the first job.[4] If the wage rate on the second job lies between this minimum, $w_m^r$, and the primary wage rate $w_0$, he will take a second job, and the total hours worked will be somewhat fewer than the number he desired to work on his first job. If the wage rate on the second job exceeds that on his first job, depending on his preference pattern, he may decide to work even more hours than he originally desired. Moreover, if there are no limits on the amount of time he can spend on the second job, he may even substitute it for his primary employment—as sometimes occurs when people make their avocation their vocation. However, the general character of second jobs often limits the number of hours that can be worked to less than "full time" (for example, seasonal work), or is contingent upon or complementary to the primary employment (for example, when a school teacher tutors students after class), or has an unacceptable uncertainty of income given the person's risk aversion. If an individual is completely free to determine the number of hours he wants to work, at a high enough secondary wage he may develop a backward bending supply curve; and an increase in his secondary wage might result in a decrease in the number of hours worked.

Changes in the primary wage alter the minimum wage necessary to induce people to take a second job. In theory, an increase in the primary wage rate can result in an increase or a decrease in the minimum acceptable second-job wage rate. Moreover, an increase in the primary wage can increase or decrease the hours offered on the secondary labor market.

Just as a change in the primary wage rate affects both the reservation wage for moonlighting and the hours offered in the secondary labor market, so will a change in the primary job hours affect these two variables. An increase in the first-job hours $L_0$ can result in an increase or a decrease in the moonlighting reservation wage, though a large increase in $L_0$ will probably result in an increase in that wage. An increase in $L_0$ can result in an increase or a decrease in the moonlighting hours offered to the market, depending only on whether the moonlighting wage is greater or less than the primary job wage, and on whether leisure is a superior good. If the primary wage rate exceeds the moonlighting wage rate *and* leisure is a superior good, moonlighting hours offered will unambiguously decrease. If the primary wage rate equals the moonlighting wage rate, then the situation depicted in Figure 1 prevails, and moonlighting hours offered will be decreased on a one-for-one basis as primary hours increase. Only if the primary wage rate is less than the moonlighting wage rate could an increase in primary hours result in an increase in moonlighting hours offered.

### B. *Multiple Job Holding—A Mathematical Treatment*

Although geometric techniques are useful in explaining economic relationships,

[4] The minimum second-job wage rate above which the individual will accept secondary employment is called the second-job reservation wage. Let $w_m^r(w_0, L_0)$ designate this reservation wage when $w_0$ and $L_0$ are the first-job wage and first-job hours, respectively.

a more precise formulation can be presented mathematically. Consider a representative individual with a utility function embodying a general consumption good $x$, and leisure $l$. Suppose this person holds a primary job that contractually calls for $L_0$ hours of work at a fixed wage rate $w_0$. Assume further that he is underemployed in this situation (as in Figure 1) and seeks $L_m$ hours of secondary employment. The magnitude of $L_m$ depends upon the moonlighting wage rate $w_m$, which the job holder is powerless to affect. The individual then maximizes $U(x, l)$ subject to

$$(1) \qquad A_0 + w_0L_0 + w_mL_m - x \geq 0$$

$$(2) \qquad N - L_m - L_0 - l \geq 0$$

$$(3) \qquad x, l, L_m \geq 0$$

where the price of $x$ is taken as the numeraire, $N$ is the fixed number of hours per unit of time available for work or leisure, and $A_0$ is nonlabor income.

Define the function[5]

$$\psi(w_m; Y_0) = \max U(x, l)$$

subject to

$$(4) \qquad Y_0 - x - w_ml \geq 0$$
$$x, l \geq 0$$

where

$$(5) \qquad Y_0 = w_0L_0 + w_m(N - L_0) + A_0$$

Then the supply function for moonlighting labor is

$$(6) \qquad L_m = N - L_0 + \frac{\partial \psi}{\partial w_m} \bigg/ \frac{\partial \psi}{\partial Y_0}$$

The third term of the right-hand side of equation (6) is the negative quantity of leisure demanded at price $w_m$. Substituting this expression for $l$ in equation (2), which holds with equality at an optimum, the supply of moonlighting labor is obtained as the complement of the demand for leisure. The properties of this supply function can be uncovered by totally differentiating the first-order conditions,[6] equations (7)–(9), to obtain (10).

$$(7) \qquad U_l - U_xw_m = 0$$

$$(8) \qquad A_0 + w_0L_0 + w_mL_m - x = 0$$

$$(9) \qquad N - L_0 - L_m - l = 0$$

$$(10) \qquad \Lambda \begin{bmatrix} dL_m \\ dl \\ dx \end{bmatrix} = J$$

where

$$\Lambda = \begin{bmatrix} w_m & 0 & -1 \\ -1 & -1 & 0 \\ 0 & (w_mU_{xl} - U_{ll}) & (w_mU_{xx} - U_{xl}) \end{bmatrix}$$

and

$$J = \begin{bmatrix} -dA_0 - w_0dL_0 - L_0dw_0 - L_mdw_m \\ dL_0 \\ -U_xdw_m \end{bmatrix}$$

The second-order conditions at equilibrium guarantee that $\Lambda > 0$, since

$$\Lambda = -w_m(w_mU_{xx} - U_{xl}) + (w_mU_{xl} - U_{ll}) = H^*/U_x^2 > 0$$

where $H^*$ is the bordered Hessian of the utility function $U$. Let $\Lambda_{ij}$ denote the cofactor of the $i$-$j$th element of $\Lambda$, e.g., $\Lambda_{11} = -(w_mU_{xx} - U_{xl})$. The slope of the moonlighting supply function with respect to $w_m$ is given by

$$(11) \qquad \frac{\partial L_m}{\partial w_m} = \frac{U_x}{\Lambda} - L_m\left(\frac{\Lambda_{11}}{\Lambda}\right)$$

This is of course the Hicks-Slutsky equation. The first term, $U_x/\Lambda$, which is unam-

[5] It can easily be shown that $\psi(w_m; Y_0)$, the indirect utility function, has the following partial derivatives:

$$\partial\psi/\partial w_m = -\lambda l \qquad \partial\psi/Y_0 = \lambda$$

[6] Let the first and second partials of $U$ be denoted in the conventional manner by subscripting $U$. The function $U$ is assumed to be twice continuously differentiable and quasi concave.

biguously positive, indicates that as the opportunity cost of *not* moonlighting increases, there is an increase in hours offered. The second term is the "income term." If leisure is a superior good, then $\Lambda_{11}/\Lambda$ is positive; the sign of the right-hand side of equation (11) is then ambiguous. If leisure is an inferior good, then $\Lambda_{11}/\Lambda$ is negative, and the income and substitution effects operate in the same direction.

The effect of an increase in the first-job wage rate $w_0$ can be seen from

$$\frac{\partial L_m}{\partial w_0} = - L_0\left(\frac{\Lambda_{11}}{\Lambda}\right) \tag{12}$$

which is negative if leisure is superior. The effect of a change in the number of first-job hours is given by

$$\frac{\partial L_m}{\partial L_0} = - 1 + \left(\frac{\Lambda_{11}}{\Lambda}\right)(w_m - w_0) \tag{13}$$

From equation (13), it can be seen that if leisure is superior and the moonlighting job pays less than the first job, then an increase in the number of hours contractually required on the first job will mean a decrease in the number of moonlighting hours offered. However, if the moonlighting job pays more than the first job, then the result is ambiguous. If both jobs pay the same, there is a one-for-one tradeoff in the supply function.

An increase in nonwage income can be expected to affect the supply of moonlighting labor. The magnitude of this effect is given simply by the income term, since

$$\frac{\partial L_m}{\partial A_0} = - \left(\frac{\Lambda_{11}}{\Lambda}\right) \tag{14}$$

## II. Data and Statistical Procedure

### A. *The Income Dynamics Panel*

A major problem in estimating the moonlighting supply curve has been the difficulty in finding an appropriate data base. Most data sources, for example the decennial Census, do not disaggregate yearly earnings between primary and secondary jobs. In contrast, the Income Dynamics Panel (*IDP*) of the University of Michigan's Survey Research Center does provide detailed information on family composition and earnings, as well as the wage rate and hours worked on the primary and secondary jobs of the family's head.[7]

The *IDP* contains a representative cross-section of the United States as well as a supplemental sample of families known to have low incomes. Members of the Panel interviewed in the spring of 1968, 1969, and 1970 supplied information on their employment experience in 1967, 1968, and 1969. The interviews were designed to collect information that explained short-term changes in the economic status of individuals and families. Between 1968 and 1970 the representative cross-section sample netted 2574 cases and the supplemental sample netted 1891 cases.

We divided the sample of male heads of households who were employed full time into two groups according to their participation in the secondary labor market. The first group consisted of 318 people who did some moonlighting in 1969. A second group of 1801 had not engaged in secondary employment in 1969. About 15 percent of those surveyed had second jobs—a somewhat greater percentage than may be expected in the general population. Table 1 presents the general profile of individuals in the two groups.

### B. *Statistical Procedure*

The average number of hours worked per week on the second job was made the

| **Sample Size** | 318 | 1,801 |

[a] Numbers in parentheses are standard deviations.

dependent variable in the statistical estimation of the moonlighting supply curve. This variable is characteristic of many economic variables obtained from surveys of households in that it has a limiting value and a large number of respondents grouped at that limit. As previously indicated, about 85 percent of the sample population were clustered at the limiting value of zero hours of moonlighting.[8]

As James Tobin has pointed out, "An explanatory variable in such a relationship may be expected to influence both the probability of limit responses and the size of nonlimit responses" (p. 24). If the probability of participation in the secondary job market were the only variable of interest, the probit model would be sufficient.[9] But using the probit model, Tobin points out, would be inefficient since information on the magnitude of the dependent variable (in this case, moonlighting hours) is being thrown away. Given a large concentration of observations at the zero moonlighting value, multiple regression analysis would not be appropriate either since the assumptions of that model would not be satisfied. In particular, a set of independent variables could take on values such that the expected value of the dependent variable, moonlighting hours, is below its limiting value 0. Clearly, this violates the assumption of a limited or bounded dependent variable.

The Tobit model, which combines the properties of the probit and multiple re-

[8] We could not assume that nonmoonlighters were in equilibrium at their first-job wage $w_0$ and hours $L_0$. Had such an assumption been made, then a moonlighting supply curve could have been estimated simply by *OLS* as follows:

for nonmoonlighters: $L_0 = g(w_0, A_0)$;

for moonlighters: $L_0 + L_m = g(w_m, A_0 + (w_0 - w_m)L_0)$

Essentially, by adjusting "nonlabor income" for moonlighters by $(w_0 - w_m)L_0$, total hours worked by both moonlighters and nonmoonlighters would be explained by the same equilibrium structure.

[9] In the probit model, the true proportion $p_i$ of heads of households with nonstochastic characteristics $x_{1i}$, $x_{2i}$, $x_{3i}$, . . . , $x_{ni}$ who moonlight would be estimated as $F(v_i)$ with

$$v_i = \beta_0 + \sum_{k=1}^{n} \beta_k x_{ki}$$

where $\beta_0$, $\beta_i$, . . . , $\beta_n$ are parameters to be estimated and $F$ is the cumulative normal distribution function.

gression models and is therefore more appropriate for an estimation of the moonlighting supply curve, selects a set of coefficients $\beta=(\beta_1, \ldots, \beta_n)$ that maximizes the limited dependent variable likelihood function. The first-order conditions for the maximum form a set of non-linear equations which can be computationally solved by an iterative procedure.

For the vector $X=(X_1, \ldots, X_n)$ consisting of observations on the set of independent variables, the unconditional expected value of the dependent variable $E(Y)$ is given by

$$E(Y) = P\cdot X\beta + (1-P)\cdot L + \sigma f\left(\frac{X\beta - L}{\sigma}\right) \tag{15}$$

where $L$ = limit value
$P$ = the probability of observing $Y>L$ given $X$, i.e., $P=\int_{-\infty}^{(X\beta-L)/\sigma} f(\xi)d\xi$
$\sigma$ = the standard error around the Tobit "index," $X\beta$
$f$ = ordinate of the unit normal density function[10]

The expected value of the dependent variable conditional on $Y>L$ is just $X\beta$.

## III. Estimating the Moonlighting Supply Function

One of the most important explanatory variables used in estimating the moonlighting supply function is the wage received or offered on the moonlighting job. For nonmoonlighters this information is not known. Therefore, we used the information on the 318 moonlighters to estimate a reduced form ($OLS$) equation with which we predicted the moonlighting wage for each member of the entire population. In effect, a two-stage procedure was performed. First, we projected moonlighting wages, based on a reduced form equation. Second, we fitted the data set of independent variables, including the reduced form prediction, to the Tobit model. This procedure is essentially an instrumental variable technique. Unfortunately, $OLS$ instrumental variable techniques lose their consistency property when combined with non-linear maximum likelihood procedures, such as the Tobit.[11]

Many factors could account for the variation in observed moonlighting wages. Typically in labor supply studies, variables reflecting personal characteristics such as education, race, age, and marital status are used along with variables reflecting regional labor market differences. We included these variables in our $OLS$ estimate of the moonlighting wage. In addition to these variables, we had another

[10] The elasticity of the predicted probability with respect to $X_i$ can be obtained as follows:

Let $$P = \int_{-\infty}^{(X\beta-L)/\sigma} f(\xi)d\xi = F\left(\frac{X\beta - L}{\sigma}\right)$$

then $$\frac{\partial P}{\partial X_i} = f\left(\frac{X\beta - L}{\sigma}\right)\frac{\beta_i}{\sigma}$$

and $$\frac{X_i}{P}\frac{\partial P}{\partial X_i} = \frac{\beta_i X_i}{\sigma}\frac{f\left(\frac{X\beta-L}{\sigma}\right)}{P} = \frac{\beta_i X_i}{\sigma}\frac{f\left(\frac{X\beta-L}{\sigma}\right)}{F\left(\frac{X\beta-L}{\sigma}\right)}$$

The elasticity of the expected value with respect to the variable $X_i$ can be obtained by differentiating equation (15).

$$\frac{\partial E(Y)}{\partial X_i} = P\beta_i$$

$$\frac{X_i}{E(Y)}\frac{\partial E(Y)}{\partial X_i} = \frac{\beta_i X_i F\left(\frac{X\beta - L}{\sigma}\right)}{E(Y)}$$

Further, if $z$ is a variable which appears in several $X_i$, then

$$\frac{\partial P}{\partial z} = \sum_{i=1}^{n}\frac{\partial P}{\partial X_i}\frac{\partial X_i}{\partial z}$$

$$\frac{\partial E(Y)}{\partial z} = \sum_{i=1}^{n}\frac{\partial E(Y)}{\partial X_i}\frac{\partial X_i}{\partial z}$$

[11] This point was made to us by T. Paul Schultz of Yale University. Consistent and asymptotically efficient estimators for this kind of problem have been developed. However, they are not as yet widely available.

valuable piece of information, namely the actual wage on the primary job. This variable can be thought of as reflecting a number of personal productivity characteristics not captured in the vector of demographic type variables. The *OLS* estimates for the reduced form of the moonlighting wage equation are:[12]

$$(16)\quad w_m = \underset{}{47.07} + \underset{(.062)}{.403}\, w_0 - \underset{(24.47)}{90.06}\, Race + \underset{(21.60)}{75.51}\, Urban + \underset{(23.42)}{47.33}\, Hisch + \underset{(27.62)}{113.64}\, Reg + \underset{(.94)}{2.26}\, Age$$

where

$$w_m = \text{moonlighting wage (¢/hr)}$$
$$w_0 = \text{primary wage (¢/hr)}$$
$$Race = \begin{cases} 0 & \text{white} \\ 1 & \text{nonwhite} \end{cases}$$
$$Urban = \begin{cases} 0 & \text{nonurban} \\ 1 & \text{urban} \end{cases}$$
$$Reg = \begin{cases} 0 & \text{non-West} \\ 1 & \text{West} \end{cases}$$
$$Hisch = \begin{cases} 0 & \text{nongraduate} \\ 1 & \text{high school graduate} \end{cases}$$
$$Age = \text{age (years)}$$
$$R^2 = .34$$
$$F(6,312) = 25.82$$

The above equation was used to predict the moonlighting wage rate $w_m$ for the entire sample population.[13]

To test the simple theory presented in Section I, equation (17) below was estimated using the Tobit procedure and the computed moonlighting wage rate from equation (16).

$$(17)\quad L_m = \alpha_0 + \alpha_1 w_m + \alpha_2 w_0 + \alpha_3 L_0 + \alpha_4 I_0 + \alpha_5 A_0 + \text{descriptive variables} + \text{error term}$$

A constraint on equation (17) is that $L_m \geq 0$ for each observation, where $w_m$ is the moonlighting wage rate, $w_0$ is the first-job wage rate, $L_0$ is first-job hours,[14] $I_0$ is an interaction term involving $w_m$, $w_0$, and $L_0$, and $A_0$ is a nonlabor income term. This form is useful because it allows for direct calculation of the partial derivatives of $L_m$ with respect to the variables $w_m$, $w_0$, $L_0$, and $A_0$.[15] Comparison of these partial

[12] Numbers in parentheses indicate the standard error of the coefficient. All of the variables in equation (16) had significant coefficients at the .05 level. Another regression with marital status included produced an insignificant coefficient for this variable. Ninety-two percent of the heads of households were married.

[13] This procedure may introduce a selectivity bias, which arises if moonlighting wage offers are stochastic *and* there is a systematic propensity for actually observed moonlighting wage rates to come from the upper (or lower) tail of the distribution. Imputing a moonlighting wage rate from observed wage rates usually overestimates the actual offers faced by those who do not moonlight. The effect of this overimputatation is to bias toward zero the effect of the moonlighting wage rate on the moonlighting hours in the Tobit equation. Selectivity biases are usually present in labor supply studies unless specific assumptions regarding the distribution of wage offers are made. We chose not to make such assumptions for this study. Instead, we simply note that the observed mean moonlighting wage was \$3.40 per hour and the estimated mean hourly moonlighting wage was \$3.41 for moonlighters and \$3.43 for nonmoonlighters. An alternative approach would be to use a totally reduced-form Tobit equation in which no estimate of the moonlighting wage offer appears, but this would thwart any effort to compare the moonlighting supply elasticity estimated from empirical work with the theoretical elasticity.

[14] $L_0$ is considered an independent variable which, according to the simple theory, is fixed for each individual; across individuals it is a parameter which can take on many values. The question of when $L_0$ is "fixed" (before or after he chooses his first job) is critical because if he is able to choose from a set of first jobs which offers a range of working hours, then utility maximization would require that the best combination of $L_0$ and $L_m$ be chosen. Our theory, however, views $L_0$ as fixed and not subject to manipulation by the individual. We observe that a large proportion of full time jobs generally demand some fixed commitment around 35 to 40 hours per week and that this artifact is an important feature of the *U.S.* labor market.

[15] Equation (17) as a Tobit index can also be viewed in the following instructive way: moonlighting, according to the theory, occurs when the moonlighting wage offer $w_m$ exceeds the second-job reservation wage $w_m^r$. The reservation wage for an individual may plausibly be made a function of $w_0$, $L_0$, and $A_0$, which formally

TABLE 2—COMPARISON OF SIMPLE THEORY AND EQUATION (17)[a]

| Partial Derivative | From simple theory | From equation (17): Specification $A$ | Specification $B$ |
|---|---|---|---|
| $\frac{\partial L_m}{\partial w_m}$ | $\frac{U_x}{\Lambda} - L_m\left[\frac{\Lambda_{11}}{\Lambda}\right]$ | $\alpha_1 + \alpha_4 L_0$ | $\beta_1$ |
| $\frac{\partial L_m}{\partial w_0}$ | $-L_0\left[\frac{\Lambda_{11}}{\Lambda}\right]$ | $\alpha_2 - \alpha_4 L_0$ | $\beta_2 + \beta_4 L_0$ |
| $\frac{\partial L_m}{\partial L_0}$ | $-1 + \left[\frac{\Lambda_{11}}{\Lambda}\right](w_m - w_0)$ | $\alpha_3 + \alpha_4(w_m - w_0)$ | $\beta_3 + \beta_4 w_0$ |
| $\frac{\partial L_m}{\partial A_0}$ | $-\left[\frac{\Lambda_{11}}{\Lambda}\right]$ | $\alpha_5$ | $\beta_5$ |

[a] For purposes of exposition, and to distinguish the two models, let the coefficients of equation (17) be $\alpha$ for specification of $A$ and $\beta$ for specification of $B$.

derivatives with equations (11) through (14) provides some testable hypotheses of the simple theory.

Equation (17) was actually estimated separately for two alternative specifications: in specification $A$, the interaction term $I_0$ was $(w_m - w_0)L_0$; in specification $B$ the interaction term was $w_0 L_0 + Z_0$, where $Z_0$ is labor income earned by members of the family other than the head of the household, so that $I_0$ was in effect total family labor income less moonlighting income. We chose to use alternative specifications because the different interaction terms yield different implications about the moonlighting supply curve. In specification $A$, the pure substitution term (in the neighborhood of equilibrium) is a linear function of $L_m$ and $L_0$, while in specification $B$ the pure substitution term is a linear function of $L_m$ only. Table 2 establishes the crucial links between the theoretical model and the empirical work.

Table 3 presents the results of fitting the *IDP* data and the computed moonlighting wage, equation (16), to both specifications of equation (17) using the Tobit procedure.

accounts for their presence in equation (17). If $\Phi$ is the cumulative distribution function for the second-job reservation wage $w_m^r$, then $\Phi(w_m) = P(w_m^r \leq w_m)$ = the probability of moonlighting given a moonlighting offer of $w_m = F$ (the normalized Tobit index).

Unlike many labor supply studies, the estimated effect on the supply of secondary labor to changes in the wage, primary hours, and nonlabor income variables is remarkably insensitive to the particular specification, i.e., $A$ or $B$. Note that the coefficients of $w_m$ and $w_0$ are statistically insignificant in specification $A$ while they are significant in specification $B$. Yet as Table 4 shows, the estimated changes in $L_m$ due to marginal changes in the variables $w_m$, $w_0$, $L_0$, and $A_0$ (evaluated at the mean value of the independent variables taking just moonlighters) are not statistically different.

## IV. Test of the Simple Theory

The simple theory was based on an individual for whom $L_m > 0$; for this individual the Tobit index is the moonlighting supply curve. The simple theory can be tested against the data by noting the relationships among the estimated coefficients of equation (17), as presented in Table 2.

For each specification a hypothesis about each partial derivative was constructed by setting the expression for that partial derivative from equation (17) equal

| (3) | $H_0$: $\hat{\alpha}_3+(\hat{\alpha}_4+\hat{\alpha}_5)(\bar{w}_m-\bar{w}_0)+1=0$ | −11.167 | $H_0$: $\hat{\beta}_3+\hat{\beta}_4\bar{w}_0+\hat{\beta}_5(\bar{w}_m-\bar{w}_0)+1=0$ | −12.216 |

[a] Variables with bars over them indicate that they are to be evaluated at the mean using the nonlimit (i.e., moonlighters) subsample.

respectively. For both specifications one cannot reject the second null hypothesis. Indeed, it seems reasonable to say that the simple theory is confirmed here. However, for both specifications, one must reject the third hypothesis, and this represents a a failure of the simple theory. This, of course, does not mean that the simple theory is to be discarded.

## V. Some Implications

As mentioned earlier, a change in an explanatory variable in a Tobit regression is likely to affect the probability of a limit response and the magnitude of nonlimit responses. How might the total supply of moonlighting labor be affected by a change in $w_m$, $w_0$, and $L_0$? The results presented in Table 3 indicate that the supply of moonlighting labor increases with the moonlighting wage rate $w_m$ and falls with primary job earnings $w_0L_0$. An increase in the moonlighting wage rate will increase the labor supplied by moonlighters and cause previous nonmoonlighters to enter the secondary market. To put this in quantitative terms, specification $A$ would predict that a 10 percent increase in the moonlighting wage rate results in moonlighters increasing their hours worked by 26.0 percent. This can be obtained easily by converting the slope in Table 4, which is conditional on $L_m>0$, to an elasticity. More importantly, unconditional expected moonlighting hours worked increase 17.7 percent while the probability of entering the secondary labor market increases by 9.6 percent.

A given increase in first-job earnings will have a negative effect, as seen by the signs on the primary wage, the primary hours, and interaction terms. However, the magnitude of the change depends upon whether the increase was affected by a change in the primary wage rate or by a change in hours worked on the primary job. The negative elasticity with respect to primary hours appears to be greater in absolute value than the negative elasticity with respect to primary wage, because a change in the latter affects only earnings but a change in the former also reduces the time available to moonlight.[17]

Family size (a proxy for consumption) is significant and positively related to moonlighting hours. Furthermore, as is consistent with the life cycle consumption

[17] There may be a certain amount of simultaneity in the determination of the first-job wage rate and first-job hours: in fact as stated earlier $w_0$ and $L_0$ may be negotiated together. In addition, we have not taken income tax liabilities into account since both $w_0$ and $w_m$ are pretax wage rates. If the avoidance of income taxes is systematically easier or more prevalent for moonlighting income than for primary income we have understated the relative return to moonlighting. If there are fixed costs associated with a moonlighting job, then the simple theory would predict a higher reservation wage and a discontinuity in an individual's moonlighting supply curve at the new reservation wage. Further, if moonlighting does occur and leisure is superior, the number of moonlighting hours offered at each such $w_m$ is greater if there are fixed costs than if there are no fixed costs. Unfortunately, it was not possible to incorporate fixed-job costs into our empirical work with the available data.

hypothesis, age which can be considered an inverse proxy for unmet family needs shows a significantly negative relationship to moonlighting hours.

# Interdependent Preferences

By Robert A. Pollak*

In this paper I set out a model of interdependent preferences—preferences which depend on other people's consumption—and examine its implications for demand behavior. It is a commonplace that preferences are influenced by other people's consumption, but this insight has never been incorporated into demand analysis in a satisfactory way. I believe that tractable models of interdependent preferences can be constructed in much the same way that the other major form of endogenous taste change, habit formation, was analyzed in my 1970 article; indeed, I suggested in that paper that the general approach used there could also be used to analyze interdependent preferences.

In Section I, I specify a short-run model of interdependent preferences, "linear" interdependence. I introduce linear interdependence in the context of the linear expenditure system by postulating that the necessary quantities depend linearly on other people's past consumption. By specifying that interdependent preferences operate through *past* consumption, I avoid the need to determine everyone's consumption simultaneously, and by working with a complete system of demand functions, I guarantee that the budget constraint will be satisfied. I consider a number of alternative specifications of the interdependence relationship, and extend the results from the linear expenditure system to more general systems of demand functions. The discussion in Section I focuses on individual behavior in the short run.

In Section II, I investigate the per capita demand functions implied by the model of interdependent preferences introduced in Section I; in Section III, the long-run or steady-state equilibrium of these per capita demand functions is characterized. I emphasize the per capita rather than the individual demand functions because the outcome of the mutual interaction of consumption and tastes which characterized interdependent preferences is manifested only in the long-run per capita demand functions.

Finally, in Section IV, I summarize the discussion of interdependent preferences, discuss simultaneous interdependence, a specification in which preferences are influenced by other people's current consumption, suggest several areas in which further work is needed, and discuss a problem which interdependent preferences poses for welfare economics.

One of the most interesting conclusions to emerge from this examination of interdependent preferences has to do with the role of expenditure distribution as a determinant of per capita consumption patterns.[1] One might expect that with interdependent preferences expenditure distribution would play a significant role. But analysis of a number of different specifications shows that this is not the case; with some it matters, while with others it does not.

Another important conclusion is that many specifications of interdependent

* University of Pennsylvania. This research was supported in part by the National Science Foundation. I am grateful to an anonymous referee for helpful comments.

[1] Throughout this paper I have refrained from using "income" to mean "total expenditure on goods and services"; instead, I have used "expenditure." The terminology takes some getting used to, especially when discussing the effect of the "distribution of expenditure" on the per capita consumption pattern.

preferences cannot be distinguished from linear habit formation on the basis of the implied per capita demand behavior. In these cases it is only by observing individual demand behavior in successive periods that we can distinguish between interdependent preferences and habit formation.

The literature on interdependent preferences in demand analysis is relatively sparse. The lead provided by James Duesenberry was never systematically explored. S. J. Prais and H. S. Houthakker (Section 2.5) discuss a model of interdependent preference in a budget study context, but their analysis refers to a single commodity and is never integrated into a theory of maximizing behavior. An interesting paper by Wulf Gaertner develops a model of interdependent preferences which parallels some of the analysis presented here.

## I. Individual Demand Functions in the Short Run

In this section I examine the individual demand functions corresponding to a number of alternative specifications of interdependent preferences. For expositional convenience, they are introduced and discussed in the context of the linear expenditure system; it is then argued that they can be generalized to a wide variety of systems of demand functions.

In the linear expenditure system the demand function of individual $r$ for good $i$ in period t is given by

$$(1) \quad \overset{r}{q}_{it} = h^{rit}(P_t, \mu_t)$$
$$= \overset{r}{b}_{it} - \frac{\overset{r}{a}_i}{p_{it}} \sum_k p_{kt}\overset{r}{b}_{kt} + \frac{\overset{r}{a}_i}{p_{it}} \overset{r}{\mu}_t$$

Individuals are identified by superscripts on $a$, $b$, $q$, and $\mu$, but everyone faces the same prices.

I propose to incorporate interdependent preferences into the linear expenditure system by postulating that some of the parameters of the demand functions depend on other people's consumption. For reasons of tractability, I shall assume that the $a$ are constant and that interdependence operates through the $b$. The most straightforward assumption is that the $b$ depend linearly on other people's consumption:

$$(2) \qquad \overset{r}{b}_{it} = \overset{r*}{b}_i + \sum_{\substack{s=1 \\ s \neq r}}^{R} \overset{rs}{\beta}_i \overset{s}{q}_{it}$$

where $R$ is the number of individuals.[2] As a specification of interdependent preferences, (2) has two major defects. First, it involves too many interdependence coefficients—$n \times R-1$ for each individual. And second, because each person's tastes depend on everyone else's current consumption, the determination of an equilibrium consumption pattern for everyone in the society is a formidable task.

Instead of specifying that each individual's preferences depend on everyone else's current consumption, I shall assume that they depend on other people's past consumption. This assumption has the merit of analytical tractability, a virtue not to be despised. It is also consistent with the belief that the acquisition of preferences is part of the process of socialization. It is tempting to argue that lagged interdependence is more plausible than simultaneous interdependence, but since nothing has been said about the length of the periods, such arguments are fragile.

To incorporate lagged interdependence into the linear expenditure system, I postulate that $\overset{r}{b}_{it}$ depends linearly on each individual's consumption of good $i$ in the previous period:

[2] One would expect the $\beta$ to be nonnegative, so that an increase in someone else's consumption of a good implies, *ceteris paribus*, an increase in its consumption by individual $r$. As in habit formation models, dynamic stability conditions imply restrictions on the $\beta$; these are discussed briefly in Section IV.

$$(3)\qquad b_{it}^{r} = b_i^{r*} + \sum_{s=1}^{R} \beta_i^{rs} q_{it-1}^{s}$$

This specification differs from (2) both because it embodies the hypothesis of *lagged* rather than simultaneous interdependence, and because the summation in (3) runs over *all* individuals, not just *all other* individuals. One might argue that pure interdependence requires the "own effect" $\beta_i^{rr}$ to be zero, and that when it is nonzero the interdependence model is contaminated by traces of habit formation, but I prefer the more general model, especially since we are free to consider pure interdependence as a special case.

The linear interdependence specification (3) involves an unmanageably large number of interdependence coefficients or "weights": unless there is a systematic relationship among the $\beta$, each individual assigns $n \times R$ independent weights. In order to reduce the number of interdependence parameters to manageable proportions, I now consider alternative assumptions about the $\beta$.

I begin by treating two closely related cases: (a), in the first, individual $r$ gives equal weight to everyone's past consumption, including his own:

$$(4a)\qquad \beta_i^{rs} = \beta_i^{r} \qquad s = 1, \ldots, R$$

and, (b), in the second, he gives equal weight to everyone else's past consumption and 0 weight to his own

$$(4b)\qquad \beta_i^{rs} = \begin{cases} \beta_i^{r} & s=1,\ldots,r-1, r+1,\ldots,R \\ 0 & s=r \end{cases}$$

In both of these cases it is possible to discuss interdependent preferences in terms of *per capita* past consumption, $\bar{q}_{it-1}$.

Under (4a), (3) becomes

$$(5a)\qquad b_{it}^{r} = b_i^{r*} + \hat{\beta}_i^{r} \bar{q}_{it-1}$$

where

$$(6)\qquad \bar{q}_{it-1} = \frac{1}{R} \sum_{s=1}^{R} q_{it-1}^{s} \quad \text{and} \quad \hat{\beta}_i^{r} = R\beta_i^{r}$$

Under (4b), it becomes

$$(5b)\qquad b_{it}^{r} = b_i^{r*} + \hat{\beta}_i^{r} \bar{q}_{it-1} - \beta_i^{r} q_{it-1}^{r}$$

In both cases, $b_{it}^{r}$ depends linearly on per capita past consumption, although in (5b) an adjustment is made for the individual's own past consumption.

Substituting (5a) or (5b) into the linear expenditure system (1) and dropping individual subscripts on $a$ and time subscripts on $p$ and $\mu$ yields the demand functions of individual $r$:[3]

$$(7a)\qquad q_{it}^{r} = b_i^{r*} - \frac{a_i}{p_i} \sum p_k b_k^{r*} + \frac{a_i}{p_i} \mu + \hat{\beta}_i^{r} \bar{q}_{it-1} - \frac{a_i}{p_i} \sum p_k \hat{\beta}_k^{r} \bar{q}_{kt-1}$$

or

$$(7b)\qquad q_{it}^{r} = b_i^{r*} - \frac{a_i}{p_i} \sum p_k b_k^{r*} + \frac{a_i}{p_i} \mu + \hat{\beta}_i^{r} \bar{q}_{it-1} - \frac{a_i}{p_i} \sum p_k \hat{\beta}_k^{r} \bar{q}_{kt-1} - \beta_i^{r} q_{it-1}^{r} + \frac{a_i}{p_i} \sum p_k \beta_k^{r} q_{kt-1}^{r}$$

Duesenberry, p. 27, points out that changes in tastes are caused by frequent contact with superior goods, not by mere knowledge of their existence. That is, a

[3] This model of interdependent preferences, like the habit model, can be extended in a number of directions. For example, per capita consumption in the more distant past may influence current tastes or $b$ may depend linearly on the previous peak of per capita consumption, with or without a "discount factor" which causes the influence of the peak to diminish as it recedes into the past. This introduces a "ratchet effect" of the type proposed by Duesenberry, p. 115. The linearity assumption can be dropped to permit $b$ to be non-linear functions of per capita consumption in the previous period, or, more generally, of per capita consumption in the more distant past.

man's preferences will be influenced more by the consumption of those with whom he has close contact than by those with whom his contact is more distant. Duesenberry's observation implies that individual demand depends on the distribution of consumption in the previous period, not just on its average; if he is correct, then the assumption that the $\beta$ are the same for all individuals is unsatisfactory and individual consumption patterns will depend on the distribution of consumption in the previous period.

I now describe several models of interdependent preferences based on the premise that individuals are arrayed in a hierarchy in which each individual's preferences are influenced by the consumption behavior of those above him. For definiteness, one can think of each individual as attempting to imitate the consumption behavior of individuals who he perceives as having higher status, but this interpretation is not necessary. Position in the hierarchy is defined in terms of who influences whom, and no sociological concepts need be invoked.[4] It is convenient to number individuals in terms of their position in the hierarchy, so that Mr. 1 is at the top and Mr. $R$ at the bottom.

A simple model of interdependent preferences can be built on the assumption that each individual is concerned only with the consumption of the man one rung above him in the hierarchy.[5] To close the model the behavior of the first man must be specified. Since there is no one above him, it could be argued that the most appropriate specification is $\beta_i^{1s}=0$ for all $s$, so that $b_{it}^1=b_i^{1*}$. This, however, implies a sharp break between the preference pattern of the first man and those immediately below him. I prefer to assume that Mr. 1's preferences depend on his own past consumption, as in the habit formation model.

A "two-class" model of interdependent preferences in which the members of the lower class ($L$) emulate the consumption standards of the upper class ($U$) is another version of the hierarchy model. Again working with the linear expenditure system, suppose that the necessary basket of an individual in the lower class depends linearly on the average consumption of those in the upper class. We could assume that for members of the upper class $b_{it}^r=b_i^{r*}$, but I prefer to postulate that their tastes are influenced by the average past consumption of their own class.

Any of the specifications of interdependent preferences can be applied to any system of demand functions locally linear in total expenditure.[6] W. M. Gorman has shown that any system of demand functions locally linear in total expenditure and derivable from a well-behaved utility function are of the form

$$(8)\quad q_{it}^r = b_i + f_i - \gamma^i \sum p_k b_k - \gamma^i f + \gamma^i \mu$$

where $\gamma^i=g_i/g$ and $f(p)$ and $g(p)$ are functions homogeneous of degree one. To introduce interdependent preferences, we postulate that the $b$ are given by one of the specifications of interdependent preferences discussed above.

More generally, any of these specifications of interdependent preferences can be applied to systems of demand functions which are non-linear in income, provided the system contains $n$ independent parameters, $b_t=(b_{1t}, \ldots, b_{nt})$: $q_t=h(P_t, \mu_t; b_t)$, but the resulting system may be nonlinear in past consumption.

[4] To simplify the exposition, I assume that there are no "ties," although these could be accommodated without altering the substance of the analysis.

[5] An individual need not recognize the entire hierarchy but only the man above him. The hypothesis is that patterns of influence are consistent with an underlying structure in which individuals are arrayed in a one-dimensional hierarchy.

[6] This is not quite true; regularity conditions may cause trouble.

## II. Per Capita Demand Functions in the Short Run

In Section I, I examined a number of alternative specifications of "linear" interdependent preferences and discussed their implications for the short-run demand behavior of an individual. In this section, I consider a society made up of individuals whose preferences are interdependent and examine the implied short-run per capita demand functions. The emphasis on per capita rather than market demand functions is a matter of form rather than substance. It is convenient to state results in this way to facilitate comparisons with both the individual demand functions of Section I and the habit formation model of my 1970 article.

Although the short-run per capita demand functions are of interest for their own sake, I treat them primarily as a bridge between the short-run individual demand functions of Section I and the long-run per capita demand functions of Section III. I emphasize the long-run per capita demand functions because the ramifications of interdependent preferences are only apparent in the long run, when the full consequences of each person's consumption on everyone else's preferences have manifested themselves.

I base the exposition on the linear expenditure system, but the results generalize immediately to any system of demand functions locally linear in total expenditure. As was pointed out in Section I, the specifications of interdependent preferences introduced there can be applied to individual demand functions which are non-linear in total expenditure. But even in the absence of interdependent preferences, the per capita demand functions implied by systems of individual demand functions non-linear in total expenditure depend on the distribution of expenditure among individuals. In Section III, when I discuss the long-run per capita demand functions, I shall focus on the effect of the distribution of expenditure among individuals on the per capita consumption pattern. In order to isolate the effect of interdependent preferences, I consider only short-run individual demand functions which are locally linear in total expenditure. In this case, provided everyone has the same marginal budget shares, if the distribution of expenditure has any influence on the long-run per capita consumption pattern, it can be attributed to interdependent preferences.

If the short-run per capita demand functions are locally linear in per capita expenditure, then the distribution of expenditure has no direct effect on the long-run consumption pattern; any influence it has must be indirect and operate through interdependent preferences. If the short-run per capita demand functions are locally linear in per capita expenditure and independent of the distribution of past consumption, then the long-run demand functions will be independent of the distribution of per capita expenditure. Under some specifications of interdependent preferences, the distribution of past consumption is a significant determinant of the short-run consumption pattern, while under others it is not. In this section I examine the short-run per capita demand functions corresponding to various specifications of interdependent preferences and see which ones fall into each category.

I opened the discussion of interdependent preferences in Section I by considering two specifications in which an individual gives equal weight to everyone else's past consumption. They differed in that one specification, (4a), gives the individual's own past consumption the same weight as anyone else's, while the other, (4b), gives it 0 weight. With the linear expenditure system, the individual demand functions corresponding to these two specifications are given by (7a) and (7b), re-

spectively. To examine the market or per capita demand functions implied by these individual demand functions, we assume that everyone has the same marginal budget shares and the same interdependence coefficients; that is,

$$(9) \qquad a_i^r = a_i \qquad r = 1, \ldots, R$$

$$(10) \qquad \beta_i^r = \beta_i \qquad r = 1, \ldots, R$$

These assumptions enable us to drop the individual superscripts on the $a$ and $\beta$. Individual differences in demand behavior reflect differences in total expenditure or differences in tastes, but the only admissible differences in tastes are differences in the $b^*$.

The per capita demand functions are obtained by summing the individual demand functions over all individuals and dividing by $R$. If each individual gives equal weight to everyone's past consumption including his own, (4a), this yields

$$(11a) \quad \bar{q}_{it} = \bar{b}_i^* - \frac{a_i}{p_i} \sum p_k \bar{b}_k^* + \frac{a_i}{p_i} \bar{\mu}_t + \hat{\beta}_i \bar{q}_{it-1} - \frac{a_i}{p_i} \sum p_k \hat{\beta}_k \bar{q}_{kt-1}$$

where $\bar{b}^*$ and $\bar{\mu}_t$ denote the average values of $b_i^{r*}$ and $\mu_t^r$:

$$(12) \qquad \bar{b}_i^* = \frac{1}{R} \sum_{s=1}^{R} b_i^{s*} \qquad \bar{\mu}_t = \frac{1}{R} \sum_{s=1}^{R} \mu_t^s$$

If each individual gives equal weight to everyone else's consumption in the previous period and 0 weight to his own, summing the individual demand functions (7b) and dividing by $R$ yields

$$(11b) \quad \bar{q}_{it} = \bar{b}_i^* - \frac{a_i}{p_i} \sum p_k \bar{b}_k^* + \frac{a_i}{p_i} \bar{\mu}_t + \overset{*}{\beta}_i \bar{q}_{it-1} - \frac{a_i}{p_i} \sum p_k \overset{*}{\beta}_k \bar{q}_{kt-1}$$

where $\beta_i^*$ is defined by

$$(13) \qquad \overset{*}{\beta}_i = (R-1)\beta_i = \hat{\beta}_i - \beta_i$$

Thus, the alternative specifications (4a) and (4b) lead to per capita demand functions which are essentially identical. It would not be surprising to find that they imply similar per capita demand functions —if the number of individuals is large and income is fairly evenly distributed, the difference between the average of everyone's past consumption and the average of everyone else's past consumption must be small. But my assertion is stronger; the per capita demand functions (11a) and (11b) differ only in that the interpretation of one coefficient in terms of individual demand functions is slightly different in the two cases. The systems of equations to be estimated from market data are indistinguishable.

In both of these cases the distribution of consumption in the previous period has no influence on the current per capita consumption pattern. In (11a), when each individual is influenced by the average of everyone's past consumption including his own, this is trivially obvious: since the individual demand functions are independent of the distribution of past consumption, so are the per capita demand functions. In (11b), when each individual is influenced by the average of everyone else's past consumption, individual demand is influenced to some degree by the distribution of past consumption, although the influence is small unless the community is small or the distribution of past consumption very unequal. In the limit, as the community grows large or as the distribution of past consumption approaches equality, the individual demand functions approach independence of the distribution of past consumption.

My claim about the per capita demand functions is not merely an assertion about these limiting cases. It does not depend on the size of the community or the degree of

inequality in the distribution of past consumption. When each individual is influenced by the average of everyone else's past consumption, the per capita demand functions depend only on average past consumption, and not on its distribution.

I now examine the implications for the per capita demand functions of the models of interdependent preferences based on a hierarchy in which each individual is influenced by the consumption behavior of those above him. Again assuming that everyone has the same $a$ and $\beta$, (9) and (10), the market demand functions, are obtained by summing over all individuals. When each individual is concerned with the consumption of the man above him in the hierarchy, one might expect the distribution of past consumption to be a major determinant of the present per capita consumption pattern. Surprisingly enough, it is not. The only parameter of the distribution of past consumption other than its average which enters the per capita demand functions is the range of the distribution, $q^1_{it-1}-q^R_{it-1}$.[7] But the range enters only in terms of the form $\bar{q}_{it-1}+(q^1_{it-1}-q^R_{it-1})/R$, and average past consumption, $\bar{q}_{it-1}$, is likely to swamp the effects of the range, since the latter is divided by $R$. Unless the community is small or the distribution of past consumption very unequal, the influence of the distribution of past consumption is small.

In the hierarchy model, the consumption pattern of each individual depends on the past consumption of the man above him, but not on anyone else's past consumption. Hence, the distribution of past consumption has a substantial impact on individual consumption patterns. But while individual demand functions depend significantly on the distribution of past consumption, the per capita demand functions do not. There is nothing paradoxical about this. In the habit models of my 1970 article, each individual's demand functions depend only on his past consumption, yet it is easy to verify that the implied per capita demand functions are independent of the distribution of past consumption. Similarly, with interdependent preferences, if each individual is concerned with the average of everyone else's past consumption, the individual demand functions depend on the distribution of past consumption but the per capita demand functions do not. In general, if the individual demand functions are independent of the distribution of past consumption, then so are the per capita demand functions. But the converse need not hold: as this example shows, the per capita demand functions may be independent of the distribution of past consumption even when the individual demand functions are not.

In the two-class models the current per capita consumption pattern does depend significantly on the distribution of past consumption. The model assumes that everyone has the same marginal budget shares, (9), and the same interdependence coefficients, (10); since the lower class's $\beta$ represent the influence of higher status individuals while the upper class's $\beta$ represent the influence of their peers, this is a very strong assumption.

### III. Long-Run Demand Functions

In this section I examine the "long-run" per capita demand functions corresponding to various specifications of interdependent preferences. The definition of the long-run or steady-state demand functions in the interdependent preferences model is essentially the same as in the habit model (see my 1970 article, p. 751). Given the per capita consumption vector of period one, the short-run per capita demand functions yield a consumption vector for period one.

[7] Strictly speaking, this is not the range of the distribution since we cannot identify $q^1$ and $q^R$ with the highest and lowest consumption in the community.

In a "steady-state" or "long-run equilibrium" the consumption vector in every subsequent period will also be equal to the consumption vector of period zero. The long-run demand functions associate a steady-state consumption pattern with every price-income situation.[8]

It is only in the long run that one can observe the full effects of interdependent preferences. In the short run, the distribution of expenditure among individuals can influence the per capita consumption pattern only if different individuals have different marginal budget shares. When the short-run individual demand functions are locally linear in expenditure and everyone has the same marginal budget shares, then the distribution of expenditure among individuals has no direct influence on the short-run per capita consumption pattern, but the distribution of expenditure can influence the long-run consumption pattern indirectly, through the interdependent preferences.

The exposition in Section II was based on the linear expenditure system. In this section, I use a more general framework, namely, demand functions locally linear in expenditure. I emphasized in Section II that the results obtained there extend immediately to this more general setting. I use it here to emphasize the similarity of the long-run per capita demand functions which arise in the model of interdependent preferences with the long-run individual demand functions of the habit formation model of my articles cited in the references.

I begin by discussing specifications of interdependent preferences in which each individual is influenced by average past consumption. There are two such specifications, (4a) and (4b), which differ only in their treatment of the individual's own past consumption. For definiteness, I shall discuss the specification in which each individual is influenced by the average of everyone else's past consumption, but since both specifications imply the same short-run per capita demand functions, they must also imply the same long-run per capita demand functions.

[8] This assumes the existence of such a steady state.

The long-run per capita demand functions can be found by solving this system of short-run demand functions under the assumption that $\bar{q}_{it}=\bar{q}_{it-1}=\bar{q}_i$, for all $i$. Mathematically, this problem is identical to one considered in my forthcoming article where it was found necessary to solve the system of short-run demand functions implied by habit formation to find the long-run demand functions. There is no need to repeat here the argument used there; I shall simply assert its conclusion.

THEOREM: *Suppose that the short-run per capita demand functions are locally linear in per capita expenditure,*

$$(14)\quad \bar{q}_{it} = b_{it} + f_i(P_t) + \gamma^i(P_t)\left[\bar{\mu}_t - f(P_t) - \sum p_{kt}b_{kt}\right]$$

*and* $b_{it}$ *is given by*

$$(15)\qquad b_{it} = \bar{b}_i^* + \beta_i\bar{q}_{it-1}$$

*Then the long-run per capita demand functions are given by*

$$(16)\quad h^i(P,\mu) = B^i(P) - \Gamma^i(P)\sum p_k B^k(P) + \Gamma^i(P)\bar{\mu}$$

*where*

$$(17)\qquad B^i(P) = \frac{\bar{b}_i^* + f_i(P)}{1-\beta_i}$$

$$(18)\qquad \Gamma^i(P) = \frac{\dfrac{\gamma^i(P)}{1-\beta_i}}{\sum \dfrac{p_k\gamma^k(P)}{1-\beta_k}}$$

With interdependent preferences one might expect the distribution of expenditure among individuals to play a significant part in determining the long-run con-

sumption pattern. Our theorem implies that this need not be true: under the specifications of interdependent preferences in which each individual is influenced by average past consumption, the long-run per capita demand functions depend only on per capita expenditure, and not on its distribution. The simplistic notion that interdependent preferences imply that the distribution of expenditure among individuals must influence the long-run consumption pattern is false. With some specifications it matters and with others it does not.

Now consider the specification in which each individual is influenced by the past consumption of the man above him in the hierarchy. Assuming only that the demand functions are locally linear in expenditure, these short-run per capita demand functions can be solved for the long-run equilibrium values, just as in the habit formation models. Thus, the long-run per capita demand functions, like their short-run counterparts, depend on per capita expenditure and on the range of the distribution of consumption. It is conceptually awkward to include the long-run consumption of individuals 1 and $R$ as arguments of the long-run per capita demand functions. We could use the habit formation results to determine the long-run consumption pattern of individual 1, and by substitution replace the $q^1$ by functions involving $\mu^1$, but since we cannot eliminate the $q^R$ in a similar manner, the form involving both $q^1$ and $q^R$ is more transparent.

Except for the terms involving the range, these demand functions are identical to those implied by the average past consumption specification, (16). In the limit, as the size of the community increases while the range of the distribution of consumption remains bounded, the terms involving the range approach zero and the demand functions approach those of the average past consumption specification. In this limiting case, the distribution of expenditure among individuals is not a determinant of the long-run consumption pattern. One must be careful, however, about applying this conclusion to large finite communities, since we would not expect the range to be independent of the size of the community.

Now consider the two-class model of interdependent preferences in which the tastes of both classes depend on the average past consumption of the upper class. Assuming linearity in expenditure and the same interdependence coefficients for both classes, the short-run per capita demand functions are easily determined. Since the behavior of the upper class is determined by habit formation, the long-run per capita demand functions of the upper class are given by the habit formation formula. Substituting this result into the short-run per capita demand function for the lower class yields the long-run consumption pattern of the lower class. It is easily seen that in the two-class model the long-run per capita consumption pattern does depend on the distribution of expenditure between classes.

In the two-class model the distribution of expenditure plays a significant role in determining the long-run consumption pattern. I shall not discuss "class" models with more than two classes, but one would expect distribution to matter if the number of classes is small. The two-class model is a polar case of the hierarchy specification corresponding to $R=2$. In the opposite polar case—when the number of individuals is very large and each individual's expenditure is small relative to the total—the per capita demand functions approach those of the average past consumption specification.

Perhaps because interdependent preferences were introduced in the context of the consumption function where they were generally supposed to lead to models in which the distribution of wealth or income influenced saving, it is widely believed that

interdependent preferences imply that the consumption pattern depends on the distribution of expenditure among individuals. After investigating a number of specifications of interdependent preferences, it is clear that whether or not the distribution of expenditure influences the long-run consumption pattern depends on the precise specification employed, and also, in some cases, on apparently extraneous factors such as the size of the community. Certainly specifications in which individual short-run demand functions depend on the distribution of past consumption need not imply short- or long-run per capita demand functions which depend on the distribution of expenditure among individuals.

## IV. Conclusion

I begin this section by tentatively evaluating the specifications of lagged interdependent preferences introduced above and comparing them with simultaneous interdependence, a specification in which preferences are influenced by other people's current consumption. I then discuss the dynamics of interdependent preferences and describe a specification which combines interdependence and habit formation. I conclude by describing a difficulty which interdependent preferences poses for welfare economics.

All of the specifications of linear interdependent preferences I have discussed have been introduced in conjunction with specific systems of demand functions. I have relied heavily on the linear expenditure system for exposition but the results apply to all systems of demand functions locally linear in expenditure. In most cases further extensions are possible, but they often involve substantial complications and I have not considered them in detail. The emphasis on simple and specific functional forms has been deliberate and reflects more than a desire to avoid mathematical difficulties. Empirical demand analysis requires specific functional forms, and I have emphasized classes of demand functions which are suitable for econometric work.

The various models of interdependent preferences begin with assumptions about the preferences or behavior of an individual, so they are suitable for interpreting budget study data. However, I have emphasized their implications for the per capita rather than the individual demand functions because the full ramifications of interdependent preferences depend on the reciprocal interaction of all individuals, and the outcome of this interaction manifests itself only in the long-run per capita demand functions. I have focused on demand functions locally linear in expenditure, so that the distribution of expenditure has no direct effect on per capita consumption patterns, and demand functions depend linearly on other people's consumption. The linearity assumption can be weakened, but the cost in additional complexity is likely to be high.

One of the most interesting substantive results to emerge from this investigation of interdependent preferences relates to the role of income or expenditure distribution as a determinant of long-run per capita consumption patterns. Although my initial intuition was that expenditure distribution should matter, there are a number of plausible cases in which it does not. Whether expenditure distribution matters depends on the detailed structure of the specification of interdependence employed; the notion that interdependence automatically implies a significant role for expenditure distribution is false.

Economists' views of interdependent preferences have been largely shaped by Duesenberry's simultaneous specification, and some will be uncomfortable with the lagged formulation proposed here. A significant advantage of lagged interdependence is that it implies a specific gradual adjustment path from one equilibrium to

another. Subject to the usual caveat about the length of the time period, I believe this is an important consideration. Unless the periods are very long, a specification which implies an immediate adjustment from one equilibrium to another must be supplemented by an *ad hoc* adjustment mechanism; *ceteris paribus*, a theory which implies a plausible adjustment process is preferable to one which does not.

Corresponding to each specification of pure lagged interdependence (i.e., lagged interdependence untainted by habit formation) is a related specification of simultaneous interdependence. If a specification of pure lagged interdependence is replaced by the corresponding model of simultaneous interdependence—that is, by the specification obtained by replacing each lagged value by the corresponding current value—then the demand functions of the simultaneous specification are identical with the long-run demand functions of the lagged specification. With simultaneous interdependence, there is no distinction between the short and long run, because the long run works itself out in a single period.

The relative merits of lagged versus simultaneous interdependence should be judged on their empirical usefulness, so it would seem that there is little to be said. My preference is for lagged interdependence because I believe that it is more plausible than simultaneous interdependence and because it is more tractable. One defect of simultaneous interdependence is its implication that the complete adjustment from one equilibrium to another takes place in a single period, but it is misleading to characterize simultaneous interdependence as a specification in which adjustment is instantaneous: the response to changes in prices and expenditure works itself out in a single period, but this is not a serious objection if the periods are long enough, say, a decade or a generation. On the other hand, the gradual adjustment implied by lagged interdependence seems more plausible for quarterly or annual data.

The dynamics of interdependent preferences are somewhat different from those of habit formation.[9] Even though the per capita demand functions appear identical, the dynamic analysis of the per capita demand functions should be based on the individual demand functions and these are not identical. In the linear expenditure system, regularity conditions require that each individual's expenditure be at least as great as the cost of his "necessary basket." With habit formation, this depends on his own lagged consumption, and the demand system is locally stable if the $\beta$ are all less than one. With interdependent preferences, if an individual is influenced by the average of everyone's past consumption, then regularity conditions will not be satisfied for individuals at the bottom of the expenditure distribution unless the $\beta$ are substantially less than one, but if an individual is influenced by the consumption of the man above him in the expenditure hierarchy, and the distribution of expenditure among individuals does not change drastically from one period to the next, then $\beta$ slightly less than one will imply stability.

Habit formation and interdependent preferences can operate together. In particular, suppose that each individual is equally concerned with everyone else's past consumption, so that $\beta_i^{rs} = \beta_i^r$, $r \neq s$, and that $\beta_i^{rr}$ is allowed to assume a distinct value. The implied individual demand functions are slightly messy, but the short-run per capita demand functions (derived under the assumption that all individuals have the same interdependence coefficients, the same marginal budget shares, and the same habit formation coefficients)

[9] The dynamics of the habit formation model with a one-period lag are analyzed in my 1970 article. M. D. McCarthy extends these results to a more general lag structure in which the memory coefficient need not be zero.

are of the same form as those obtained under the separate hypotheses of habit formation and interdependent preferences. It follows that the long-run per capita demand functions must also be of the same form as the long-run demand functions under either hypothesis alone. Hence, on the basis of the per capita demand functions, one cannot distinguish among habit formation, interdependent preferences, and a combination of the two: to do so, we must observe individual behavior.

Because we can distinguish between interdependent preferences and habit formation by observing individual behavior, these two hypotheses are not simply alternative names for the same device for introducing more flexibility into empirical demand equations. They are empirically distinct hypotheses whose implications happen to coincide for one particular type of data, but they are clearly distinguishable.

I conclude this section by discussing a problem which arises in using interdependent preferences as a basis for welfare judgments. If an individual is a price taker in markets for *all* of the goods which enter his preference ordering, then we can infer his preferences from his market behavior. In the present context, this condition will be satisfied only if he participates in markets in which he can pay other people to consume greater or smaller amounts of various goods. If the individual regards other people's consumption as given when he makes his market decisions, then we observe "conditional demand functions" of the form $q^r = h^r(P, \mu^r; q^{\bar{r}})$, where $q^r$ denotes the individual's intertemporal consumption vector and $q^{\bar{r}}$ denotes everyone else's intertemporal consumption pattern. From these demand functions one can infer the individual's preference ordering over $q^r$ conditional on the value of $q^{\bar{r}}$; we denote the implied conditional utility function by $V^r(q^r; q^{\bar{r}})$. The complete utility function, $U^r(q)$, must be consistent with the conditional utility function; this implies

$$U^r(q) = W[V^r(q^r; q^{\bar{r}}), q^{\bar{r}}]$$

where $W_1 > 0$, but the individual's market behavior implies no further restrictions on $W$.

This is disturbing because it implies that with interdependent preferences we cannot base judgments about individual welfare on the preference ordering revealed by market behavior; to make judgments about the welfare of an individual we need more information. To forestall confusion, it should be emphasized that this conclusion is unrelated to problems of cardinal utility or interpersonal comparisons of utility. Even if we are concerned only with judgments about the welfare of individual $r$ on the basis of his own ordering of social consumption vectors, we cannot identify this ordering without more information than market behavior provides.

# Years and Intensity of Schooling Investment

By Arleen Leibowitz*

In estimating human capital earnings functions it has been assumed in the literature that during schooling years 100 percent of gross potential earnings are invested in acquiring human capital, while in on-the-job training this percentage is smaller and declines with age. The assumption that the proportion of gross potential earnings invested ($K$) is unity during schooling years is useful in empirical work. It allows the identification of an estimate of the rate of return to schooling from a regression of earnings on years of schooling.

This paper argues that contrary to the usual assumptions in the literature, the percentage of gross earnings invested may fall below 100 percent well before schooling is ended, that this percentage is likely to be correlated with years of schooling, and thus the assumption that $K=1$ yields only a biased estimate of the rate of return to schooling. In this paper, a unique data set, the Terman sample, is used to calculate earnings functions. Because the Terman sample contains data on the costs of schooling (including tuition and net opportunity costs) as well as earnings over a 20-year period for a sample of 822 men, two of the limitations of census-type data can be overcome. First, returns to schooling costs rather than schooling years have been estimated. The percentage of gross potential earnings invested in schooling has been calculated and related to earnings. In addition, problems of estimating lifetime income profiles from cross-section data are overcome with data on lifetime earnings of the Terman sample. Lifetime earnings of men in the Terman sample, who were all in the top 1 percent of the IQ distribution in childhood, are compared with earnings of average ability males, and it is argued that much of the return to high ability results from more intensive schooling and early entry into the labor force.

Section I provides a review of the literature and argues that it is necessary to know the intensity of schooling investment ($K$, the proportion of gross potential earnings invested) in order to calculate rates of return to human capital investment. Section II utilizes the Terman sample to calculate intensities of investment and to estimate earnings functions. In Section III earnings of men in the Terman sample are compared with earnings of men of average ability.

## I. Intensity of Investment

### A. *The Bias in Earnings Functions not Specifying the Intensity of Investment*

The rate of return is a central parameter in human capital analysis. Although in the theoretical development of human capital,

I also benefited from the helpful comments of G. Becker, B. Chiswick, B. Friedman, J. Mincer, S. Polachek, P. Wachtel, and the managing editor of this *Review*. This research was sponsored by a grant from The National Institute of Child Health and Human Development to the National Bureau of Economic Research and later by Grant HS01623-01 from the National Center for Health Services Research. The following paper is not an official National Bureau publication since the findings reported herein have not yet undergone the full critical review accorded the National Bureau's publications, including approval of the Board of Directors.

the rate of return on an investment is defined as that discount rate which equates the present value of returns over the lifetime of a given individual with the present value of costs of that investment (see, for example, Gary Becker, 1964, p. 39), the empirical work has generally had to rely on cross-section data. Since lifetime income histories for given individuals have only recently become available, cross-section data on people of various ages have been used to approximate lifetime earnings of an individual (see, for example, Becker, 1964, and Giora Hanoch).

A less laborious method of estimating rates of return from cross-section data was proposed by Becker and Barry Chiswick. This method also made possible simple controls for factors such as ability and other human capital investments, which were difficult to incorporate in the discounted present value approach. Becker and Chiswick reformulated the analysis in a way that allowed the rate of return to be estimated as a parameter in a regression where earnings was the dependent variable and the investment period was the independent variable. They define $K_{ij}$ to be the percent of potential earnings that individual $i$ invests in year $j$ $(0 \leq K_{ij} \leq 1)$. Then, abstracting from depreciation, gross earnings in year t can be expressed as a function of the initial stock of human capital $E_{0i}$, the series of $K_{ij}$, and the rate of return on these investments:

$$(1) \qquad E_{it} = E_{0i} \prod_{j=1}^{S} (1 + K_{ij} r_{ij})$$

But since $K_{ij} \leq 1$ and $r_{ij}$ is small, this can be written:

$$(2) \qquad \ln E_{it} = \ln E_{0i} + \sum_{j=1}^{S} K_{ij} r_{ij}$$

Assume either that all available time is invested in schooling during the "schooling years," and there are no direct costs of schooling such as tuition so that the costs are the wages foregone or, alternatively, that part-time earnings exactly offset direct schooling costs. Then $K_{ij} = 1$ for all $i$ and $j$. Assuming also that $r$ is constant over individuals and years of schooling, and that there is no postschool investment, then we have

$$(3) \qquad \ln E_{it} = \ln E_{0i} + rS_i$$

where $S_i$ is the number of investment years where $K_{ij} = 1$.

This formulation appears to allow the estimation of the rate of return to schooling investments from the relationship of a simple function of earnings and years of schooling. A further advantage of this procedure is that it allows one to hold constant in the estimating equation other forms of capital accumulation, such as ability or postschool investment. The literature which has grown up in these two areas has indeed relied heavily on the semilog functional form derived by Becker and Chiswick.[1]

The period of specialization in human capital investment, when all resources are devoted to acquiring human capital and $K = 1$, has generally been assumed coincident with the period an individual is enrolled in school (see, for example, Yoram Ben-Porath, Thomas Johnson). An exception is the work of William Haley, who explicitly allows $K$ to fall below unity before formal schooling is terminated.

Because of the prevalence of part-time schooling and market work undertaken during the schooling years, $K$ need not equal unity. However, simply dividing the coefficient $r$ by $K$ will not yield an unbiased estimate of the rate of return. A proof of this statement follows.

It is easy to show that even if $K_{it} = 1$ on average, unless $K_i$ is independent of $S_i$, $r$ in equation (3) is a biased estimate of the

[1] See, for example, Zvi Griliches and William Mason, John Hause, and Jacob Mincer (1974).

rate of return to schooling.[2] Let $\overline{K}$ be the average percentage of gross earnings invested in schooling over all individuals and all years of schooling, and $h_{it}$ be the deviation from this average for the $i$th individual in the t-th investment year.

$$K_{it} = \overline{K} + h_{it}$$

$$\sum_{t=0}^{S} K_{it} = S_i\overline{K} + \sum_{t=1}^{S} h_{it}, \qquad \sum_{it} h_{it} = 0$$

Let
$$h_i = \frac{\sum_{t=0}^{S} h_{it}}{S_i}$$

be the $i$th person's average annual deviation in percent of gross earnings invested per school year. Then equation (3) can be rewritten:

$$log\ E_{it} = log\ E_{0i} + r_1 S_i \overline{K} + r_2 S_i h_i$$

where $r_1$ is the rate of return on years of average intensity schooling and $r_2$ is the rate of return on deviations from the average intensity. From this equation, it is clear that if $S_i h_i$ and $S_i$ are correlated, one cannot in general identify the rate of return to schooling investments from a regression like equation (3) of *log* earnings on years of schooling alone, even if the average intensity of investment $\overline{K}$ is known. The omission of intensity of schooling in previous empirical estimates of earnings functions has led to biased estimates of the rate of return to schooling, for two reasons. First, the fact that average intensity $\overline{K}$ may differ from unity is ignored. The estimated coefficient $r$ is biased upward (downward) as $\overline{K}$ is greater than (less than) unity. Second, the correlation between $S_i h_i$ and $S_i$ is ignored leading to a bias in the estimated coefficient of $r_2 b$, where $b$ is the regression coefficient of $S_i h_i$ on $S_i$. Ignoring the positive relation between intensity and years of schooling imparts an upward bias to the rate of return estimated from equation (3). In Section II we estimate the correctly specified equation.[3]

### B. *The Interpretation of Years of Schooling in Earnings Functions*

Because data on the intensity of schooling investment have not been readily available, earnings functions of the form of equation (3) have been estimated. The relationship between earnings and years of schooling has been amply demonstrated. What interpretation can this relation be given? It is neither the market rental on human capital, which plays an important role in much of the theoretical analysis (see Ben-Porath), nor is it a rate of return on investment costs since years of schooling accurately reflect neither human capital stocks nor investment costs. To clarify these issues, consider two alternative ways of decomposing $E_{it}$ earnings of individual $i$ in year t. (Hereafter the subscript $i$ will be dropped.) The approaches are the market rental and rate-of-return calculations. In the market rental analysis earnings are the scalar product of a vector $H$, of quantities of various kinds of human capital possessed by the individual at time t, and the vector of markets rents, $W$, available on these various kinds of capital.

$$E_t = \sum_{j=1}^{M} W_{tj} H_j \tag{4}$$

A perfectly competitive market for human capital services is assumed and $W_{tj}$ does not vary across individuals.

An alternative approach is to consider the relationship between earnings and the cost of producing the stock of capital

[2] Chiswick, pp. 2–13a, notes that some of the variance in income may be due to the covariance of $rK$ and $S$.

[3] The derivation of equation (3) by Mincer (1974, pp. 9–11) is not dependent upon the assumption of the independence of $h_i$ and $S$. However, the Mincer proof requires that all individuals have identical present values of earnings.

which is rented in the market. Assume a production process whereby a vector of inputs $I$ is transformed into a vector of human capital outputs $H$. The production process may be characterized by the matrix $A$ which defines the linear transformation of input vector $I$ into the vector of human capital outputs $H$. The cost per unit of input is given in the vector $C$.

$$H_j = \sum_{k=1}^{N} A_{jk} I_k \tag{5}$$

$$E_t = \sum_{k=1}^{N} r_{tk} C_k I_k \tag{6}$$

where $r_{tk}$ is the rate of return for each kind of capital in year t. Assume constant returns to scale for all types of capital investments so that marginal returns equal average returns and assume also that returns are constant over time. Since an optimizing individual would equate returns on various types of capital at the margin, we can write earnings as the product of a constant rate of return on the various investments:

$$E_t = r_t \sum_{k=1}^{N} C_k I_k \tag{7}$$

Thus $r_t$ can be defined as the individual's rate of return in year t for his human capital investments:

$$r_t = \frac{\sum_{j=1}^{M} W_{tj} H_j}{\sum_{k=1}^{N} C_k I_k} \tag{8}$$

The problem in estimating equation (3) above is that years of schooling correspond most closely to a quantity of inputs $I$, whereas the rate of return calculation requires the denominator of equation (8) of which $I$ is only one part. Years of schooling is equally inappropriate for estimating the market rental of human capital $W$ (as in Johnson, p. 551) since the transformation of inputs into human capital outputs described by (5) is ignored.

### C. *The Relationship of Intensity to Years of Schooling*

While it is easy to show (see Ben-Porath, 1970) that the proportion of gross potential earnings that an individual allocates to investment decreases over his lifetime, the relationship between years and intensity of schooling across individuals is not obvious. If individuals faced identical marginal productivity and supply of funds schedules, and they chose schooling attainment randomly, we would then expect a negative correlation between intensiveness (resources per year) and extensiveness (the number of years) of schooling investment, since intensiveness and extensiveness would be substitutes in producing the (identical) total stock of human capital. However, individuals are not identical, and it seems likely that some of the factors which affect the choice of years of schooling affect the desired intensity of schooling in the same direction, leading to a positive correlation between the two.[4]

Holding ability and other factors affecting the marginal productivity of schooling constant, consider the supply curve of funds which relates the cost of financing the investment to the intensity of the investment process in a given year of schooling. For any given number of years of schooling, more intensive investment can be financed only at greater cost per unit of investment. In Figure 1 the supply of funds curve $K_2$ referring to greater intensity of investment is above curve $K_1$,

[4] Several recent papers have taken the length of the period of specialization as endogenous (Haley, Lee Lillard, Dudley Wallace and L. A. Ihnen), but most except Haley have taken the specialization period as coincident with years of schooling. Haley considers the case where the only input to investment is time, and he shows that quantity and the proportion ($K$) of human capital stocks allocated to producing more human capital declines strictly monotonically, after the period of specialization when $K=1$ (p. 934).

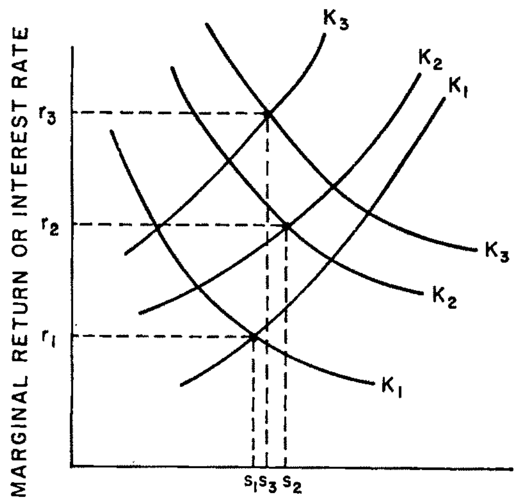

FIGURE 1. YEARS OF SCHOOLING

indicating that for any given number of years of schooling, higher interest rates must be paid to finance a greater proportion of gross potential earnings. As Becker has pointed out the funds "available to any person from the cheaper sources are usually rationed since the total demand for funds tends to exceed their supply" (1967, p. 9). Thus as increasing amounts of funds are required within a given year, students shift from gifts from relatives and grants from government or schools (which usually are subject to a maximum amount per school year) to subsidized loans from government or universities (also subject to a maximum amount per year). Finally they may turn to loans at commercial interest rates or to reduced consumption.

In Figure 1 we also see that the interest rate required to finance schooling will be a positive function of the total number of years of schooling at any given intensity. This is so because the dollar outlay corresponding to any given value of $K$ rises with schooling, which increases earnings. Secondly, since the total amount invested is rising with $S$, the interest rate should too.

Next consider the relationship between the return and the intensity of investment of a marginal year of schooling. This will determine the demand for schooling intensity for one additional year. Assume that the amount of human capital produced in a school year is a positive function of the intensity of schooling, and that employers are able to distinguish the greater human capital stocks of persons who invest more intensively.[5] Psychologists have shown that even during the time that students are ostensibly learning, they may be diverting a considerable proportion of their resources to noninvestment uses (see, for example, Lorin Anderson). These studies using both experimental and naturalistic classroom situations find that the percentage of "time on task" ($K$) is positively related to the amount learned (human capital developed). Although additional resources invested imply additions to the stock of human capital, because of the strict limit on the amount of time available to an individual, diminishing returns to producing additional capital are assumed. Figure 1 indicates that those with intensity of investments $K_1$ would get $S_1$ years of schooling and a rate of return (or borrowing cost) of $r_1$, while schooling intensity $K_2$ would be associated with $S_2$ and $r_2$. Now it is clear from Figure 1 that, holding ability constant, either positive or negative correlation between $S$ and $K$ is possible.

Ability affects the productivity of time in schooling positively, so that for any given intensity, the more able students' demand for schooling curve lies above that of the less able student. On the supply side the more able students are more likely to obtain grants or low-cost loans from their universities or from the government, and

[5] If this were not true, students could maximize the rate of return on the $j$th year of schooling by investing the minimum amount which would allow them to claim they had "completed" $j$ years of school.

to come from higher income families, who can more easily finance schooling, so that their supply of funds curves lie to the right of less able students. Both supply and demand forces thus lead the abler student to demand more years of schooling. Confronted by schooling "careers" which meet the demand of the average student, and call for no more than five or six years of training beyond the B.A., abler students can adapt by investing more intensively. Thus the rate of return on the years of schooling of abler students tends to overestimate the rate of return on the cost of schooling, since they have an incentive to invest more intensively.

Holding ability constant, there is no clear prediction about the sign of the correlation between years and intensity of schooling. Thus the direction of bias in rate of return estimates based on the assumptions $K=1$ and independent of $S$ is an empirical question. Bodies of data with cost of schooling and information on earnings are rare, which is one reason for the widespread use of equation (3) as an estimating function. However, the Terman data, which are described in the following section, can provide an illustration of some of the points raised above.

## II. Earnings Functions Based on Cost of Investment

### A. *The Terman Sample*

The Terman sample consists of persons whose measured IQ fell within the top 1 percent of the IQ distribution when they were tested as children in 1921–22.[6] This sample of 1,528 persons with IQs of 135 and above was originally selected from the population of California school children by Lewis Terman, a Stanford University psychologist. Data on the earnings and schooling of these high ability individuals were updated by resurveys in 1929, 1940, 1950, and 1960.

In the 1940 questionnaire the Terman sample members were asked to supply the name of the college they attended, the amount of scholarships and assistantships they had received and their total earnings as undergraduates. We developed a tuition series for six different colleges named for the years 1921 to 1940. Of the individuals who reported cost data, 95 percent attended the six colleges for which tuition data were obtained. Cost data were supplied by 85 percent of the sample members who attended college. Using data on age at high school graduation and age at receipt of B.A., we developed an estimate for each individual of the direct costs of his undergraduate schooling. Net indirect costs were estimated by using the data on scholarships, assistantships, and earnings. Opportunity costs were estimated to be \$1,092 per year in 1927 dollars. This figure was arrived at by using data from Terman (III, pp. 137–38) which showed that average weekly compensation for full-time jobs in 1927 was \$21 for male college students in the Terman sample and \$22 for men in the sample who were not in school. However, if actual earnings exceeded this estimate of opportunity costs, actual earnings were used as the measure of full-time earnings capacity.[7] All figures were put in constant (1947) dollars, the total cost of schooling was calculated as:

$$
\begin{aligned}
\text{Total Cost} = {} & \text{Tuition} + \text{Opportunity Cost} \\
& - \text{Total Scholarships} \\
& - \text{Total Assistantships} \\
& - \text{Earnings}
\end{aligned}
$$

Then $$K = \frac{\text{Total Cost}}{\text{Opportunity Cost}}$$

Table 1 presents mean values for the

[6] I am indebted to Robert Sears and Melieta Oden at Stanford University for making these data available.

[7] This accounts for the opportunity costs of college dropouts exceeding opportunity costs of graduates.

TABLE 1—AVERAGE COMPONENTS OF COLLEGE COSTS BY FINAL SCHOOLING LEVEL (in 1947 dollars)

| Schooling Level in 1940: | $12<S<16$ | $S=16$ | $S=16$ | $S>16$ |
|---|---|---|---|---|
| Schooling Level in 1950: | | $S=16$ | $S>16$ | |
| Average Yearly Schooling Costs | | | | |
| Tuition | 176.8 | 223.2 | 285.1 | 247.0 |
| Scholarships | 100.4 | 20.1 | 12.9 | n.a. |
| Assistantships | 202.6 | 1.08 | 20.0 | n.a. |
| Earnings | 702.2 | 450.4 | 239.0 | 330.9 |
| Opportunity Cost | 1648 | 1485 | 1472 | 1476 |
| $K$ = Percent of Opportunity Cost Invested | .55 | .84 | 1.01 | n.a. |
| Number of Observations | 87 | 134 | 19 | 248 |

*Source:* Calculated from the Terman sample.

entire sample of the cost components of undergraduate schooling as well as for $K$. For the entire sample with complete cost data, $K=.75$. Table 1 indicates that the percent of potential earnings per year invested in schooling increased with final schooling level attained.[8] For persons with less than a B.A. in 1940, the annual percent of gross earnings potential invested in schooling, $K=.55$. For those with a B.A. in 1940 who had not increased their schooling level by 1950, $K=.84$, while those who earned advanced degrees after 1940 invested 101 percent of gross annual earnings in their undergraduate schooling.[9] Thus, only the group who went on to graduate studies spent 100 percent of gross potential earnings in investment during their undergraduate years. Unfortunately, because graduate and undergraduate scholarships and assistantships awarded up to 1940 were not segregated in the data, it is not possible to calculate $K$ for persons with graduate training before 1940. Table 1 shows that those who completed a higher level of schooling spent more money per year for tuition and diverted less of their available time to the labor market during their schooling years.[10]

### B. *Earnings as a Function of Years and Cost of Schooling*

For the subsample of individuals on whom cost data are available, we first estimate the relationship between earnings and years of schooling in order to have a baseline with which to compare earnings functions based on costs.[11] The methodology is to combine income data from the three dates (1940, 1950, 1960) for all males on whom we had cost and income data to estimate a lifetime earning function. For this group each additional year of college increases wages by 6.9 percent, while each year of graduate schooling (obtained after 1940) increases income by 4.7 percent. (See Table 2, col. 1.)

If we were to assume that years and intensity of schooling were uncorrelated, we could derive an estimate of the rate of

[8] The anomalous result that those who did not complete their schooling until after 1940 had greater annual investments in undergraduate training than those who already had some graduate work by 1940 may be due to a cohort effect, since the former group is likely to be younger and have started to school in slightly better times.

[9] These estimates are similar to those computed by Paul Wachtel.

[10] The lower earnings of those who completed more years of schooling imply less time in the labor market. The earnings data imply that if they spent the same amount of time working, their wages were only 34 to 64 percent of those earned by students who completed less schooling. This seems unlikely even though the students who did not complete college may have failed to do so because of higher opportunity costs.

[11] A subsample of 306 individuals who had no more than 16 years of schooling in 1940 was used. Some had obtained graduate schooling by 1950 and 1960.

TABLE 2—ANNUAL EARNINGS AS A FUNCTION OF HUMAN CAPITAL INVESTMENTS

| | (1) | (2) | (3) | (4) |

[a] Total Cost $= \sum_{j=1}^{S} K_{ij}$

[b] $K_{Tuition}$ is the percentage of gross potential earnings spent on tuition; $K_{scholarship}$, $K_{assistantship}$, and $K_{earnings}$ are the percentages of gross potential earnings covered by scholarships, assistantships, and earnings.

return to schooling by dividing the schooling coefficient in equation (1) by .75, the sample average value of $K$.[12] That estimate of the rate of return is 9.2 percent. However, since we know years of schooling and $K$ are positively correlated, this is an overestimate, as shown above.

The availability of cost data allows a direct estimate of $r$. In column 2 of Table 2, the results of regressing earnings on sum of the elements of $K$ are presented. The estimated rate of return of 6.5 percent is surprisingly close to the estimate derived from equation (1) with the assumption that $K=1$. This occurs because of two offsetting biases. The coefficient on years of schooling in equation (1) is biased downward because no account is taken of the fact that $K<1$. However, ignoring the positive correlation between $K$ and $S$ imparts an upward bias to the coefficient. Note also that the coefficient on years of graduate schooling rises in magnitude and significance, since those who invested more in their undergraduate schooling were more likely to obtain graduate schooling. Without accounting for the greater $K$ of these people, the coefficient on college years was biased upward, and consequently, the coefficient on years of graduate schooling was biased downward.

Since a B.A. is a prerequisite to most graduate programs, this suggests that more intensive undergraduate work may provide its return by allowing entrance to a gradu-

[12] This reasoning has been applied, for example, by Lewis Solomon, pp. 28–29. Chiswick, pp. 3–15, applies a similar procedure.

ate program. The coefficients in equation (2) should not be taken to mean that the rate of return to graduate school is twice as great as the rate of return to undergraduate schooling, for reasoning as we did above, the coefficient on years of graduate school cannot be interpreted as a rate of return. And if the intensity and years of graduate schooling are positively correlated, the coefficient of equation (2) is an overestimate of the rate of return.

The relationship between earnings and the various components of average $K$—tuition, fellowships, foregone earnings, etc., can be determined. $K_{ij}$ can be decomposed into the fraction of schooling investment accounted for by opportunity costs and the fraction accounted for by the other components of $K$, as is shown below.[13] Since:

$$r\sum_{j=1}^{S_i} K_{ij} = rS_i + r\left[\frac{T_i - F_i - A_i - E_i}{O_i/S_i}\right]$$

$T_i$ = average yearly tuition for $i$th individual

$F_i$ = average yearly scholarship for $i$th individual

$A_i$ = average yearly assistantship for $i$th individual

$E_i$ = average yearly earnings for $i$th individual

$O_i$ = average yearly opportunity cost

$S_i$ = years of college

The results of estimating this equation are shown in column 3 of Table 2.

The hypotheses about the signs of these variables depend on their effects on the amount of human capital acquired per school year. Because it is assumed that greater yearly tuition will correspond to greater school inputs per academic year, the partial effect of tuition is expected to be positive.[14] The percent of opportunity cost covered by earnings is a proxy for the amount of time allocated to nonacademic uses per school year. Thus undergraduate earnings should be negatively related to human capital acquired, and thus to future income. However, undergraduate earnings may be a measure of market ability, and therefore positively related to future earnings. Assistantships usually require working in the university, therefore allocating time away from studies, and are expected to be negatively related to future earnings. However, since the most able students are the recipients of assistantships, the coefficient in the regression may be biased toward zero. Scholarship holders, like recipients of assistantships, should be an exceptionally able group. However, since scholarships do not usually require taking a university job, their net effect on later earnings should be positive.

In column 3 of Table 2 we see that although all the components of schooling intensity have the expected signs, only years and tuition intensity have significant effects on later earnings. Although scholarship holders had higher earnings than assistantship holders, or those with jobs, these differences are not significant. We can infer, at least for the very able, that a little hard work never hurt anybody (in terms of future earnings).

When a comparable equation is estimated for the 645 observations on students with at least some college, the results are quite similar in terms of the proportion of gross earnings invested in tuition, assistantships, scholarships, and earnings (see col. 4). However, the opportunity cost component of investment (represented by college years) drops in significance,

[13] A similar approach has been taken by Wachtel, p. 5a.

[14] If tuition is related positively to parental wealth and not at all to the quantity of school inputs purchased, its expected sign would still be positive. In this context, the two hypotheses cannot be differentiated.

TABLE 3—RATIO OF MEAN INCOMES OF TERMAN SAMPLE TO CENSUS BY AGE AND EDUCATION: 1940, 1950, 1960

[a] The ratio of earnings of Terman sample members of the age indicated are given relative to earnings of men who are two years older, but have the same number of years of experience in the labor market.

while the coefficient of graduate years rises.

### III. Ability, Intensity, and Earnings

Ability is a major factor shifting the marginal productivity and marginal cost curves for intensity and years of schooling. To see how high ability affects the market rental on equivalent years of schooling, earnings of the high ability males from the Terman sample are compared with earnings of males reported in the U.S. Census in this section.

Table 3 reports ratios of mean income earned by Terman sample members to mean incomes of males reporting income in the 1940, 1950, and 1960 census. The data for the Terman sample were collected from questionnaires administered in 1940, 1950, and 1960 and the data for the three years are defined as follows:

1940: Monthly wage and salary income, times 12, for sample members who were employed full time;
1950: Annual employment income in 1949 for sample members employed full time;
1960: Annual employment income in 1959 for sample members employed full time.

The income data are presented in the Appendix, along with census data for comparison. Ratios of the incomes of Terman subjects to incomes of census respondents are presented in Table 3.

In all census years for all education and age groups, average incomes of the Terman sample exceeded the mean incomes of the population at large. Where comparisons are possible of similar age-education groups in 1940, 1950, and 1960, no marked trends are discernible. That is, the ratio of Terman incomes to census incomes for individuals of a given age and education does not rise or fall in a systematic way between 1940 and 1960.

However, if a given cohort is followed through the three census years, the percentage by which their income exceeds census income shows a pronounced downward trend. (There are decreases in 16 of 18 cases.) The null hypothesis that there is no trend in the ratios (i.e., the probability of decrease $=.5$) can be rejected at the .001 level of significance, using a binomial test. Unusually high ratios in 1940 may be due to a sampling bias in the 1940 census, since earnings were reported only

for persons with no more than \$50 of other income. Because of this restriction many persons with high earnings may have been excluded, leading to a downward bias in the earnings data reported by the Census. However, since the comparisons in 1940 cover primarily the early years of the life cycle, the census sample may not be overly biased. Earnings of the Terman sample may also have been overestimated due to the assumption that sample members worked a full year. However, the trend in income ratios over time is not solely an artifact created by data deficiencies, since the ratios of Terman to census incomes also falls between 1950 and 1960. Furthermore, there is a decrease in the ratio with age within education groups in a given year in 18 of 22 cases. (The probability of obtaining this result when $p=.5$ is .002.)

Figure 2 illustrates the situation. While the earnings of Terman sample members are always greater than mean earnings from the Census, they rise at a less rapid rate.

The finding that both over time and within a given year, relative earnings of high ability males fall with age is surprising and contrasts with the findings for relative earnings over the life cycle for persons who differ in the amounts they

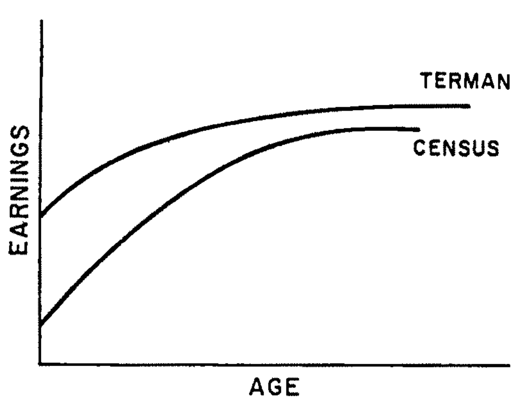

FIGURE 2. LIFETIME EARNINGS OF TERMAN AND CENSUS SAMPLE OF SAME SCHOOL AND AGE COHORT

possess of another kind of human capital—years of schooling. Mincer finds (1974, p. 70) that relative wages of the more schooled increase with age, although experience-income profiles are nearly parallel for *log* of weekly earnings and tend to converge for *log* of annual earnings. Using equation (2) to compare earnings of groups $m$ and $n$ with different initial endowments of ability, $E_0$, but the same number of years of schooling, we can write:

$$(9)\quad ln\left(\frac{E_{mj}}{E_{nj}}\right) = (ln\ E_{0m} - ln\ E_{0n}) + r_s \sum_{t=0}^{S} (K_{tm} - K_{tn}) + r_t \left[ \sum_{t=S+1}^{j-1} (K_{tm} - \delta_{tm}) - (K_{tn} - \delta_{tn}) \right] + ln\,(1 - K_{jm}) - ln\,(1 - K_{jn})$$

Schooling investments, which occur until time $S$, have been separated from postschool investments. Net postschool investments (over depreciation) earn a return of $r_t$, while the return on schooling investments is $r_s$.

Since the difference between the initial endowments and the schooling investments of the two groups remains constant over time, the only source of variation in their relative incomes over the life cycle is in the term $(K_t-\delta_t)$, reflecting postschool investments and depreciation.

In this model postschool investments are financed by lower net (observed) earnings. Thus the less steeply rising earnings profile of the Terman group implies that a vis-à-vis the census group either their postschool investments are a smaller proportion of gross potential earnings (although the value of these investments may be greater than those of the census group) or that the depreciation on their human capital is greater.

Mincer concludes (1974, ch. 2) that persons with more human capital in the form

of years of schooling also have greater money expenditures for postschool investments. But he finds a zero or negative correlation between time spent in schooling and in postschool investments. The census and Terman earnings profiles converge even more rapidly than those of various schooling groups. There are three possible explanations of this convergence:

1) Percentage of gross earnings invested in postschool investment is lower for the Terman group. The Terman group was selected because of high IQ scores; and the one thing IQ scores predict best is ability to succeed (i.e., acquire human capital) in school. Thus the "ability" criterion may be defined in such a way as to have a nonneutral effect on productivity in producing human capital in school and on the job. High IQ persons may invest more intensively during school years because they are relatively efficient at acquiring capital through schooling, while others invest more intensively on the job.

2) A more rapid rate of depreciation among the very able is another possible source of their slower rate of increase in net earnings. The impact of family characteristics which are known to be associated with higher earnings do affect initial earnings to a greater extent than later earnings. In the Terman sample (see my 1974 paper) the positive impact of family income on the subjects' earnings decreases over time. Thus the shrinking differential between high and average ability persons may be due to the falling value of family contacts with which the Terman sample was more heavily endowed than others in their age cohort.

3) Although men with the same numbers of years of schooling and continuous labor force experience should have the same number of years of labor force experience, this may not be the case in this sample. Because Terman sample members showed high IQs while still in grade school, many were accelerated in their schooling. Nearly half (49.3 percent) of the sample graduated from high school before age 17 and the mean age at college graduation was 21.5,[15] whereas the mean age for all college graduates was calculated as 24 by Hanoch.

Because of the greater intensity of their early schooling, Terman sample members have approximately two more years of market experience for any given schooling level. This would mean that the earnings function of Terman subjects diagrammed in Figure 2 should be shifted to the left to compare with persons of equivalent experience from the Census. When incomes are again computed, we see that the ratios decline less steeply over time and with age. (See Panel II, Table 3). Using "experience adjusted" comparisons, the proportion of declines from one census year to the next remains significantly different from .5 at the 1 percent level, but the fraction of declines within age groups is only significantly different from one-half at the 22 percent level. Before correcting for their accelerated schooling, the high ability sample earned from 10 percent to 280 percent more than persons with average ability and the same age and schooling. Much of the difference in lifetime earning patterns disappears when the data are adjusted to account for the greater intensity of early schooling of the high ability sample.

The much greater earnings of high ability males shown in this sample for given schooling levels contrasts with rather modest effect of ability on earnings found by Griliches, Hause, and Paul Taubman. Given the very high IQ level in the Ter-

[15] Terman, Vol. III, pp. 264–69. The modal and median value was 21.5 (my calculation) for college graduation. The mean age at high school graduation was 17.0 years (Terman, Vol. III, p. 266). Within the Terman sample the brighter students were accelerated. The students with IQs above 170 finished high school at 16.2 years on average. Of this group the 39 who completed college did so at an average age of 20.9 years.

man sample, this may imply a strong nonlinear effect of ability on earnings. Some of the differential between earnings of the high ability sample and those of average ability may be due to correlation of ability with other factors such as higher quality of schooling or higher family incomes.[16] It is not possible to test these alternatives given the lack of a detailed longitudinal data for persons of average ability comparable to the Terman study.

However, one of the causes of differences in the rates of change of income does appear to be related to different ages of labor force entry in the two samples, caused by accelerated schooling of the more able. Whereas comparisons of earnings among individuals who differ only in amount of schooling should properly be adjusted for years of market experience,[17] comparisons among individuals differing only in ability should not. One of the major routes for collecting the return to high ability would appear to be early entry to the labor force, since earnings in the early years of the life cycle have a substantial weight in the calculation of present value of income streams.

[16] The importance of the quality of schooling can be gauged by the effect of tuition on earnings within the Terman sample, as discussed in Section II above. The importance of background variables for the Terman sample is discussed in my earlier paper.

### IV. Summary

The purpose of the present paper has been to argue that years of schooling do not adequately characterize the inputs

or the outputs of the process of investing in human capital. In particular, it has been demonstrated that the rate of return on schooling investments cannot be identified from the linear regression of *log* incomes on years of schooling, even given the knowledge of the average ratio of expenditures to full-time earnings. Empirically, I have shown that this ratio, $K$, is positively related to years of schooling, and that consequently rates of return which do not account for this correlation are biased upward. Lastly it has been shown that greater intensity of schooling investments may allow high ability students to enter the labor force earlier than their peers of average ability, and that the consequent increase in discounted value of lifetime earnings may be a major route of collecting the returns to high ability.

# International Trade, Factor Market Distortions, and the Optimal Dynamic Subsidy

*By* HARVEY E. LAPAN*

International trade theorists have long favored free trade, arguing that the only proper basis for a tariff is in response to some monopoly power in international trade. Pragmatic politicians, on the other hand, wary of the wrath of their constituents, have often resorted to the use of tariffs, arguing that the protection afforded by tariffs was necessary to prevent unemployment. Recent papers on the theory of domestic distortions and optimal policy interventions can be interpreted as an attempt to reconcile these two divergent views. For example, if factors are immobile and if distortions exist in the factor markets (due to factor price rigidities), then it is argued that the optimal policy intervention is not a tariff, which destroys the equality between the marginal rate of substitution (*MRS*) and foreign rate of transformation (*FRT*), but rather a wage subsidy. This policy prescription, which recognizes the pragmatic difficulties politicians must face, offers a feasible remedy that is proved superior to the use of tariffs.

However, one can argue that the theory of optimal policy intervention goes a bit too far. While it may well be true that factors are not instantaneously mobile, they certainly do become mobile through time; capital depreciates, new workers enter the labor force, and factories can be moved intertemporally. The policies that eliminate unemployment at the same time destroy the incentives for resource reallocation (particularly if the institutional constraint stipulates that factor prices must be the same in all sectors). Thus, while the standard wage subsidy that would promote full employment may be efficient in the short run, it may prove inefficient in a dynamic setting.

Nevertheless, this does not imply that the efficient long-run policy entails no intervention; rather, it is likely that it will call for some wage subsidy which is smaller than the static optimum subsidy. It is the purpose of this paper to discuss how this dynamic optimum subsidy is determined and to specify its implications for the economic system.

## I. The Problem

For the analysis, I shall use a standard two-sector, one-factor trade model.[1] Let the two commodities be $M$ and $C$, and let $N_m$ and $N_c$ represent the labor employed in each sector. Then:

$$(1) \qquad M = F_m(N_m), \qquad C = F_c(N_c)$$
$$F_i' > 0, \quad F_i'' < 0; \qquad i = c, m$$

Furthermore, choose $C$ as the numeraire and let $P$ represent the relative price of $M$.

In addition, assume that the number of potential workers in each sector ($L_i$) is fixed at any moment, and that the total

* Associate professor of economics, Iowa State University. I am indebted to Gordon Rausser and Walter Enders for their valuable comments and suggestions.

[1] If desired, it can be assumed that other factors are used in each sector, but that these are fixed for the period under study. John Harris and Michael Todaro use this model.

supply of available workers is fixed for the period in question:

$$(2) \qquad N_i \leq L_i, \qquad i = c, m$$
$$L_c + L_m = \bar{L}$$

Institutionally, it is assumed that firms behave competitively in factor (and product) markets, so that workers are paid their marginal value product (and there cannot be excess demand for factors in either sector). However, it is also assumed that because of distortions in the factor market, the wage rate must be the same in each sector.[2] Thus, in the absence of any wage subsidies, we have:

$$(3) \qquad F_c'(N_c) = PF_m'(N_m)$$
$$N_c = L_c \quad \text{or} \quad N_m = L_m$$

The above three equations constitute a long-run equilibrium if commodity markets clear and if full employment occurs in each sector.

To simplify the analysis, let us assume that the economy in question is open and "small," so that it can trade at unchanging terms of trade.[3] Assuming the economy is in long-run equilibrium it will be producing at some point (such as $B$ in Figure 1) on the long-run production possibility frontier and will consume somewhere on the price line tangent to the production possibility frontier at $B$.[4]

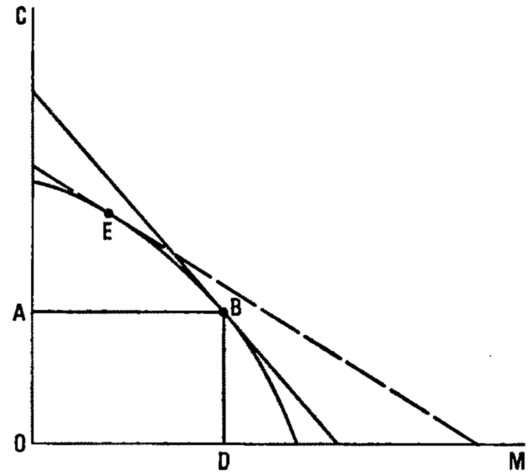

Figure 1

Now suppose that due to external conditions, the terms of trade shift; for example, assume the country was exporting $C$ and let its terms of trade improve ($P$ falls). If factors are immobile, the short-run production possibility frontier is given by $ABD$; and if no distortions exist in the factor markets, the country will continue to produce at $B$ and will benefit from the improved terms of trade. However, if factors are immobile and if factor prices must be the same in each sector, an excess supply of labor will develop in $M$ and output will occur somewhere along the open segment $AB$. Thus, it is conceivable that the improved terms of trade might leave the country worse off.

As has been demonstrated in the literature,[5] the optimal policy under these circumstances is a wage subsidy to $M$ that restores production at point $B$. Thus, if we let $\bar{P}$ be the old price at which resources were fully employed, and $P^*$ the new world price ($P^* < \bar{P}$), and if $S$ represents the optimum wage subsidy to sector $M$, then:

[2] A common alternative assumption is that "real" wages are rigid downward; the implications of this assumption depend on the definition of real wages. If they are defined in terms of $C$, then (assuming we start from full employment) a fall in $P$ will create unemployment, but a rise in $P$ will have no adverse effect on employment; opposite results hold if real wages are defined in terms of $M$. Finally, if they are defined in terms of some weighted price index, any change in $P$ will cause unemployment; this latter assumption gives results that are qualitatively the same as assuming wages must be equalized across sectors.

[3] This assumption, which is commonly used (see Jagdish Bhagwati and T. N. Srinivasan) allows us to ignore the utility function and it implies the optimum tariff is zero. The results would not be significantly altered by dropping this assumption.

[4] The long-run production possibility frontier represents the efficient production locus when labor is assumed perfectly mobile.

[5] For example, see the articles by Harry Johnson and Stephen Magee.

$$(4)\quad F_c'(L_c) = \bar{P}F_m'(L_m) = P^*F_m'(L_m)/(1-S)$$
$$S = [(\bar{P} - P^*)/\bar{P}] > 0$$

This subsidy restores full employment and enables the country to benefit from its improved terms of trade.

However, this equilibrium is still suboptimum in a long-run context since the change in the terms of trade moves the long-run optimum production point from $B$ to $E$ (in Figure 1). The obvious question is what determines intertemporal factor migration and what is the best policy to be pursued in a dynamic context? If, for example, factor migration between sectors is determined by economic factors, such as different wages or unemployment rates in each sector, then the static optimum subsidy ($S$) destroys any economic incentives for migration since, by assumption, wages are equalized between sectors while, by choice, unemployment is reduced to zero in each sector. Thus, while $S$ may be efficient in a short-run context, it may not be optimal when considered in a long-run context.[6]

Clearly, the government may have other tools at its disposal that will enable it to maintain full employment in the short run while encouraging migration in the direction of long-run equilibrium. One policy tool, suggested in Harris and Todaro, would be simply to force (or restrict) migration in a particular direction while maintaining the optimal subsidy $S$ needed to guarantee full employment of resources if there were factor market distortions (naturally, $S$ changes through time as labor migrates). However, this particular policy is most likely to be opposed because it infringes on personal liberty (and it is not likely to be very efficient if all workers are not identical).

The economic tools the government should use to maintain full employment and encourage migration depend upon the causes of migration and the institutional constraints.[7] If migration rates between sectors depend upon differences in real incomes between the sectors, the government should attempt to enlarge these differences, while at the same time pursuing a policy that maintains full employment in all sectors. For example, if we do *not* assume that wages must be equalized across sectors, then the government could apply large wage subsidies to sector $C$ (where labor is more productive) to encourage migration toward $C$, while at the same time use the minimum wage subsidy necessary to promote full employment in $M$. Even if wages *must* be equalized across sectors, the government could encourage migration to $C$ by imposing a lump sum tax on workers in $M$ (or a lump sum transfer to workers in $C$), while at the same time subsidizing wages in $M$ in order to promote full employment.

However, the above analysis is subject to criticism on several grounds. It assumes that somehow labor (effectively) demands a minimum real wage but apparently cannot effectively demand a minimum real standard of living. Specifically, the above policy can work because it assumes that a wage subsidy can be applied to sector $M$ to meet minimum wage demands and promote full employment, while (some of) the income from this wage subsidy can be removed by lump sum taxation (to promote real income differences between the sectors) without altering the wage demands of laborers in this sector.

Moreover, it can be argued that the

[6] Even if no distortions exist in factor markets, so that full employment (at $B$) occurs without subsidization, it does not follow that this solution is optimal in a long-run context when we are interested in encouraging migration between sectors.

[7] In the following analysis it is assumed that labor's marginal value product is higher in $C$, so that the government wishes to encourage migration toward $C$ while maintaining full employment in $M$ (by means of an optimum subsidy).

economic efficiency of the wage subsidy to $C$ (to promote migration) depends crucially upon the assumption that the return to labor is a pure economic rent. If each individual's labor supply decision were responsive to the wage rate, then the subsidy in $C$ would create inefficiencies by causing a discrepancy between the marginal value product of labor and that worker's marginal rate of substitution between consumption and leisure. Thus, while the wage subsidy (to the more efficient sector) attempts to promote migration, and hence dynamic efficiency, it produces static inefficiency.

Given the preceding discussion, we are skeptical about the ability of the government to costlessly reallocate resources in the economy. Thus for the remainder of the paper we explicitly assume this reallocation *cannot* be achieved costlessly, and that it is the unemployment rate (in $M$) that determines the rate of out-migration. One might rationalize this assumption by arguing that workers are risk averse and hence are unwilling to move to an unfamiliar situation (a new industry) if there is a reasonable chance of finding a job in their own sector. In addition, if it is *assumed* that wages must be the same in all sectors, the assumption that unemployment rates determine migration is equivalent to the assertion that migration is determined by the differences in expected wages between the sectors.[8]

In the analysis that follows, no explicit assumption will be made about wage rigidity in either sector; rather, the key relation will be the effect of unemployment rates on migration. The central planner's task is to determine the time path of the unemployment rate that balances the costs of unemployment (due to lost output) against the gains from migration (due to a more efficient labor allocation). However, given the institutional constraints (shown in fn. 8), the optimal wage subsidy can be inferred from the time path of the unemployment rate.

In the following section we develop the formal model and discuss the properties of an optimal solution; attention is focused on determination of the optimal unemployment rate. The principal conclusion of the section is that for long planning horizons (or small discount rates), some unemployment is desirable during early stages of the plan. Since this implies that the static subsidy is not in general dynamically efficient, the properties of the optimal dynamic subsidy are discussed in Section III.

## II. Optimal Labor Transfer

Suppose the economy is out of long-run equilibrium in the sense that labor's marginal value product is larger at full employment in sector $C$ than in $M$.[9] Furthermore, assume that labor is not instantaneously mobile, but that it moves through time in response to unemployment. We seek to determine the optimum time path of unemployment, assuming that the central planner wishes to maximize the present discounted value of the stream of income over the interval (0, T).[10,11]

Let production and factor endowments be as described in equations (1) and (2).

[8] For further discussion of the role of expected wages, see Harris and Todaro. The particular institutional assumptions we make for the analysis of Sections II and III are: (i) Wages to workers must be the same in each sector and there cannot be an excess demand for labor in either sector: $W_c = W_m = \text{Max}[F_c'(L_c), PF_m'(L_m)]$; (ii) Migration between sectors occurs due to differences in the expected wage rate, and hence responds to differences in the unemployment rate between sectors; (iii) The government controls the unemployment rate through wage subsidies. Consequently, there is a tradeoff between current output and future output in that large subsidies that promote full employment do so at the expense of migration that would ultimately raise the value of output.

[9] The difference in marginal value products may have arisen because of some exogenous change in the terms of trade. Also, the analysis could readily be generalized to handle the case in which labor's marginal value product is larger in $M$.

[10] Given the assumption the economy is open and "small," maximization of the present value of the in-

Since we wish to encourage migration towards $C$, it will always be optimal to maintain full employment there. Thus, labor migration towards $C$ can be postulated as a function of the unemployment rate ($u$) in $M$:

$$(5) \quad \frac{dL_c}{dt} = \frac{-dL_m}{dt} = \Phi(u)L_m, \quad u \in [0, 1]$$

$$\Phi(0) = 0; \quad \Phi' > 0, \ \Phi'' \leq 0$$

From the definitions and the initial conditions:

$$(6) \quad N_c = L_c, \quad N_m = L_m(1 - u)$$

$$(7) \quad F_c'(L_c(0)) > PF_m'(L_m(0))$$

Given (1), (2), (5), (6), and (7), we seek to maximize:

$$(8) \quad V = \int_0^T [F_c(L_c) + PF_m(N_m)]e^{-rt}dt$$

The central planner must determine the time path of the unemployment rate that maximizes the present discounted value of $GNP$ over the interval. Since the costs of unemployment depend upon labor's marginal value product in $M$ (and are immediate), while the benefits due to migration depend upon the differences in marginal value products between sectors and are deferred, it follows that the optimal policy (at each period) depends upon the current labor allocation, the discount rate, and the amount of time left in the planning horizon. Intuitively, we expect that unemployment is undesirable near the end of the planning horizon, but (relatively) more desirable during the early stages of the plan.[12]

Formally, we seek to determine the time path of the unemployment rate $u^*(t)$ that maximizes (8) subject to (1), (2), (5), (6), and (7). The problem as stated is an optimal control problem in one state variable $L_c(t)$ and one control variable ($u$). The Hamiltonian is:[13]

$$(9) \quad H = [F_c(L_c) + PF_m(N_m)]e^{-rt} + \lambda[L_m\Phi(u)]$$

In (9), $\lambda(t)$ represents the value, discounted to time 0, of transferring a worker at time t to sector $C$. It is convenient to define $q(t)$ to represent the value at time t of such a transfer:

$$(10) \quad q(t) = \lambda(t)e^{rt}$$

Optimizing the Hamiltonian over $u$ yields:[14]

$$(11) \quad H_u = L_m e^{-rt}[q\Phi'(u) - PF_m'(N_m)] \leq 0 \qquad u \in [0, 1]$$

In addition, for an optimum path we derive the canonical equations and the transversality condition:

$$(12) \quad \frac{dq}{dt} = [r + \Phi(u)]q - [F_c' - P(1 - u)F_m']$$

come stream is equivalent to utility maximization if either: (i) the marginal utility of income is constant and $r$ is the rate of time preference; or (ii) the country can borrow or lend on world capital markets at the rate $r$. In the latter case, the planner must still determine the optimum consumption stream. Our results would be qualitatively the same if we worked directly with a utility function.

[11] If labor supply decisions are made under utility maximization, then it is necessary to choose an objective function that contains leisure as a variable. Moreover, we could not use a community indifference curve for the analysis since expected wages would differ across sectors; rather, we would need a Bergson-type Social Welfare Function. We assume labor supply is exogenous because this is in the spirit of the previous work on factor market distortions.

[12] The unemployment rate plays a role similar to that of savings in the one-sector growth models. Savings is undesirable during the latter stages of those models unless a value is placed on the terminal capital stock.

[13] The model (1)–(8) can be used to analyze optimal labor transfer even if no factor price rigidities exist (or if it is not unemployment that induces mi ration), provided this transfer is costly due to time lost from work.

[14] We assume $F_m'(0) = \infty$; thus some employment is always desirable in $M$. Also, we assume $\Phi'(0)$ is finite; if it is not, some unemployment will always be optimal (if marginal value products differ), and the static subsidy will always be inefficient.

$$\frac{dL_c}{dt} = L_m\Phi(u) \tag{13}$$

$$q(\mathrm{T}) = 0, \qquad L_c(0) \text{ given} \tag{14}$$

By the assumptions on $F_i''$ and $\Phi''$, any path that satisfies (11)–(14) constitutes an optimum solution to the problem. In order to characterize the properties of this solution, it is helpful to construct the phase diagram for the system of differential equations in $(L_c, q)$ space.[15]

First, consider (11) which serves to determine (for given $q$, $L_c$) the optimal unemployment rate; it states that if some unemployment is desirable, then the social value attributable to an additional unemployed worker (due to induced migration and equal to $q\Phi'(u)$) should equal the value of output lost due to his unemployment. However, if $H_u < 0$ for all $u$, then full employment is desirable. Thus, the boundary between full employment and some unemployment is defined by the locus such that $H_u = 0$ for $u = 0$:

$$g(q, L_c) = [q\Phi'(0) - PF_m'(L_m)] = 0 \tag{15}$$

As shown in the Appendix, this curve (and all iso-unemployment curves) is positively sloped in $(L_c, q)$ space and is asymptotic to the line $L_c = \bar{L}$. Larger values of $q$ are associated with higher unemployment rates (given $L_c$); thus, points above the $g(q, L_c)$ locus correspond to $u > 0$, $(dL_c/dt) > 0$, whereas points below it correspond to $u = 0$, $(dL_c/dt) = 0$. The curve $AB$ in Figure 2 depicts this locus.

Next, consider how $q(\mathrm{t})$ changes along

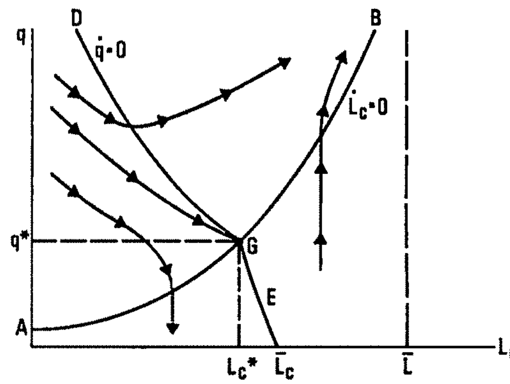

FIGURE 2

an optimum path. Since $q(\mathrm{t})$ is the value of labor transfer at time t, it must fall through time since: (i) the differences in marginal value products between sectors is a nonincreasing function of time, and (ii) as time passes, less time (for finite T) remains to reap the benefits of further labor transfers. To determine the optimal region in $(L_c, q)$ space it is useful to sketch the curve $(dq/dt) = 0$. From (11), $u$ can be written as an implicit function of $L_c$ and $q$; substitution in (12) yields:

$$\begin{aligned} dq/dt = h(q, L_c) = {} & (r + \Phi)q \\ & - [F_c' - P(1-u)F_m'] = 0 \end{aligned} \tag{16}$$

In the Appendix it is shown this locus is negatively sloped and intersects the $q = 0$ axis at $\bar{L}_c$, the labor allocation that equalizes marginal value products across sectors.[16] Points above the locus correspond to $(dq/dt) > 0$, whereas those below correspond to $(dq/dt) < 0$; this locus is sketched in Figure 2 as the curve $DE$.

Given this phase diagram, $q(0)$ must be chosen to satisfy (14), the transversality condition; from the previous arguments, $(dq/dt) < 0$ and thus $q(0)$ lies below $DE$. Once $q(0)$ is chosen, the unemployment rate (and the subsidy rate) can be de-

[15] In the following, we assume $r > 0$; even if the social discount rate is zero, it is appropriate to choose $r > 0$ if borrowing and lending can occur (at a positive rate) on world capital markets. When it is appropriate, we shall indicate the implications of assuming $r = 0$. Note that if $r = 0$, (8) will not converge as $\mathrm{T} \to \infty$. However, an equivalent problem would be to minimize the deviation of actual output from maximum output: $[F_c(\bar{L}_c) + PF_m(\bar{L}_m) - F_c(L_c) - PF_m(N_m)]$, where $F_c'(\bar{L}_c) = PF_m'(\bar{L}_m)$. Since this integral converges, and since the two problems give equivalent conditions, we can proceed with the problem as stated.

[16] For $r = 0$, the locus $(dq/dt) = 0$ intersects the $g(q, L_c) = 0$ locus at $\bar{L}_c$, and it becomes vertical at this point, intersecting the $q = 0$ locus at $\bar{L}_c$. However, for $u > 0$, the locus is negatively sloped.

duced from Figure 2. To further clarify the nature of the solution, define $(L_c^*, q^*)$ as the point ($G$ in Figure 2) at which (15) and (16) intersect. Solving these equations simultaneously yields:

$$(17)\quad F_c'(L_c^*) - PF_m'(L_m^*) = PF_m'(r/\Phi'(0)) > 0;$$
$$q^* = PF_m'/\Phi'(0), \quad L_c^* < \bar{L}_c \quad \text{for } r > 0$$

If $L_c(0) \geq L_c^*$, then full employment is always optimal, regardless of the length of the planning horizon.[17] Since $L_c^*$ is a decreasing function of $r$, it follows that for relatively large discount rates or a relatively small misallocation of labor, it does not pay to incur unemployment, and thus the static subsidy is dynamically efficient.[18]

However, if $L_c(0) < L_c^*$, the optimal solution depends on T. For this case, it can be shown that the solution to the differential equations is a saddlepoint, and that the unique path which converges to $(L_c^*, q^*)$ is the turnpike—the optimum solution for the infinite time horizon problem.[19] The infinite time horizon problem is characterized by decreasing $q(\mathrm{t})$ and increasing $L_c(\mathrm{t})$, and thus falling unemployment rates. Note that even in this case, it does not pay to equalize labor's marginal value product across sectors.[20]

For any finite T, it is clear that the choice of $q(0)$ lies below the turnpike—and thus less labor will be transferred during the planning period. Moreover, it is readily seen that the shorter the time horizon, the less desirable unemployment becomes, so that the initial unemployment rate (and $q(0)$) decreases, and the total labor transfer decreases, as T decreases. Since $q(\mathrm{t})$ falls along an optimum path, the unemployment rate falls (for $u>0$) along this path.

Moreover, the terminal stage of any finite horizon path must be characterized by full employment. To show this, assume an optimal path has been followed during the interval $(0, \mathrm{T}-\tau)$, and let $L_c(\mathrm{T}-\tau)$ represent the corresponding labor allocation. The cost of incurring unemployment during the interval $(dt)$ is $A$:

$$(18)\qquad A \simeq PL_m u F_m' d\mathrm{t}$$

The increased flow of output due to this labor transfer, assuming full employment subsequently, is:

$$(19)\qquad B = (F_c' - PF_m')\Phi(u)L_m d\mathrm{t}$$
where $dL_c = \Phi(u)L_m d\mathrm{t}$

Discounting future benefits and integrating over the remaining time yields:

$$(20)\quad B' \simeq (F_c' - PF_m')\Phi(u)L_m[(1-e^{-r\tau})/r]dt$$

If $(B'-A)$ is nonpositive for all $u$, then full employment is optimal for the whole interval. Thus, $u=0$ if:[21]

$$(21)\quad e^{-r\tau} \geq [F_c' - PF_m'(1 + [r/\Phi'(0)])] / (F_c' - PF_m') \qquad r > 0$$

If the numerator on the right-hand side is nonpositive $(L_c \geq L_c^*)$, then full employment is optimal, regardless of $\tau$. Even for

[17] By assumption, $L_c(0) < \bar{L}_c$; for $r=0$, $L_c^* = \bar{L}_c > L_c(0)$. For $r>0$, $L_c(0) \geq L_c^*$, $u \equiv 0$ is optimal; $q(0)$ is chosen so that $q(\mathrm{T})=0$. If the horizon is infinite, $q(0)$ is chosen so that $(dq/d\mathrm{t})=0$.

[18] This is analogous to the results of the one-sector growth model when there is no population growth or capital depreciation. In this model, steady-state per capita consumption is maximized at the capital-labor ratio $(k^*)$ such that $f'(k^*)=0$. However, the modified golden rule determines $\hat{k}$ such that $f'(\hat{k})=r$. If $k^* > k(0) > \hat{k}$, then the optimal policy is to do nothing; if $k(0) < \hat{k}$, some savings will be optimal for a sufficiently long planning horizon.

[19] Naturally, if T is unbounded, the transversality condition given by (14) must be suitably modified.

[20] For $r=0$, the marginal value products are equalized asymptotically. It can be shown that for the infinite horizon case, $(L_c^*, q^*)$ is not reached in finite time; thus some unemployment is always desirable, though $u(\mathrm{t}) \to 0$. The proof is omitted to save space.

[21] If $r=0$, (21) becomes $\tau \leq PF_m'/[\Phi'(0)(F_c' - PF_m')]$. Thus, for $r=0$, large $\tau$ implies $u>0$. Nevertheless, it is clear that it does not pay to equalize labor's marginal value product for any finite horizon.

$L_c(0) < L_c^*$, full employment is optimal for small $r$ (since the right-hand side of (21) is less than one). Thus, for short planning periods, and for the terminal stage of any finite plan, it is optimal to maintain full employment.

From (21), it is apparent that given $r$ and $L_c(0) < L_c^*$, there exists a $T^*$ such that for $T < T^*$, $u(t) \equiv 0$; for $T > T^*$, the initial stages of the optimal solution are characterized by positive but decreasing unemployment rates, and the terminal stage by full employment. As noted earlier, $L_c(T)$ is an increasing function of T;[22] thus (21) implies that the length of the period of full employment increases as T increases.

To recapitulate, I have shown that (for $r>0$) it is never optimal to fully reallocate labor between the sectors. Also, we have seen full employment is always optimal either if the discount rate is large or the planning horizon is short; in these cases, the static subsidy that maintains full employment is optimal. However, if $r$ is not large (or initial misallocations of labor are large) and if the planning horizon is sufficiently long, unemployment is desirable during the initial stages of the plan; for these cases, the static subsidy is inefficient. Therefore, I conclude that the static subsidy represents myopic behavior because it discourages resource reallocation.

## III. The Economic Properties of the Optimal Path

The preceding section discussed the qualitative properties of an optimal solution; we now derive some of the quantitative properties of this solution. Specifically, I shall discuss how: (i) *GNP*, (ii) employment in *M*, and (iii) the optimal subsidy change through time.

If full employment is always optimal, then all economic variables are constant, and the static subsidy is dynamically efficient. However, we have argued that this solution represents myopic behavior; in the following analysis it is assumed that some unemployment is optimal for the initial stage of the plan.

First, consider the marginal value product of labor in each sector. Given the assumptions, $F_c'(L_c) > PF_m'(L_m)$; however, since there is unemployment in *M*, it does not immediately follow that $F_c'(L_c) > PF_m'(N_m)$. From (11) and (12) we have, for $u>0$:

$$(22)\quad dq/dt = [r + \Phi - u\Phi']q - [F_c' - PF_m'(N_m)] < 0$$

since $q(t)$ falls along the optimum path. But $[\Phi - u\Phi'] \geq 0$ for all $u$, since $\Phi'' \leq 0$; thus (22) implies $F_c'(L_c) > PF_m'(N_m)$ along the optimum path.

Consider how *GNP* changes through time; I have shown that $L_c(t)$ increases and $u(t)$ decreases through time ($u>0$). From (22) it immediately follows that *GNP* is increasing through time since total employment is rising and labor is being reallocated to its more productive use.

Less apparent is how total employment in *M* changes through time—$u(t)$ is falling, as is $L_m(t)$, so the net result could be ambiguous. Without further assumptions on $\Phi''$ or $F_i''$, it does not appear possible to describe how $N_m$ changes through time. However, if $\Phi''=0$, the answer is apparent. From (11), for $u>0$:

$$(11')\quad \Phi'(u)\cdot q = \Phi'(0)\cdot q = PF_m'(N_m)$$

$$\frac{dq}{dt} < 0$$

Since $q$ decreases if $\Phi''=0$, then $PF_m'(N_m)$ must also decrease through time. Thus, for $\Phi''=0$, total employment in *M* rises along the optimum path ($u>0$).

Furthermore, this same result holds during the final portion (of the period of unemployment) for any finite horizon path.

[22] This can be demonstrated by comparing the optimal paths for the horizons T and (T+$d$T), respectively.

During this portion $u$ must be small, and since $dq/dt$ does not tend to zero as $u$ tends to zero (for finite T), it follows that $\Phi'(u)\cdot q$ and hence $PF'_m(N_m)$ must be falling.[23] Therefore, towards the end of the period of unemployment, $N_m$ must rise.

Finally, we consider the behavior of the optimum dynamic subsidy $S^*(t)$, assuming wages must be equalized across sectors. Given this assumption, the static subsidy needed to maintain full employment is:[24]

$$(23)\quad S(t) = 1 - [PF'_m(L_m)/F'_c(L_c)] > 0 \qquad L_c < \bar{L}_c$$

The dynamic subsidy depends upon the unemployment rate:

$$(24)\quad S^*(t) = 1 - [PF'_m(N_m)/F'_c(L_c)] \qquad S^* < S, \quad u > 0$$

Note that (22) implies $S^*(t)>0$. Since $S^*<S$ for $u>0$, and $S^*=S$ for $u=0$, the gap between these subsidies must eventually be eliminated for any finite horizon. However, without further assumptions, it does not appear possible to conclude that the gap monotonically decreases through time.

If we compare the fraction of wages paid by employers under each subsidy, we can determine how this ratio changes through time if the production function in $M$ is isoelastic. Specifically, let:

$$(25)\quad F_m(N_m) = N_m^{\alpha}, \qquad \alpha \in (0, 1)$$

From (23) and (24) we have, given (25):

$$(26)\quad [(1 - S^*)/(1 - S)] = [F'_m(N_m)/F'_m(L_m)] = (1 - u)^{\alpha-1} > 1, \qquad u > 0$$

Since $du/dt<0$, $(1-S^*)/(1-S)$ decreases through time, approaching one. Therefore, the ratio of the percent of wages paid by employers in the dynamic case to the static case decreases through time. However, even this does not imply $(S-S^*)$ monotonically decreases through time; without (25) it does not appear possible to reach specific conclusions.

The final issue to be resolved concerns the time path of the optimum subsidy. From (24) it is apparent that if $N_m(t)$ decreases through time, then $S^*$ also decreases. However, we have shown that $dN_m/dt>0$ for $\Phi''=0$ and for latter portions of the optimal path. Thus, the time path of $S^*(t)$ is not immediately apparent.

Further information can be obtained by considering the time derivative of (24). Letting $PF'_m=q\Phi'$ in (24) and differentiating yields:

$$(27)\quad \frac{dS^*}{dt} = \frac{-\Phi''q(du/dt)}{F'_c} - \frac{\Phi'(dq/dt)}{F'_c} + \frac{F''_c\Phi'q(dL_c/dt)}{(F'_c)^2}$$

While the sign of (27) is not known for all t, it is clear that $dS^*/dt>0$ near the end of the period of unemployment (for finite T). Therefore, the optimum subsidy must be rising during the final stages of unemployment.[25]

Rewriting (27), assuming $\Phi''=0$, yields:

$$(27')\quad dS^*/dt = -[q\Phi'/F'_c]\left[r - \frac{S^*\Phi'}{(1-S^*)} + \frac{\beta\Phi L_m}{L_c}\right]$$

where $\beta\equiv-(L_cF''_c/F'_c)>0$. Assuming $\beta$ is constant, differentiating (27′) with respect to t and evaluating it at $[dS^*/dt]=0$ yields:

[23] For any $u$, $\Phi(u)=\Phi(0)+\Phi'(0)\cdot u+\Phi''(\hat{u})\cdot u^2/2$, for some $\hat{u}\in[0, u]$. Thus, if $u$ is small, we can approximate: $\Phi(u)=\Phi'(0)\cdot u$, since $\Phi(0)=0$.

[24] Naturally, the static subsidy changes as the labor allocation changes; thus, $S(t)$ decreases as $L_c(t)$ increases.

[25] This result holds for finite T since $u$ is a continuous function of time, and thus $(dL_c/dt)$ and $(du/dt)$ tend to zero as $u\to0$. However, $(dq/dt)<0$ and $\Phi'>0$ implies $(dS^*/dt)>0$ as $u\to0$.

$$(28)\quad \left[\frac{d^2S^*}{dt^2}\right]_{dS^*/dt=0} = -\left[\frac{q\Phi'}{F_c'}\right]\left[\frac{\beta\Phi' L_m(du/dt)}{L_c} - \frac{\beta\Phi^2\overline{L}L_m}{L_c^2}\right] > 0$$

The sign of (28) follows directly from the result $du/dt<0$ for $u>0$.

Equation (28) says that once $S^*(t)$ starts to increase, it must continue to do so. It follows that for any finite horizon path, if ever $[dS^*/dt]<0$, this must occur early in the plan. For infinite horizon paths, (28) is even more informative; if $r=0$, $S^*(t)\to 0$ asymptotically. Since $S^*(t)>0$ for $u>0$, it follows that the optimal subsidy falls monotonically for the infinite horizon, zero-discount case (given the constancy of $\beta$ and $\Phi'$).

Similar results hold for $r>0$. Let $\hat{S}$ be the optimum subsidy corresponding to the stationary point $(L_c^*, q^*)$; asymptotically $S^*(t)\to\hat{S}$ for the infinite horizon path $(L_c(0)<L_c^*)$. From (17) and (24):

$$(29)\quad \hat{S} = [r/(\Phi'+r)]$$
$$\hat{S}/(1-\hat{S}) = (r/\Phi')$$

From (27′) it is clear that $dS^*/dt<0$ for $S^*\leq\hat{S}$, $u>0$; but this implies that $S^*(t)$ tends to $\hat{S}$ from above, so that $S^*(t)$ decreases monotonically for the infinite horizon case.[26]

Equations (27′), (28), and (29) imply that for any finite T, $S^*(t)>\hat{S}$, since $S^*(t)$ rises during the terminal stages of the finite horizon path. Moreover, these equations imply that for large T, $S^*(t)$ must be decreasing during early stages of the plan. This result holds since, given $L_c(0)$, the larger is T, the larger is $u(0)$, and the smaller is $S^*(0)$; further, as T increases, these values approach the rates for the infinite horizon solution, and I have already shown $S^*(t)$ decreases monotonically

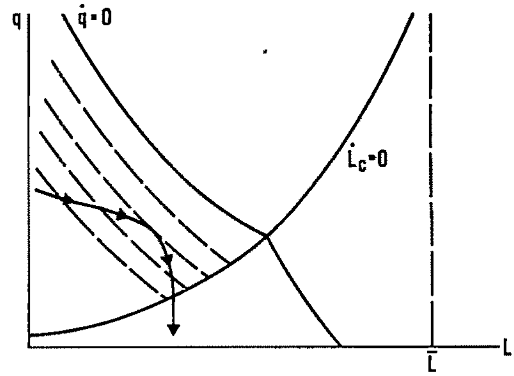

FIGURE 3

in that case. Thus, given $L_c(0)<L_c^*$, there exists a $\overline{T}$ such that for $T<\overline{T}$, $S^*(t)$ rises monotonically along the optimum path, whereas for $T>\overline{T}$, $S^*(t)$ first decreases, reaches a minimum (which exceeds $\hat{S}$), and then starts increasing (for $u>0$).

Thus, the time path of $S^*(t)$ for any finite horizon can be characterized as follows:

(i) for small T, $S^*$ is constant and equal to the static subsidy;
(ii) for intermediate values of T, $S^*(t)$ rises for $u>0$, and then remains constant for $u=0$;
(iii) for larger values of T, $S^*(t)$ initially decreases, reaches a minimum, then increases until $u=0$.[27]

Figures 3 and 4 depict these results (the dashed curves in Figure 3 represent iso-

[26] I have shown $S^*(t)>\hat{S}$; thus $S^*(t)$ approaches $\hat{S}$ monotonically from above since once $S^*$ starts to increase, it must continue to do so.

[27] For initially large misallocations of labor, it is likely that $dS^*/dt<0$ during early stages of the plan. To see this, rewrite (27′) as:

$$\frac{dS^*}{dt} = -\left(\frac{q\Phi'}{F_c'}\right)\left[r+\Phi'+\frac{\beta\Phi' uL_m}{L_c} - \frac{\Phi' F_c'}{PF_m'}\right)$$
$$= -\left(\frac{q\Phi'}{F_c'}\right)\left[r+\Phi'+\frac{\Phi'}{L_c}\left\{\beta uL_m - \left(\frac{L_cF_c'}{F_c}\right)\left(\frac{F_c}{PF_m'}\right)\right\}\right]$$

where $\Phi=\Phi'(0)\cdot u$ since $\Phi''=0$. Given T, let $L_c(0)\to 0$; then, if $F_c=L_c^{1-\beta}$, $F_c\to 0$ as $L_c\to 0$ and $(L_cF_c'/F_c)=(1-\beta)$; also $(uL_m)$ increases as $L_c(0)$ decreases and $PF_m'$ remains nonzero, given finite $\overline{L}$. Thus, there exists $\hat{L}_c$ such that for $L_c(0)<\hat{L}_c$, $(dS^*/dt)(0)<0$, indicating $S^*$ decreases during early stages of the plan.

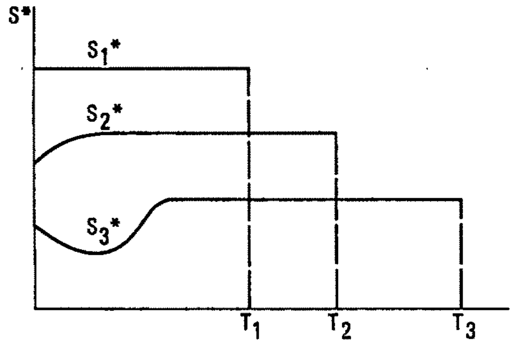

FIGURE 4

subsidy lines). Figure 4 is drawn under the assumption that $L_c(0)$ is constant; all that varies is the length of the planning horizon.[28] Finally, note that regardless of the assumptions on $\Phi''$ and $[L_cF_c''/F_c']$, $S^*(t)$ must increase during the final stages of unemployment for any finite horizon path.

## IV. Conclusion

We have seen that if resources cannot be transferred costlessly, the static subsidy is inefficient in a dynamic context unless the planning horizon is short, or discount rates are large. Thus in some sense the static subsidy represents myopic behavior. Moreover, I have shown how the optimum path can be determined and have characterized the properties of the path. In particular, we have seen that for long time horizons and low discount rates, it will always be optimal to have some unemployment initially; and the initial level of unemployment increases with the time horizon. Nevertheless, if wages must be equalized across sectors, some subsidy will always be needed; and we have discussed how this subsidy changes through time. Thus, a realistic policy must recognize that resources are not instantaneously mobile, but it must also recognize that too large a subsidy removes the incentives for intertemporal reallocation of resources.

[28] In Figure 4, the vertical broken lines are meant to indicate the end of the planning horizon, at which time the subsidy program ends.

## APPENDIX

To show iso-unemployment loci are positively sloped, consider (11), which defines an implicit function in $u$, $L_c$, and $q$. Differentiating (11) yields:

$$\text{(A1)} \quad \partial u/\partial q = -\Phi/[q\Phi'' + PL_mF_m''] > 0$$

$$\text{(A2)} \quad \partial u/\partial L_c = -[(1-u)PF_m''] \,/\, [q\Phi'' + PL_mF_m''] < 0$$

Thus, all iso-unemployment loci are positively sloped; also from (11) it is clear that as $L_c \rightarrow \overline{L}$, $q \rightarrow \infty$ for $H_u = 0$. From (A1), it is seen that points above the $g(q, L_c) = 0$ locus represent positive unemployment.

For the locus $h(q, L_c) = 0$, defined by (16), we find by differentiating:

$$\text{(A3)} \quad \partial h/\partial q = [r + \Phi] - PN_mF_m''(\partial u/\partial q) > 0$$

$$\text{(A4)} \quad \partial h/\partial L_c = -F_c'' - [P(1-u)^2 q\Phi''F_m''] \,/\, [q\Phi'' + PL_mF_m''] > 0$$

Equations (A1) and (A2) are used in deriving (A3) and (A4) since $u$ is defined as an implicit function of $L_c$ and $q$ by (11). Thus, the $(dq/dt) = 0$ locus is negatively sloped. However, for $r = 0$, $u = 0$, $(\partial h/\partial q) = 0$, indicating that the locus becomes vertical at the point where it crosses the $g(q, L_c) = 0$ locus. For $r > 0$, $u = 0$, it is readily seen from (11) that $(dq/dt) = 0$ at $q = 0$, $F_c' = PF_m'$. Finally, (A3) asserts that points above the $h(q, L_c) = 0$ locus correspond to $(dq/dt) > 0$.

# Population Density, Agricultural Technique, and Land Utilization in a Village Economy

*By* J. DIRCK STRYKER*

Various writers have explored theoretically the range of economic decisions made by peasant families or communities in less developed countries. This has involved the linking of consumption and production choices (see Chihiro Nakajima and Don Winkelman) and the inclusion of nonagricultural productive activities (see Stephen Hymer and Stephen Resnick), land tenure relationships (see P. K. Bardhan and T. N. Srinivasan), and family planning (see Philip Neher). Attention has also focused on the risk inherent in agricultural activity or participation in the wage labor force (see Peter Gould, Michael Todaro, Jerome Wolgin).

An important dimension of peasant decisions which has not been fully explored is that of time. As Gary Becker has shown, the inclusion of this variable leads to important insights into family behavior. The common practice of dividing all time into two components, labor and leisure, however, inhibits the development of many of these insights. One exception has been consideration of the cost of travel time in studies of modern transportation systems, but there has been little attention to its cost in traditional economies.

Aside from the allocation of time, the other major variable over which the peasant family or community has control is the use of land. Most rural economy models assume that the amount of land available to each farmer is fixed and that he has only to decide the intensity of its use and the pattern of cropping.[1] Although this may be appropriate for densely populated regions, it is not applicable to areas of sparse population where land is in abundant supply. Due to the primitive means of transportation existent in such areas, the major constraint on the land brought into cultivation is not the boundaries of land belonging to others but rather the cost in terms of time of traveling between the fields and the farmer's place of residence.

This paper develops a model of an agricultural economy in which the area farmed is constrained only by the time required for this travel. With labor assumed to be the only other factor input, the intensity of land use is determined by the implicit cost of this travel in terms of time. Furthermore, the cost of using land depends not only on the area farmed by each family but also on the number of persons who choose to live together in a single hamlet or village. The model is applied both to subsistence production and to commercial agriculture, and the effects of changing population and relative prices are examined. Finally, the major hypotheses generated by the model are summarized and their implications assessed.

[1] In some cases allowance is made for the existence of a land market, but it is usually assumed to be very imperfect. See, for example, Amartya Sen.

## I. A Subsistence Economy

It is assumed that the population of a given region is concentrated in nucleated villages from which farmers go to work in surrounding fields. Assuming no limit to land of homogeneous quality available for cultivation, its only cost is the time required by each farmer to go to and from his fields. If these fields are located so that the burden of travel time is shared equally by all farmers, the time required per farmer is given by a function $t(aN)$, where $a$ is the average amount of land cultivated by each and $N$ is the size of the village population, assumed to be the same as the work force. Since more travel time is required per farmer the larger is the area cultivated by each, the partial derivative of t with respect to $a$, $t_a$, is positive. The second-order partial derivative $t_{aa}$ may be either negative or positive.[2] The partial and cross-partial derivatives $t_N$ and $t_{aN}$ are reasonably assumed to be positive.

Assume further that the utility functions of all persons in the village are identical, that decisions are made by the village collectively, and that all individuals are treated in the same manner. All farmers have equal access to land, work the same number of hours, and employ the same technique.[3]

Per capita leisure $s$ is rather broadly defined to include all the time left over from a fixed number of hours $\bar{y}$ after subtracting agricultural labor $l$ and travel time t.[4] At first it is assumed that the village, with a fixed population size, seeks to maximize its leisure subject to the constraint that per capita agricultural output $x$ must equal the subsistence standard $\bar{x}$. The production function is given by $x(l, a)$ and we assume that $x_l$, $x_a$, $x_{al}>0$ and $x_{ll}$, $x_{aa}<0$, where subscripts denote first- and second-order partial derivatives.

Forming the Lagrangean expression $\bar{y}-l-t(a)-\lambda(\bar{x}-x(l, a))$ and setting the partial derivatives with respect to $l$, $a$, and $\lambda$ equal to zero, the following first-order conditions are obtained:[5]

$$-1 + \lambda x_l = 0 \tag{1}$$

$$-t_a + \lambda x_a = 0 \tag{2}$$

$$x(l, a) - \bar{x} = 0 \tag{3}$$

Equations (1) and (2) give the equilibrium condition

$$\frac{x_a}{x_l} = t_a \tag{4}$$

The ratio of the marginal products, or the marginal rate of technical substitution in production between labor and land, is equal to the marginal rate at which time can be exchanged for land by intravillage travel.

The equilibrium condition (4) is shown diagrammatically in Figure 1. For any

[2] The area of land expands more rapidly than the distance traveled as successive increments of land are brought into cultivation. If travel time is proportional to distance traveled, the cost in terms of travel time of bringing each new plot into cultivation tends to fall. Let $t=\gamma R$, where $\gamma$ is a constant and $R$ is the radius of a circle representing the total land area $A$ cultivated by the village. Since $A=\pi R^2$ and $a=A/N$, $t=\gamma'(Na)^{1/2}$, $t_a>0$ and $t_{aa}<0$. In order for the second derivative to be nonnegative, travel time must vary with at least the square of the distance traveled.

[3] This is consistent with an egalitarian type of tribal organization frequently found where land is abundant (see George Dalton).

[4] Hymer and Resnick have analyzed an agrarian economy in which the concept of leisure is extended to include such nonagricultural activities as food processing, housebuilding, recreation, and transportation. Since labor time is the only input assumed to be used in the production of these goods and services, and since we are not concerned with increases of labor productivity in this sector, we assume that welfare is a function of the inputs of time instead of the outputs resulting from its use outside of agriculture. This assumption also avoids some of the questions which Becker has raised concerning the effects of differences in the time intensity of consumption of various goods and services.

[5] Throughout the paper we are concerned only with solutions for which all variables take on nonnegative values.

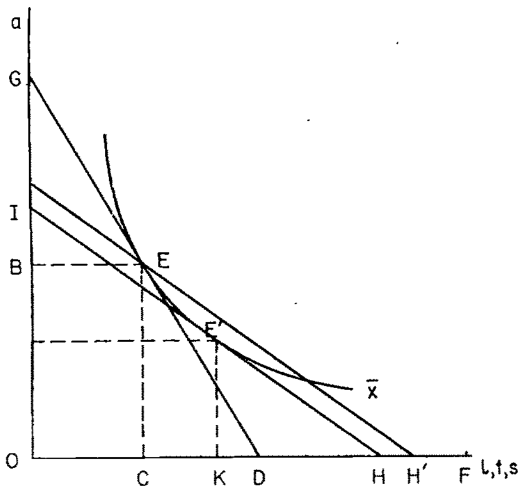

FIGURE 1

given value of $s$ and $N$ the equation $\bar{y}=s+l+t(a)$ is represented by a curve indicating the possible tradeoff between labor and agricultural land made available by the use of time for traveling. In Figure 1, $DG$ is such a curve corresponding to $DF$ of leisure, given the total time available $OF$.[6] The tangency at point $E$ of $DG$ and the isoquant corresponding to $\bar{x}$ represents the equilibrium condition of equation (4). In equilibrium $OC$ units of labor are combined with $OB$ units of land, requiring $CD$ units of travel time.

If equations (1)–(3) are differentiated totally, one obtains (5):

$$(5)\quad \begin{bmatrix} \lambda x_{ll} & \lambda x_{la} & x_l \\ \lambda x_{al} & -\mathrm{t}_{aa}+\lambda x_{aa} & x_a \\ x_l & x_a & 0 \end{bmatrix} \begin{bmatrix} dl \\ da \\ d\lambda \end{bmatrix} = \begin{bmatrix} 0 \\ \mathrm{t}_{aN}dN \\ 0 \end{bmatrix}$$

[6] For purposes of clarity and because of a lack of presumption of the direction of curvature, this equation is represented diagrammatically by a straight line. The analysis, however, does not depend on this assumption but only on satisfying second-order conditions discussed below.

In order for leisure to be maximized, it is a sufficient condition that the determinant $|D|$ of this system of equations be positive. This will occur as long as $\mathrm{t}_{aa}$, the curvature of $DG$, is either positive or, if it is negative, has an absolute value less than that of $d^2l/da^2$, the curvature of the isoquant at the point of equilibrium. Assuming that this second-order condition is satisfied, the effect of a change in population $N$ on $l$ and $a$ is seen by applying Cramer's rule:

$$(6)\qquad \frac{dl}{dN} = +\frac{\mathrm{t}_{aN}x_l x_a}{|D|} > 0$$

$$(7)\qquad \frac{da}{dN} = -\frac{\mathrm{t}_{aN}x_l^2}{|D|} < 0$$

An increase in $N$ thus changes the effective price of land in terms of time and causes the curve $DG$ in Figure 1 to be rotated about the given isoquant ($x=\bar{x}$) to $HI$, establishing a new equilibrium at $E'$.

From equations (6) and (7), $l$ increases and $a$ decreases as $N$ increases. What is the effect on the total area $A$, travel time t, and leisure time $s$? The value of $dA/dN$ is given by

$$(8)\qquad \frac{dA}{dN} = \frac{d(aN)}{dN} = N\frac{da}{dN} + a$$

Its sign will depend on the relative importance of the first term which is negative, and the second term which is positive. Similarly, the sign of $d\mathrm{t}/dN$ is given by

$$(9)\qquad \frac{d\mathrm{t}}{dN} = \mathrm{t}_N + \mathrm{t}_a\frac{da}{dN}$$

The first term is positive and indicates the increase in travel time from $CD$ to $CH'$ in Figure 1 as $N$ is increased with $a$ momentarily held constant. Intuitively, in order to accommodate the increased population each farmer must extend his fields outward if he is to farm the same total area of land. The second term shows the decrease in t

from $CH'$ to $KH$ as farmers decrease their use of land and increase that of labor along the isoquant $\bar{x}$ in response to the higher implicit price of using land.

The sign of $ds/dN$ is, however, always negative. To see this, solve equation (4) for $x_a$ and substitute both this and equation (7) in equation (6) to obtain

$$\frac{dl}{dN} = -\mathrm{t}_a \frac{da}{dN} \tag{10}$$

Differentiating the time constraint and solving for $ds/dN$,

$$\frac{ds}{dN} = -\frac{dl}{dN} - \frac{d\mathrm{t}}{dN} = -\mathrm{t}_N < 0 \tag{11}$$

since the second term of equation (9) is exactly offset by the value of $dl/dN$ from equation (10).

## II. A Commercial Economy

The transition from a purely subsistence economy to one in which most production is for commercial purposes is probably a gradual process. In the colonial empires it was often initiated by the imposition on the part of the colonial authorities of production quotas. Alternatively, a target income might be desired for the payment of taxes, a bride price, or the cost of some particular commodity. Ultimately, the expansion of demand to include a full range of goods and services originating outside the village implies the development of a utility function which includes not only leisure but also real income measured in terms of these goods and services.

It is possible to analyze each of these cases using extensions of the model. The enlargement of output due to the imposition of a quota is equivalent to an increase in $\bar{x}$. A target income might be acquired by selling surplus agricultural products, in which case the constraint becomes

$$\bar{m} = P(x(l, a) - \bar{x}) \tag{12}$$

where $\bar{m}$ is the real value of the target income and $P$ is the price ratio at which farm output may be exchanged for goods and services originating outside the village.

With the full development of commercial agriculture and of utility which is a function of real income as well as of leisure, the Lagrangian expression becomes $u(m, \bar{y}-l-\mathrm{t}(a))-\lambda(m-Px(l, a))$.[7] It is assumed that $u_m$, $u_s$, $u_{ms}>0$ and $u_{mm}$, $u_{ss}<0$. The first-order conditions now are

$$-u_s + \lambda P x_l = 0 \tag{13}$$

$$-\mathrm{t}_a u_s + \lambda P x_a = 0 \tag{14}$$

$$u_m - \lambda = 0 \tag{15}$$

$$Px(l, a) - m = 0 \tag{16}$$

yielding the equilibrium conditions

$$\frac{x_a}{x_l} = \mathrm{t}_a \tag{17}$$

$$\frac{u_s}{u_m} = Px_l \tag{18}$$

The first condition is the same as equation (4), where $x=\bar{x}$; the second condition states that the marginal rate of substitution between time and income in consumption must equal the marginal rate of substitution between time and income in production. These conditions are shown together diagrammatically in Figure 2. The upper part of that figure is similar to Figure 1. The lower part depicts a set of indifference curves with the origin at $F(\bar{y}=OF)$ and utility increasing in the southwest direction. For any function

[7] This form of the Lagrangian expression is used for convenience. Equivalent results are obtained if the expression takes the form $u(m,s)-\lambda_1(m-Px(l,a))-\lambda_2(s+l+\mathrm{t}(a)-\bar{y})$, but the analysis is mathematically more cumbersome. It is also implicitly assumed that all subsistence food requirements are met out of real income $m$. The results are substantially unchanged if, instead, the assumption is that only a surplus $(x-\bar{x})$ is sold after the village's own needs are satisfied. In this case, if $x<\bar{x}$ in equilibrium, we revert to the model described in the previous section.

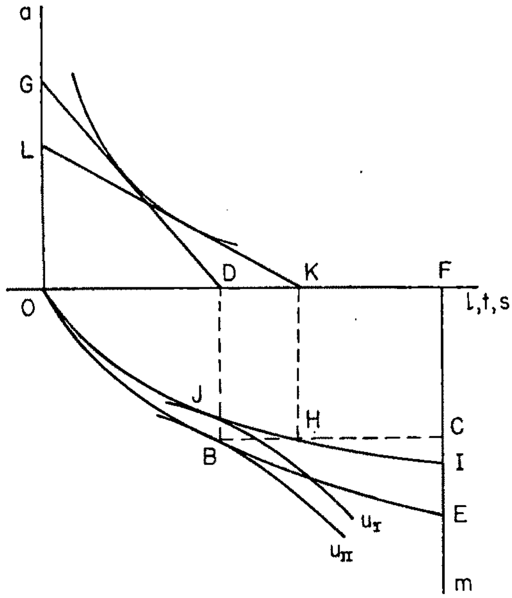

FIGURE 2

$t(aN)$ with $N$ given as a parameter of that function, there exists an equilibrium level of output for each amount of time spent in leisure. One such output multiplied by $P$ is denoted in the figure by point $B$, which corresponds to $DF$ units of leisure and $FC$ units of real income. Varying the amount of leisure traces out the curve $OE$. Differentiating $m=Px(l, a)$ and $s=\bar{y}-l-t(a)$,

$$\frac{dm}{ds} = -\frac{P(x_l dl + x_a da)}{d_l + t_a da} \tag{19}$$

Since in equilibrium $x_a = t_a x_l$, we can substitute for $x_a$ in the numerator to obtain an expression for the slope of $OE$:

$$-\frac{dm}{ds} = Px_l \tag{20}$$

Equation (18) is then represented by the tangency of $OE$ with the highest indifference curve, corresponding to a level of utility $u_{II}$.

If the area of land is fixed in supply so that $da=0$, equation (19) reduces directly to $-dm/ds=Px_l$ or $-dx/ds=x_l$. The difference between this situation and that represented by equation (20) is that in the former case $x_l$ is the slope of the usual marginal product curve of labor, while in the latter case the marginal product of labor falls less rapidly as $s$ is decreased and $l$ is increased because villagers are able to increase the total area farmed. This may be seen by examining the second derivative,

$$\frac{d^2x}{ds^2} = -\left(x_{ll}\frac{dl}{ds} + x_{la}\frac{da}{ds}\right) \tag{21}$$

If $da/ds=0$, $dl/ds=-1$ and $d^2x/ds^2=x_{ll}$. But if $da/ds<0$, the second term tends to offset the change in $x_l$ due to the first term. The value of $da/ds$ will depend, of course, on the function relating travel time to the area farmed and to the size of the village population as well as on the shape of the production function.

It is useful at this point to see what happens to the opportunity locus $OE$ when the village population changes. If $DG$ is rotated counterclockwise, indicating an increase in $N$, and kept tangent to the isoquant in Figure 2, leisure time is continually decreased for the given level of output as we move along $BC$. Point $H$ is determined, for example, by the curve $KL$. Any number of points could then be located for different levels of output and this new given level of $N$. These points all fall on the opportunity locus $OI$. The point of tangency between the indifference curve $u_I$ and $OI$ is the new equilibrium $J$.

We can examine the effects of $dN$ and $dP$ by differentiating equations (13)–(16) to obtain the system of equations shown as (22). One of the second-order conditions for maximization is satisfied if the determinant of this system is negative. We will

$$(22)\quad \begin{bmatrix} u_{ss}+\lambda P x_{ll} & t_a u_{ss}+\lambda P x_{la} & -u_{sm} & P x_l \\ t_a u_{ss}+\lambda P x_{al} & t_a^2 u_{ss}-t_{aa} u_s+\lambda P x_{aa} & -t_a u_{sm} & P x_a \\ -u_{ms} & -t_a u_{ms} & u_{mm} & -1 \\ P x_l & P x_a & -1 & 0 \end{bmatrix} \begin{bmatrix} dl \\ da \\ dm \\ d\lambda \end{bmatrix} = \begin{bmatrix} -t_N u_{ss} dN \\ t_{aN} u_s dN - t_a t_N u_{ss} dN \\ t_N u_{ms} dN \\ 0 \end{bmatrix} + \begin{bmatrix} -\lambda x_l dP \\ -\lambda x_a dP \\ 0 \\ -x dP \end{bmatrix}$$

assume this to be the case.[8]

The effects of a change in the village population are obtained by applying Cramer's Rule:

$$(23)\quad \frac{dl}{dN}=\frac{t_{aN}u_s D_{21}}{|D|} - \frac{t_N(u_{ss}D_{11}+t_a u_{ss}D_{21}-u_{ms}D_{31})}{|D|}$$

$$(24)\quad \frac{da}{dN}=\frac{t_{aN}u_s D_{22}}{|D|} - \frac{t_N(u_{ss}D_{12}+t_a u_{ss}D_{22}-u_{ms}D_{32})}{|D|}$$

$$(25)\quad \frac{dm}{dN}=\frac{t_{aN}u_s D_{23}}{|D|} - \frac{t_N(u_{ss}D_{13}+t_a u_{ss}D_{23}-u_{ms}D_{33})}{|D|}$$

where $D_{ij}$ is the cofactor of the element in the $i$th row and the $j$th column. The first term of each equation is the substitution effect resulting from the change in the implicit price of land in terms of time, initially holding per capita land, labor, and leisure constant. This term is negative for $da/dN$ and $dm/dN$.[9] It is usually positive for $dl/dN$ but could be negative if $x_{la}$ is very large. The second term shows the effect of an implicit change in the real value of total time resulting from a change in population and is always negative for $da/dN$. It is also negative for $dm/dN$ as long as $t_{aa}$ is either positive, or, if it is negative, has an absolute value less than that of $d^2l/da^2$, the curvature of the isoquant at the point of equilibrium. This was a second-order condition for maximization in the earlier model of a subsistence economy and is assumed to be satisfied here as well. Even if that condition is satisfied, however, the income effect for $dl/dN$ could still be positive if $t_{aa}$ is less than zero.

The effects of changing population on $A$, t, and $s$ may be shown by substituting equations (23) and (24) into (8), (9), and (11).

$$(26)\quad \frac{ds}{dN} = -\frac{dl}{dN}-\frac{dt}{dN} = -t_N - \frac{dl}{dN} - t_a\frac{da}{dN}$$

The terms of this equation are best understood by referring to Figure 3. Given per capita labor and land at the initial equilibrium point $M$, an increase in $N$ results in a decrease of leisure from $DF$ to $NF$, or a

[8] One term, $-u_m^2P^2(x_{ll}x_{aa}-x_{la}^2)$, in the determinant is positive if $x_{ll}x_{aa}<x_{la}^2$, a possibility if there are increasing returns to scale. The only other terms which could be positive are those including $Nt_{aa}$; these will be positive only if the value of the second derivative in these terms is negative. The second-order conditions might not be satisfied, then, in the event of strongly increasing returns to scale or a rapidly decreasing rate at which additional travel time is required as land area is increased.

[9] Explicit derivation of the signs of the terms described here is omitted, because of its mathematically cumbersome nature. Only the results are presented.

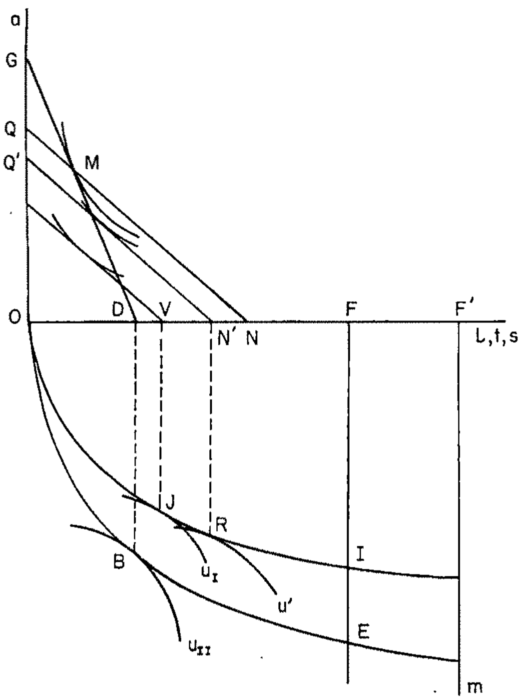

FIGURE 3

loss of $DN$. This decrease in leisure is represented by the first term $-t_N$ of equation (26). To show the substitution effect given in the last two terms of this equation, the total time available is increased by $FF'=DN$ to compensate for the loss of leisure due to the first term, and the indifference map is shifted to the right the same distance. The substitution effect, then, is shown by the movement from the initial equilibrium point $B$ to point $R$ where a shifted indifference curve is tangent to the new opportunity locus $OI$. Substituting equations (23) and (24) into equation (26), this substitution effect simplifies to

$$\frac{t_{aN}u_s u_m P}{|D|}(x_{ll}t_a - x_{la})$$

which is positive. Thus the initial leisure time represented by $DF=NF'$ is less than that indicated by $N'F'$ after the substitution effect has taken place. The movement along $OI$ from $R$ to $J$ is the income effect. Note that $J$ is the final equilibrium point representing a level of utility $u_I$ lower than that of $u_{II}$, as the indifference map is returned to its initial position. The income effect is negative for $ds$ as long as $t_{aa}$ is not negative and greater in absolute value than $d^2l/da^2$ along the isoquant, a possibility which has been ruled out. The final level of leisure represented by the distance $VF$ in Figure 3, for example, is less than $N'F'$. The total effect of a change in population on leisure will thus depend on the relative importance of the three terms of equation (26).

The effect of a change in $P$, perhaps due to an improvement in transportation to the village, is more straightforward. From the system of equations (22),

$$\text{(27)}\quad \frac{dl}{dP} = -\frac{u_m x_l D_{11} + u_m x_a D_{21}}{|D|} - \frac{xD_{41}}{|D|}$$

$$\text{(28)}\quad \frac{da}{dp} = -\frac{u_m x_l D_{12} + u_m x_a D_{22}}{|D|} - \frac{xD_{42}}{|D|}$$

Neglecting for the moment the influence of $t_{aa}$, the first term representing the substitution effect is positive in each case, and the income effect, or last term, is negative. Again, if $t_{aa}$ were negative, this would tend to offset or reverse the direction of these effects for $dl/dP$. The direction of each effect is unambiguous, however, for $dx/dP = x_l(dl/dP)+x_a(da/dP)$ as long as the condition stated earlier concerning the relationship between $t_{aa}$ and $d^2l/da^2$ continues to hold.

There is by now substantial evidence that where surplus land is available, peasant farmers have responded positively to price changes.[10] Assuming, then, that the substitution effect dominates the income effect, it is possible to compare the results shown by our model with the situation in

[10] See, for example, summaries of some of this evidence by William Jones and Raj Krishna.

which there is an absolute land constraint.

These two situations are depicted in Figure 4. The opportunity locus with land still available beyond the village is the curve $OE$. Alternatively, it may be assumed that the limits to village areal expansion are reached at point $B$, and, to the right of that point, output is given by the total product curve of labor with land held constant. This curve $BG$ lies everywhere inside of $BE$ from equation (21). To simplify the diagram, point $B$ has also been chosen as the initial equilibrium, but this assumption is not essential to the proof.

As a result of an increase in $P$, both $OE$ and $OG$ are shifted to $OC$ and $OH$, respectively. The indifference curves are drawn so that the substitution effect is greater than the income effect, and thus the new equilibrium points $I$ and $J$ lie to the right of point $B$.

If $$\left[\frac{dx}{dP}\right]_{da>0} \leq \left[\frac{dx}{dP}\right]_{da=0}$$

then $J$ must be located at, or to the right of, point $K$ along $OH$ since the level of output at $K$ is the same as at $I$. The slope of the indifference curve passing through $K$ is equal to $-u_s/u_m$. As we move from $K$ to $I$ the slope of indifference curves will decrease absolutely since $u_{ss}<0$ and $u_{ms}>0$.

But if $$\left[\frac{u_s}{u_m}\right]_K > \left[\frac{u_s}{u_m}\right]_I$$

neither $K$ nor any point along $OH$ to the right of $K$ can be a point of tangency since the slope of $OH$ at $K$ must be less than the slope of $OC$ at $I$.

Therefore, $$\left[\frac{dx}{dP}\right]_{da>0} > \left[\frac{dx}{dP}\right]_{da=0}$$

### III. Conclusions and Implications

The essential feature of the theoretical model developed in this paper is the constraint placed on the use of land, where it

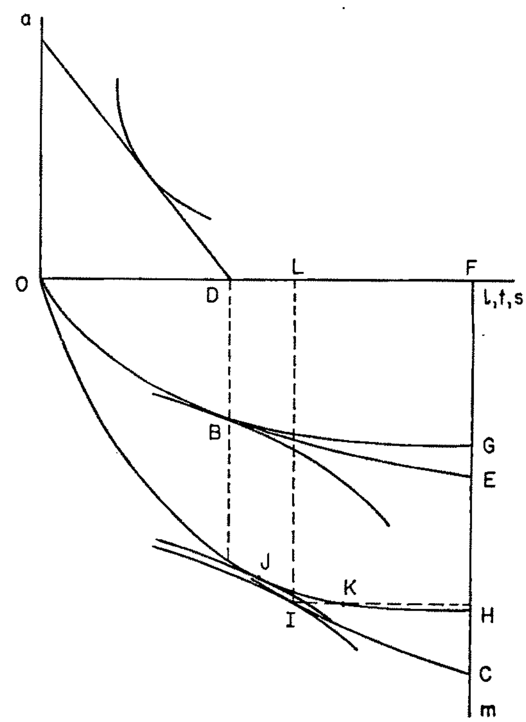

FIGURE 4

is otherwise freely available, by the time required to travel between cultivated fields and the place of residence. A major assumption is that people want to live together and are willing to sacrifice part of their scarce time in order to fulfill that desire. The degree of concentration of residences differs, however, between various societies. In some areas nuclear families live by themselves on individual farms; in others the villages or towns from which people travel to cultivate their fields are quite large.[11] The time spent traveling depends both on the means of available transport and on the relative importance which different societies attach to the frequency and extent of social contact.

Although evidence is very scattered,

[11] William Morgan has noted the existence in Africa, for example, of nucleated rural settlements of over 5000 people, requiring distances of five miles or more to be traveled regularly to reach the farthest fields.

that which exists indicates that this travel time is of considerable importance in many agricultural regions. Michael Chisholm, for example, finds that about one-third of total working hours are spent in traveling on the farm in regions as diverse as Western Europe and Nigeria. Detailed studies of rural areas by the Ministry of Planning in the Ivory Coast indicate that travel time in areas of sparse population density is between one-quarter and one-third of the total hours devoted to agriculture. These estimates are indicative of the orders of magnitude involved, but there is a need for much better information on variation in travel time between different regions and on how travel time is related to the area farmed. Because of the lack of empirical data necessary to specify the form of this relationship, it has been kept quite general in the preceding analysis.

Despite this high level of generality, however, there are a number of conclusions derived from the theory which can be summarized in the form of hypotheses susceptible to empirical verification and the implications of those hypotheses.

1. *The marginal product of land is positive and is equal to the marginal product of labor multiplied by the marginal rate at which travel time may be exchanged for land.*

Verification of this hypothesis would require estimation of both the production function and the function relating travel time to cultivated land. One implication of the hypothesis is that land is not a costless factor of production even where it is abundant, and that there may be gains from improving transportation methods within the village area—by the purchase of bicycles, for example. This improvement would result in a shift in the function involving t and *a* similar to that which would occur from a decrease in population, and thus in a substitution of land for labor. The net effect on output depends upon the type of economy, but there would be an improvement in welfare resulting from an increase in real income, leisure, or both.

2. *In a subsistence economy, an increase in population will lead to an increase in the amount of labor and a decrease in the amount of land used per person despite the availability of free land surrounding the village.*

The intensification of agriculture which accompanies a growth in population does not, therefore, depend on the limits to cultivable land. The degree of pressure exerted by population growth on land use depends on the degree of social cohesion acting to hold the village together. If the forces tending to concentrate living areas close together are strong and village transportation facilities are poor, means must be quickly employed to avoid soil depletion.[12] Where forces tending to concentrate living areas are less strong, however, relief from population pressure will occur as members of the village break away to establish new settlements outside the village perimeter.

This suggests that governments anxious to avoid soil deterioration due to population pressure in areas of otherwise abundant land should be aware of the size villages reach before significant numbers of farmers are willing to leave. It also suggests that the value of population concentration to farmers may be measured by the time required to travel to the farthest fields before they begin to found new villages, a factor which should be taken into account in the design of any resettlement schemes.[13]

[12] The problem is not so much the physical inability of farmers to maintain fertility of the soil despite shorter periods of fallow (see Ester Boserup), though this may be difficult in some ecological zones, but the speed with which new techniques must be adopted if population growth is very rapid.

[13] Chisholm, for example, finds a surprisingly consis-

3. *In a cash crop economy, an increase in population will result in a decrease in the amount of land used per capita and a decrease in the amount of per capita output despite the availability of free land surrounding the village.*

Since both income and substitution effects operate in the same direction, this conclusion is unambiguous. It implies that population growth will cause peasant farmers to shift away from production for cash, and, if carried far enough, could cause them to return to subsistence farming. The point at which villagers break off to form new settlements is of course an important determinant of the effect of population growth on production for market.

4. *In a subsistence economy, the effect of population growth is to reduce the time allocated to leisure or to nonagricultural productive activities. In a cash crop economy, the net effect on this time depends on the relative importance of terms with differing signs. There is, however, an unambiguous decrease in welfare.*

The adverse effects on welfare of population growth and increasing pressure on the land are not, therefore, confined to densely populated countries.

5. *Assuming that there is a positive production response to a change in the relative price of the cash crop, that response is greater where there is free land available than where land is fixed in supply.*

There is plentiful evidence that very rapid rates of growth in cash crop production have occurred historically in some areas of abundant land in response to the stimulus of improved transportation or favorable marketing situations.[14] Although immigrant labor has frequently been responsible for the continuation of this expansion, it has usually been initiated by the local peasantry. This growth has occurred, moreover, as a result of increases both in labor hours and in the area of land cultivated by each farmer.[15]

Although the introduction of commercial agriculture into these countries has been notably successful, there are other areas with abundant land resources where no such success has been achieved.[16] While there may be many reasons for this, such as lack of infrastructure and local agricultural experimentation as well as restrictive government policies of various sorts, my analysis suggests that attitudes towards leisure, the size of villages, the strength of forces promoting village concentration, and the degree of difficulty of traveling between village and fields may have been among the contributing factors. Where the expansion of commercial agriculture by local farmers for these reasons is unlikely, it may be possible to encourage cultivation by immigrants, provided institutional arrangements can be made for these people to obtain access to land.[17]

tent 3 to 4 kilometers of maximum travel distance to be the threshold of resettlement in many parts of the world, though there are instances in which a new settlement is established after only $1\frac{1}{2}$ or 2 kilometers is reached. Morgan, on the other hand, believes the limiting distance in Africa is 4 to 7 miles.

[14] Among the countries which have achieved these high rates of "vent-for-surplus" growth (see Hla Myint) during certain periods in the past are Burma, Ghana, Malaysia, Nigeria, South Vietnam, Thailand, and Uganda. Probably the most notable recent example is the Ivory Coast, which has sustained an average annual rate of growth of exports of agricultural and forest products since World War II of about 8 percent.

[15] See, for example, Ivory Coast, pp. 70–76, and Godwin Okurume, p. 314.

[16] Along the relatively sparsely settled coast of the Gulf of Guinea in West Africa, for example, Nigeria, Ghana, and the Ivory Coast have experienced rapid rates of growth of peasant cash crop production during various periods of their history whereas Dahomey, Togo, Liberia, Guinea, and Sierra Leone have not.

[17] The classic case of this in Africa occurred in Southern Ghana, as documented by Polly Hill.

## IV. Limitations and Extensions

The theoretical model presented here is limited to forms of traditional agriculture in which land and labor are the only inputs. Changes in agricultural technique are due to movements along a production function which is already known, at least in the neighborhood of existing methods. There is no allowance for technological improvement, which would be represented here by a shift of the production function,[18] or for the introduction of modern industrial inputs, such as chemical fertilizers. Traditional forms of capital have also not been included as an input. These could be considered as embodied forms of land and labor, leaving the conclusions of the analysis unaffected in the long run. This prevents us, however, from explicitly considering aspects of capitalization which might be related to distance within the village. In addition, it has been assumed that there is one homogeneous crop and that a single technique is employed at any given time. To conserve labor and travel time, however, several techniques might be employed simultaneously, either for the same product or for a variety of crops. Finally, the crucial assumption is made in the model that land is of homogeneous quality. To the extent that there are variations in quality, whether related or not to distance, this will obviously affect some of the results.

Extensions of the model might be directed toward the relaxation of these assumptions. Of particular importance would be the introduction of off-farm inputs, so crucial to agricultural development. There is evidence, for example, that the value of output per acre net of input costs declines much more rapidly with distance from the village center than does that of gross output.[19] Different inputs are likely to differ, furthermore, in the travel time intensity of their use. Where several crops can be cultivated using a variety of techniques, it is likely that more labor intensive methods will be employed closer to the village.[20] It is also likely that villages are situated in such a way that soil fertility declines as distance from the village center increases. Variations in the quality of land should, consequently, be introduced.

In addition, travel time is related to factors other than land area. The frequency of trips to different plots of land is often associated, for example, with seasonal factors such as the need to insure protection of crops from wild animals or birds during crucial stages of growth. Food crops, such as vegetables and herbs which may be harvested at intermittent intervals, also require more frequent trips than other crops such as grains, which are harvested within a single, fairly short space of time. Application of the model to individual situations should take into account such peculiarities.

This paper has shown that although there are advantages associated with free land, they are not costless. Unexplained, however, are many of the disadvantages related to low population density, such as the high cost of providing transportation, commercial, and government services to people in these areas. The immediate advantages of sparsely populated regions may, in fact, be outweighed by the poorer prospects for commercial agriculture, wage employment, education, and health where densities are low.

[18] Or, in terms of the analysis of Yujiro Hayami and Vernon Ruttan (pp. 82–84), a movement along a "metaproduction function," or "potential production function," which describes the technical alternatives which could be discovered given the existing fund of general scientific knowledge.

[19] See Chisholm, pp. 49–52.

[20] This pattern of cultivation has been widely observed throughout the world by such writers as W. Allen, Chisholm, Morgan, Karl Pelzer, and M. B. Gleave and H. P. White.

# Income Transfers as a Public Good: An Application to AFDC

By LARRY L. ORR*

One of the dominant features of the U.S. income transfer system is the great disparity in benefits available to similarly situated persons in different political jurisdictions. Public assistance (welfare) benefits in the most generous states are over six times as large as those in the least generous states. In recent years, this observation has increasingly provided the impetus for a movement to federalize the entire welfare program, and to establish a uniform federal benefit schedule in all states.

Unfortunately, the policy debate over federalization of welfare has proceeded in the context of an almost total ignorance of what—other than "liberality"—determines the level of income transfers in the various states under the current system.

Only recently have economists begun to develop a consistent rationale for the existence of income transfers,[1] and none of the existing theoretical models has been tested empirically. Yet, even under a federalized system, some disparities are likely to remain, since states would be free to supplement the federal payments (albeit without federal assistance), and some presumably would. Thus, it is important to understand the factors which give rise to disparate transfer levels, whether or not a wholly federal program is envisioned.

This study attempts to provide a theoretically consistent model of the federal-state transfer system in the context of a democratic decision-making framework, and provides an empirical test of that model for the largest of the existing welfare categories, Aid to Families with Dependent Children (*AFDC*). These results are useful both for understanding the structure of benefits in the existing program, and for predicting the effects on benefit levels of a variety of welfare policy options.

## I. A Theoretical Model of Redistribution

The theoretical framework treats income redistribution as a public good. The assumed rationale for redistribution is that taxpayers derive utility from increments to the income of transfer recipients. Since each taxpayer receives utility from all transfers made, but is required to pay for only a portion of the aggregate transfer cost, the theory of public goods can be applied (with certain modifications) to determine the equilibrium level of transfers. While differing in important respects from earlier models, the discussion here is very much in the spirit of the transfer models developed by Pauly, Olsen, Goldfarb, and von Furstenberg and Mueller.

In order to keep the analysis manageable, several rather stringent assumptions are made. It is assumed that:

* Director, Office of Income Security Policy Research, U.S. Department of Health, Education, and Welfare. The research reported herein benefited greatly from comments and suggestions by Edward Gramlich, Adele Massell, Irwin Garfinkel, and anonymous referees. I am also indebted to Mike Hallstrom and Jane Lee for computational assistance. I bear sole responsibility for the analysis, views, and conclusions expressed herein. Nothing contained herein represents the official policy of the U.S. Department of Health, Education, and Welfare. 

[1] See, e.g., George von Furstenberg and Dennis Mueller; Robert Goldfarb; Edgar Olsen; Mark Pauly; Harold Hochman and James Rogers; Lester Thurow; and Gordon Tullock.

1) There are two mutually exclusive groups within the transfer jurisdiction, taxpayers and recipients.

2) Transfers are financed from taxes, allocated (at the margin) among taxpayers according to exogenously determined tax shares. For simplicity, it will be assumed that all taxpayers pay an equal share of the cost of transfers.

3) All recipients receive equal amounts of transfer income.

4) Recipients' incomes enter the utility function of each taxpayer; the incomes of taxpayers enter neither the utility functions of recipients nor of other taxpayers. The first partial derivatives of each taxpayer's utility with respect to both own-income and recipients' incomes are all positive; the second partials are all negative.

5) The level of transfers is determined by majority vote of the residents of the transfer jurisdiction, including recipients.

We begin by deriving the level of transfers which would be deemed optimal by a single taxpayer with given income and tastes. By assumption 3), we can characterize the level of transfers by a single variable, $B$, the (uniform) transfer benefit per recipient per time period. By assumption 4), the $i$th taxpayer has a utility function $U_i$ of the form:

$$U_i = U_i(Y_i, Y_j) \tag{1}$$

where $Y_i$ is the after-tax income of the $i$th taxpayer, and $Y_j$ is the vector of after-transfer incomes of recipients. The utility gain (loss) to this taxpayer from a unit increase in the per recipient level of transfer $B$, is:

$$\frac{\partial U_i}{\partial B} = \frac{\partial U_i}{\partial Y_i}\cdot\frac{\partial Y_i}{\partial T_i}\cdot\frac{\partial T_i}{\partial B} + \sum_{j=1}^{p} \frac{\partial U_i}{\partial Y_j}\cdot\frac{\partial Y_j}{\partial B} \tag{2}$$

where $T_i$ is the tax liability of the $i$th taxpayer. By the assumption of equal tax shares:

$$\frac{\partial T_i}{\partial B} = \frac{p}{n} \tag{3}$$

if there are $n$ taxpayers and $p$ recipients. Setting $\partial Y_j/\partial B = 1$, $\partial Y_i/\partial T_i = -1$, and substituting $p/n$ for $\partial T_i/\partial B$, equation (2) becomes

$$\frac{\partial U_i}{\partial B} = \sum_{j=1}^{p} \frac{\partial U_i}{\partial Y_j} - \frac{\partial U_i}{\partial Y_i}\cdot\frac{p}{n} \tag{4}$$

The first-order condition for a utility maximum for the $i$th taxpayer is obtained by setting equation (4) equal to zero, or:

$$\sum_{j=1}^{p} \frac{\partial U_i}{\partial Y_j} = \frac{\partial U_i}{\partial Y_i}\cdot\frac{p}{n} \tag{5}$$

Figure 1 presents this optimality condition graphically. The function *mb* (marginal benefit) in Figure 1 gives the value of the left-hand term of equation (5) for each level of $B$. It is monotonically decreasing because by assumption (4), the taxpayer's marginal utility of transfers to each of the $p$ recipients is monotonically decreasing. The schedule *mc* (marginal cost) shows the value of the right-hand term of equation (5) as a function of $B$. It is monotonically increasing because the taxpayer has decreasing marginal utility of own-income and, therefore, his marginal utility of own-

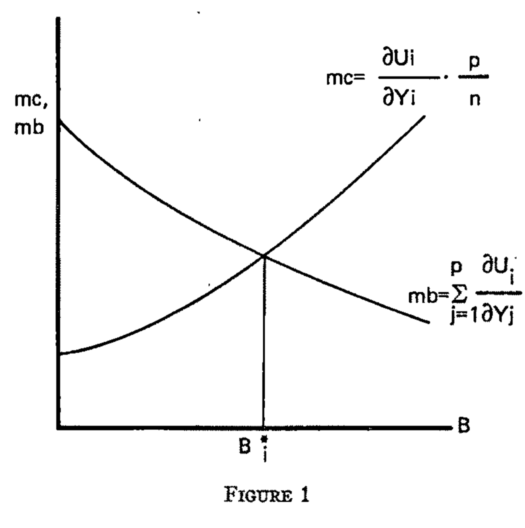

FIGURE 1

income rises with $B$ and his tax liability $T_i$.

The level of transfers which maximizes the taxpayer's utility, given his tastes, pretax income, and tax share, is given by the intersection of the two curves at $B_i^*$. At values of $B$ less than $B_i^*$, an increase in $B$ will raise his utility. At values of $B$ greater than $B_i^*$, a decrease in $B$ will increase his utility.[2]

If tastes and incomes vary among taxpayers, each taxpayer will in principle prefer a different level of transfers. Yet only one level of $B$ can be selected as public policy. This is simply the public good problem. The traditional theoretical approach to this problem has been to attempt to vary tax shares in such a way that there is unanimous agreement upon public transfer policy. (See, for example, Thurow.) Here we will adopt the less elegant (but probably more realistic) approach of assuming that differences of opinion are not eliminated by the political process; rather, a single value of $B$ is chosen as public policy by simple majority rule.

Thus, the utility maximization of individual taxpayers generates a distribution of preferred transfer levels given by the vector $B_i^*$. In addition, since recipients can vote even though they pay no taxes, the political process must take account of their preferences as well. Since increases in $B$ entail no costs but confer positive benefits for recipients, we may set their preferred level of transfers at infinity. The inputs to the political process, then, are the $(n+p)$ elements of the augmented vector $B_i^*$, where $p$ of these elements are infinite. Majority rule will select as public policy a value of $B$ equal to the median of this distribution. If any higher transfer level is chosen, a majority can be formed to lower $B$; similarly, if a lower level is set, a majority (including the recipients themselves) will exist to raise it.[3] The median of $B_i^*$, which we will denote $B^*$, is therefore a stable equilibrium level of transfers under majority rule, even though it is likely that many—indeed most—citizens would prefer a higher or lower level of redistribution.

So far, the discussion has implicitly assumed that the entire cost of transfers is borne by the taxpayers within the political jurisdiction where the transfers are made. The model can easily be extended, however, to allow for intergovernmental matching grants, whereby voters in one jurisdiction can in effect tax residents of other jurisdictions. Suppose, for example, that the federal government contributes to the cost of transfers (per recipient) in each state according to a fixed matching schedule $F(B)$, which is a function of the benefit level in the state. Assuming equal tax shares at both state and federal levels, the taxpayer's total tax liability, for transfers in all states, will be:

$$T_i = \frac{(B - F(B))p}{n} + \frac{F(B)p}{N} + \frac{F(B^0)p^0}{N} \tag{6}$$

where $p^0$ and $B^0$ are, respectively, the total number of recipients and the average transfer level in all other states, and $N$ is the total number of taxpayers in all states. Differentiating this equation to obtain the value of $\partial T_i/\partial B$ in equation (2), we have:[4]

[2] Note that while the analysis here assumes that the taxpayer's tax share is fixed exogenously, the assumption of equal tax shares is not essential to the analysis. Any fixed tax share $s_i$ could be substituted for $p/n$ in equation (5) and Figure 1. In general, however, tax shares may be expected to vary positively with $p/n$.

[3] A further necessary assumption if the median level of $B$ is to be finite is that recipients always comprise a minority of the electorate. It is also necessary to assume that there are no "side payments"; i.e., votes are not bought or sold. Otherwise, the equilibrium solution may be indeterminate. Use of the median as a decision criterion in collective choices is analyzed in Duncan Black; application of this criterion in similar contexts has been suggested by Gary Becker, p. 63, and by David Bradford and Wallace Oates, pp. 443–44.

[4] This relationship implicitly assumes that the level of transfers in other jurisdictions is unaffected by $B$.

$$(7)\qquad \frac{\partial T_i}{\partial B} = \frac{(1 - F'(B))p}{n} + \frac{F'(B)p}{N}$$

where $$F'(B) = \frac{\partial F(B)}{\partial B}$$

Substituting this expression for $\partial T_i/\partial B$ in equations (2)–(5) yields:

$$(8)\qquad \sum_{j=1}^{p} \frac{\partial U_i}{\partial Y_j} = \frac{\partial U_i}{\partial Y_i} \cdot \left[\frac{(1 - F'(B))p}{n} + \frac{F'(B)p}{N}\right]$$

as the optimality condition for the $i$th taxpayer in the presence of federal matching.

In terms of the graphical representation of the optimality condition in Figure 1, the *mb* curve which depends only on the taxpayer's utility function is unaffected by federal matching. The *mc* curve, however, is shifted by both a price and an income effect when matching is introduced. The price effect of matching shifts the *mc* curve downward, as compared with the no-matching case. If $N$ is very large relative to $n$, so that the term $F'(B)/N$ is negligibly small, the level of the *mc* curve is approximately proportional to the term $(1-F'(B))$. This term is just the marginal state share of benefits; it may be viewed as the marginal price of benefits (per recipient) to taxpayers within the state. (Empirically, in the *U.S.* welfare system, the marginal state share is an increasing function of $B$, reinforcing the positive slope of *mc*.) Increases in the marginal federal matching rate, then, will lower the *mc* curve and increase the equilibrium level of $B_i^*$.

Matching will also have an effect on *mc* through its effect on the taxpayer's after-tax income $Y_i$. Consider, for example, a change in the matching formula which leaves the marginal matching rate unchanged but raises (lowers) the average federal share of benefits. Without loss of generality, we may represent the matching formula by:

$$(9)\qquad F(B) = a + f(B)$$

The effect of a parametric shift in the intercept of this function on the marginal utility of own-income is:[5]

$$(10)\qquad \frac{\partial\left(\dfrac{\partial U_i}{\partial Y_i}\right)}{\partial a} = \frac{\partial^2 U_i}{\partial Y_i^2} \cdot \frac{\partial Y_i}{\partial a} = \frac{\partial^2 U_i}{\partial Y_i^2} \cdot \left[-\frac{\partial T_i}{\partial a}\right] = \frac{\partial^2 U_i}{\partial Y_i^2} \cdot \left[\frac{p}{n} - \frac{p}{N}\right]$$

Under the assumption of decreasing marginal utility of own-income, this expression must be negative. Therefore, the income effect of an upward shift in $F(B)$ will lower the *mc* curve, *ceteris paribus*, and a downward shift in $F(B)$ will raise the *mc* curve. The resulting changes in the equilibrium transfer level, $B_i^*$, will be positive and negative, respectively.

Finally, it should be noted that an individual taxpayer may not value transfers to all recipients equally. In general, $\partial U_i/\partial Y_j$ need not equal $\partial U_i/\partial Y_k$ for any two recipients $j$ and $k$, although by assumption they must receive equal transfers. It may well be that taxpayers systematically favor (i.e., $\partial U_i/\partial Y_j$ may be higher for) certain classes of recipients as opposed to others. To the extent that the recipient population is comprised of these

[5] Equation (10), obtained by partial differentiation of equation (6), holds constant the federal matching rate in all other states. Implicitly, then, we are evaluating only the income effect of matching rate *differentials* among states. This is consistent with the empirical tests of the following section. Clearly, a change in the matching rate applicable to a single state will have a larger income effect on transfer levels in that state than would a simultaneous change in the matching rates in all states.

favored groups, the *mb* schedule in Figure 1, and therefore $B_i^*$, will be higher than it would otherwise be.[6]

We can now summarize the determinants of changes in the level of transfers over time and/or variations in transfer levels among states. As between two different states, or the same state at two different points in time, holding everything else constant:

1. Higher income among taxpayers will lower the *mc* curve (because of diminishing marginal utility of own-income) and result in higher transfers.
2. A lower ratio of recipients to taxpayers will lower the *mc* curve and result in higher transfers.
3. A larger absolute number of recipients (holding constant the recipient/taxpayer ratio) will raise the *mb* curve and result in higher transfers, since $\partial U_i/\partial Y_j$ is assumed to be positive, and *mb* is the summation of $\partial U_i/\partial Y_j$ over all recipients.
4. A higher federal matching rate will lower the *mc* curve (via both a price and an income effect) and result in higher transfers.
5. More altruistic tastes on the part of taxpayers (holding taxpayer income and the composition of the recipient population constant) in the form of higher $\partial U_i/\partial Y_j$ will raise the *mb* curve and result in higher transfers.
6. A recipient population with a larger proportion of individuals for whom taxpayers have a high $\partial U_i/\partial Y_j$ will raise the *mb* curve and result in higher transfers.

While the analysis from which these results are derived is carried out at the individual taxpayer level, it should be noted that under the political process of majority rule assumed here they also carry over to the aggregate public policy outcome. That is, a given change in any of these variables for all taxpayers changes all of the elements of $B_i^*$ in the same direction and, therefore, changes the median value of $B_i^*$ in the same direction.

## II. Empirical Tests of the Model for the *AFDC* Program

The largest *U.S.* transfer program designed to serve a purely redistribution function is Aid to Families with Dependent Children (*AFDC*). In January 1974, there were 10.4 million *AFDC* recipients.[7] The levels of assistance payments under *AFDC* are set by the various states which administer the program. The cost of *AFDC* payments is borne jointly by the federal and state governments under two different matching formulas. Under the original public assistance matching formula, the federal government agreed to pay 83 percent of the first $18 per recipient per month, 50–65 percent (depending on state per capita income) of the next $14, and nothing for that portion of benefits in excess of $32 per recipient per month. Since 1965, however, states have been allowed the option of straight proportional federal sharing at the matching rate established for the Medicaid program. This rate varies

[6] Where there are strong and widely shared differences in taxpayers' perceptions of the "deservingness" of different groups, and it is possible to discriminate among recipients on a socially acceptable basis, the equal-benefit constraint assumed here can be circumvented by categorizing recipients into separate programs with different transfer levels. Thus, we have separate transfer programs for the aged, the incapacitated, the unemployed, Cuban refugees, disabled coal miners, veterans, single-parent families with children, and two-parent families with children. In other cases, discriminatory taxpayer preferences may be just as widely shared, but either the basis for discrimination is not a socially or legally acceptable one (e.g., race), or discrimination is administratively infeasible (e.g., as between the "voluntary" and the "involuntary" poor). Even in these cases where both groups are entitled to the same transfers, however, the common transfer level will be affected by taxpayers' perception of the composition of the recipient population.

[7] This figure for *AFDC* recipients, and the variables throughout this section, excludes recipients of assistance in the "unemployed parent" segment of *AFDC*. In January 1974, there were 439,000 such recipients.

TABLE 1—INDEPENDENT REGRESSION VARIABLES

| Variable | Definition | Proxy for: |
|---|---|---|
| *Y* | State per capita income in 1967 dollars | Real taxpayer income |
| *RPOP* | Ratio of total *AFDC* recipients to state civilian population, lagged one year | Recipient/taxpayer ratio |
| *RCPT* | Total *AFDC* recipients in 1000's, lagged one year | Absolute number of recipients |
| *MP* | Marginal state share of *AFDC* payments, as a fraction | Federal matching rate (marginal price effect) |
| *F* | Federal share of average annual *AFDC* payment to family of four, in 1967 dollars | Federal matching rate (income effect) |
| *NE, OS, BS, W* | Dummy variables for Northeast, Old South, Border States, and West | Taxpayer preferences and other regional effects |
| *NWH* | Fraction of *AFDC* families headed by nonwhites | Composition of recipient population |
| T | Time, in calendar years (1962 = 1) | Time trend (linear) |
| TSQ | $T^2$ | Time trend (non-linear) |

inversely with state per capita income, with a minimum of 50 percent and a maximum of 83 percent. As of January 1974, all but twelve states had elected to adopt this matching formula rather than the original *AFDC* formula.

The *AFDC* program provides an excellent test of the theory of redistributive transfers developed in the previous section.[8] It is a large, well-established program with an open-ended federal matching commitment of the type embodied in the theoretical model. Moreover, virtually complete state autonomy in the determination of benefits has resulted in a wide range of transfer levels, reflecting, presumably, the variation in the underlying determinants of assistance levels among the states.

[8] Several previous studies have employed cross-sectional regression analysis to analyze the determinants of state public assistance expenditures. See, e.g., Lora Collins; Peter Albin and Bruno Stein; Solomon Fabricant; Glenn Fisher; Seymour Sacks and Robert Harris; Jack Osman; and Ronald Gold. These studies have not, however, been based upon any explicit theoretical model of the transfer decision-making process, and none has dealt in a satisfactory manner with the impact of federal matching grants. Moreover, only Collins has dealt with the various public assistance programs separately, and most of the other studies have sought to explain welfare expenditures per capita, rather than the level of transfers per recipient.

The preceding section advanced six major variables as theoretical determinants of the level of transfers in a redistributive program: taxpayer income, the recipient/taxpayer ratio, the absolute number of recipients, the federal matching rate, taxpayers' preferences, and the composition of the recipient population. The analysis reported below employs multiple regression analysis to estimate state *AFDC* payment levels as a linear function of these variables or their empirical proxies. The data base includes annual observations for all states and the District of Columbia for the period 1963–72.

The basic dependent variable selected for analysis is the average real (1967 dollars) monthly payment per *AFDC* recipient. This variable was scaled upward by a factor of 48, to represent the annual payment to a family of four. This transformation was performed merely to facilitate discussion of the results in the usual terms of annual transfers to the modal family. The transformed variable is denoted *B* in the analysis.

The independent variables employed in the analysis and their relationship to the variables of the theoretical model are displayed in Table 1. Real state per capita

income ($Y$) is entered as a measure of taxpayer income. Lagged values of the recipient/population ratio ($RPOP$) and the absolute number of recipients ($RCPT$) are used, in recognition of the likelihood that it takes states some time to adjust to changes in these variables. Two separate matching variables ($F$ and $MP$) are included to capture the income and marginal price effects of matching on benefit levels. Regional dummies ($NE$, $OS$, $BS$, and $W$) are included as proxies for taxpayer preferences with respect to redistribution (and any other regional effects). The racial composition of the caseload ($NWH$) was selected as the most important characteristic upon which taxpayers might discriminate among recipients.[9] Linear and quadratic time terms are included to capture any time trend not accounted for by the other variables.

The relationship we wish to estimate (with the expected signs of the explanatory variables) is:

$$(11)\quad \begin{aligned} B = {} & a_0 + a_1Y - a_2RPOP + a_3RCPT \\ & - a_4MP + a_5F \pm a_6NE \pm a_7OS \\ & \pm a_8BS \pm a_9W - a_{10}NWH \\ & \pm a_{11}T \pm a_{12}TSQ + e \end{aligned}$$

Unfortunately, direct estimation of this equation by ordinary least squares would yield biased estimates of $a_4$ and $a_5$, the coefficients which measure the price and income effects of matching. As noted earlier, under the original public assistance matching formula the marginal state share of *AFDC* payments ($MP$) rises as $B$ increases. The independent variable $F$ is also related to the dependent variable by the equation:

$$(12)\quad F = mB$$

where $m$ is the average federal matching rate. Both variables will therefore be positively correlated with the error term in equation (11), and the ordinary least squares estimates of $a_4$ and $a_5$ will be biased upward.[10]

In order to obtain unbiased estimates of $a_4$ and $a_5$, a two-stage estimation procedure was employed here. An estimated value of $F$ was obtained from the regression:

$$(13)\quad \begin{aligned} F &= \sum_i mX_ib_i + u \\ &= \hat{F} + u \end{aligned}$$

where the $X_i$ are the independent variables (other than $F$) of equation (11), $m$ is the average federal matching rate, and the $b_i$ are least squares regression coefficients. The variable $F$ was then replaced with $\hat{F}$ in estimating equation (11).[11] A similar

[9] Data on the racial composition of state *AFDC* caseloads were available only for the years 1961, 1967, 1969, and 1971, in which the National *AFDC* Surveys were conducted. Values of $NWH$ for other years were obtained by linear interpolation or (for 1972) extrapolation. In the last two surveys, state level data on racial composition are available only for 12 and 20 states, respectively. For the remaining states, the 1967 values were extrapolated on the basis of changes in the corresponding census division. This variable is, therefore, subject to an unknown degree of measurement error, which may bias its regression coefficients toward zero.

[10] Estimation of equation (11) by ordinary least squares for the periods 1963–67 and 1968–72 yields values of 1.04 and 1.55 for $a_5$. It is interesting to compare these results with earlier estimates of the effect of federal matching grants on welfare expenditures. Both Osman and Sacks and Harris estimated state per capita welfare expenditures as a function of per capita federal welfare grants and other independent variables. While both the dependent and independent variables are thus different from those used here, it can be shown that their coefficients are conceptually equivalent to the coefficient $a_5$ of the present model, and that the numerical values of the two coefficients are therefore directly comparable. Osman obtained an estimate of 1.37 for this coefficient, and Sacks and Harris found coefficients of 1.64 and 1.68, as compared to my estimates of 1.04 and 1.55, using the same (biased) approach. In both of the earlier studies, this result was interpreted as implying that federal grants have a "stimulative" effect on state and local expenditures. The empirical results obtained in this study indicate that these ordinary least squares results are almost entirely attributable to simultaneous equation bias. (See Edward Gramlich for an excellent summary of the extensive literature on federal grants-in-aid.)

[11] It should be noted that $\hat{F}$ is *not* simply a linear combination of the other independent variables in-

technique was used to obtain an estimated value of $MP$. The dependent variable $B$ was first regressed on all of the independent variables of equation (11) except $MP$ and $F$. Then, for all states using the original *AFDC* matching formula, the marginal matching rate associated with the estimated value of $B$ was derived from the matching formula. For these states, the actual value of $MP$ was replaced with this estimated value to form the variable $\widehat{MP}$. Use of $\hat{F}$ and $\widehat{MP}$ to estimate $a_4$ and $a_5$ eliminates any simultaneity bias in these coefficients.

Using this two-stage procedure, equation (11) was estimated separately for the years 1963–67 and 1968–72; the estimated coefficients (and associated statistics) are shown in the first two columns of Table 2. Aside from the regional dummies, only the coefficients of $\hat{F}$ in both periods, and the time variables in the later period, are insignificant at the 95 percent confidence level (one-tail test).

On the basis of these coefficients, we conclude that apart from the marginal price effect measured by $\widehat{MP}$, federal matching has no significant impact on state payment levels; i.e., federal funds simply displace state funds dollar for dollar. This finding, and the relatively modest size of the estimated coefficients of $\hat{F}$, stands in marked contrast with earlier published results on the effects of matching. (See fn. 10.) This should not be a surprising result. As the theoretical model indicates, matching only has an income effect on $B$ insofar as it lowers taxpayers' liabilities, raises their after-tax income, and thereby reduces their marginal utility of own-income. While the direction of the effect is clear, its magnitude is likely to be extremely small empirically. The average federal share of *AFDC* payments per recipient in this sample is \$272. Since the average recipient/population ratio is only about .025, this amounts to an increase in annual per capita after-tax income of only about \$7, as compared with an average per capita income of \$3000. One would not expect such a minor change in after-tax income to have much effect upon the marginal utility of own-income.

Because $\hat{F}$ and the time variables are correlated with several of the other independent variables, their inclusion in the regression equation may result in inefficient estimates of the other coefficients. Therefore, equation (2) was reestimated without these three variables and equation (1) was reestimated without $\hat{F}$; the resulting estimates are shown in columns (3) and (4) of Table 2. The discussion below is based on these estimates.

Although federal matching does not appear to have a significant income effect on benefit levels, the marginal price effect is significantly different from zero at the 99 percent confidence level. The coefficients of $\widehat{MP}$ imply an elasticity with respect to the price variable of about $-.23$ in both periods, evaluated at the point of means.[12] While the estimated elasticity is thus relatively small, these estimates imply that large changes in the matching formula can have nonnegligible effects upon payment levels. For example, suppose that the current *AFDC* matching system were replaced by a federally financed benefit floor with the states allowed to provide supplementary payments at their own expense. This

cluded in the regression, because in the first-stage regression the $X_i$ are multiplied by $m$, which varies widely across states. The $R^2$ of the first-stage regression was .68 in 1963–67 and .62 in 1968–72.

[12] It should be noted that these coefficients are subject to a possible bias. As noted above, since 1965 states have been allowed the option of reimbursement for *AFDC* expenditures at the matching rate established for the Medicaid program. Under the Medicaid matching formula, the marginal price is positively correlated with state per capita income. This may impart an upward bias if the income variable used here does not adequately control for income. Thus, the price effect of matching is, if anything, stronger than indicated by these coefficients.

amounts to elimination of federal matching at the margin. The results imply that in the 1968–72 period such a change would have reduced *AFDC* benefit levels by about 16 percent, or about $320 annually for a family of four, a reduction of over $.6 billion in total *AFDC* payments.

The results also indicate, not surpris-

ingly, that the level of transfers is strongly influenced by state per capita income, as predicted by the model. The coefficients of $Y$ indicate that a \$1.00 increase in real state per capita income raises real *AFDC* payments to a family of four by approximately \$.43 in the earlier period and \$.64 in the later period. The estimated elasticities of $B$ with respect to per capita income (at the point of means) on the basis of these coefficients are .65 and 1.17. The income elasticity of *AFDC* payments thus appears to have shifted upward somewhat over the period analyzed.

The predictions of the theoretical model are also supported by the highly significant coefficients of the recipient/population ratio and the absolute number of recipients, both of which have the expected sign in both periods. The significance of these variables is probably the most stringent test of the public goods nature of income redistribution under the *AFDC* program; failure to find significant effects for these variables would cast serious doubt on the applicability of the public goods model.[13]

Several observations are in order with respect to the coefficients of *RCPT* and *RPOP*. First, consider the effect of an increase in the *AFDC* caseload on benefit levels, holding state population constant. The direct effect of an increase in the number of recipients (*RCPT*) is positive, whereas the effect of the concomitant increase in the recipient/population ratio (*RPOP*) is negative. The net effect of these two opposing influences will depend on the level of state population. For example, differentiating the regression equation for 1968–72 with respect to *RCPT* yields:

$$\partial B/\partial RCPT = .25 - 6905./POP \tag{14}$$

where *POP* is state population in thousands. This expression is negative for population values less than 27,620,000. For 1963–67, the corresponding expression is negative for population values less than 25,121,000. Thus caseload increases tend to depress benefit levels in all states. However, the net effect approaches zero as state population approaches these critical values, so that this effect is greater in small states than in large ones.

Second, the estimated coefficients of *RPOP* are roughly consistent with those estimated for $\widehat{MP}$, the marginal matching rate. In the theoretical model developed in the previous section, the recipient/taxpayer ratio and the federal matching rate both enter the determination of benefits in the same manner, as multiplicative terms of the *mc* schedule. An equiproportional change in either variable will have the same effect on equilibrium benefit levels. Thus, the theoretical model predicts that the elasticities of benefit levels with respect to the two variables will be equal. On the basis of these estimates, the elasticity with respect to *RPOP* (at the point of means) is approximately $-.12$ in both time periods. The elasticity with respect to $\widehat{MP}$, $-.23$, is at least the same order of magnitude.

The racial composition of the recipient population also exerts a strong influence on the level of payments. The coefficients of *NWH* imply that, *ceteris paribus*, a family of four in a state with an all-nonwhite recipient population would receive about \$400 per year less than one in a state where all recipients were white.[14] This is evidence of rather substantial discrimina-

[13] The only other study, to my knowledge, to use either of these variables to explain welfare payment levels is by Gold, who used the recipient/population ratio in a regression analysis of total state public assistance payments per recipient in 1957 and 1966. He estimated elasticities of $-.07$ and $-.19$, as compared with the estimate of about $-.12$ found here for both five-year periods. Gold's estimated coefficient for 1957 was insignificant, while his coefficient for 1966 was significant at the 95 percent level (one-tail test).

[14] This is probably a conservative estimate of the effect of discrimination because as noted in fn. 9 above, *NWH* is subject to measurement errors which will bias its coefficient toward zero.

tion against nonwhite recipients on the part of (predominately white) taxpayers.[15] It should be noted that the racial composition variable is not simply acting as a proxy for low incomes or a political bias against welfare in southern states with predominately nonwhite caseloads, since both income and regional variables are explicitly included in the regression equation.[16] It is of some interest to inquire, however, whether the degree of discrimination against nonwhites is more severe in the South than in the rest of the nation—i.e., whether variations in the racial composition of the caseload have a greater effect on benefit levels in these states. To test this hypothesis, two interaction variables (*NWHOS* and *NWHBS*), formed by multiplying the Old South and border state dummies by *NWH*, were added to the regression equation. The results are shown in columns (5) and (6) of Table 2. In neither time period are these coefficients significantly different from zero. Thus, it appears that the degree of discrimination against nonwhites implicit in *AFDC* benefit levels does not differ significantly between the South and the rest of the nation.

While no signs were posited for the regional dummies, the estimated regional differentials conform roughly with what one might expect on the basis of casual observation. As compared with the omitted north central region, benefits are substantially (\$685–\$690) lower in the Old South and moderately (\$137–\$248) lower in the border states, *ceteris paribus*. There is also a small (\$102) negative differential in the western region in the later period and a modest (\$81–\$148) positive differential in the northeastern region. Although the dummy variables employed here may capture a variety of regional effects, it seems plausible that these differentials reflect systematic regional differences in taxpayers' preferences for income redistribution.

To provide an indication of the relative contributions of the independent variables to regional differentials in benefit levels, Table 3 presents mean benefits by region, regional differentials from the north central region mean, and the portion of regional differentials attributable to each variable. The effect of each variable on the regional differential in benefits is the product of the deviation of its mean in that region from the north central mean and the corresponding regression coefficient. Regional differentials are dominated by the intercept shift coefficients (i.e., the regional dummies). However, differences in mean marginal matching rates and per capita income also substantially affect regional variations in benefits, particularly in the South.[17]

## III. Conclusions

The empirical estimates presented here for the *AFDC* program over the ten-year period 1963–72 are remarkably consistent with the public good model of income re-

[15] Collins also found that the racial composition of the recipient population had a significant negative effect on *AFDC* payment levels in 1960. However, she does not report the regression coefficient for the race variable. The only other significant variable in her regression is state per capita income. Gold found highly significant effects of the racial composition of the state population on total public assistance payments per recipient in both 1957 and 1966. His estimated elasticities were −.14 and −.18, as compared with elasticities of −.09 and −.11 estimated here. Again, the only other variable which was significant in both years was state per capita income.

[16] Gold also found that the inclusion of a dummy variable identical to the *OS* dummy used here had no effect on the significant negative coefficients of his racial composition variables in 1957 and 1966. Surprisingly, however, the coefficient of the regional dummy itself was insignificant in both years.

[17] It should be noted that the differentials shown in Table 3 are not in any sense an absolute measure of the "importance" of each variable in determining benefit levels, since they are conditional upon the existing regional variation in the independent variables. In some cases (e.g., the marginal matching rate), this variation is susceptible to change by governmental policy, and in all cases the interstate variation is greater than the variation in regional means.

TABLE 3—REGIONAL DIFFERENTIALS IN *AFDC* BENEFITS

| | Old South | | Border States | | West | | Northeast | |

distribution developed in Section I. State per capita income, the federal matching rate, the recipient/population ratio, the absolute number of recipients, and the racial composition of the caseload were all found to significantly affect state benefit levels in the directions predicted by the model. The significance of the recipient/population ratio and the absolute number of recipients is especially noteworthy, since these variables are particularly characteristic of the public good model.

The estimates also yield several important insights into the benefit structure of the state-run programs. The estimated elasticity of real *AFDC* benefits with respect to real state per capita income is close to unity, indicating that payment levels have kept pace with the growth of income. A more disturbing finding is the apparent discrimination against nonwhites in setting state benefit levels, which appears to exist in all regions. The estimates also reveal systematic regional differentials in *AFDC* benefits, particularly in the South, which may reflect fundamental differences in taxpayers' preferences for income redistribution.

The estimated coefficients of the recipient/population ratio and the absolute number of recipients indicate that the net effect of increases in the *AFDC* caseload is to depress benefit levels, *ceteris paribus*. The strength of this effect depends on population size, however, with larger effects occurring in the smaller states.

The empirical estimates of the effects of federal matching presented here have important policy implications. Previous studies of the effects of matching have been misspecified and have employed biased estimation techniques. When the separate price and income effects of matching are estimated, as required by the theory, it is seen that the income effect represented by the average federal share is not significantly different from zero. The price effect, represented by the marginal matching rate, is highly significant, however. Since a wide variety of possible federal welfare policies operate on these two variables independently, it is important to draw this distinction. For example, the institution of a federally financed benefit floor which eliminated federal matching at the margin while holding constant—or even increasing—the average federal share of benefits would reduce benefit levels by about 16 percent on the basis of these estimates.

# The Production Function and Technical Change in Postwar Soviet Industry: A Reexamination

By PADMA DESAI*

In a pioneering article in a recent issue of this *Review*, Martin Weitzman rigorously analyzed the phenomenon of postwar economic growth in Soviet industry. His paper represents the first systematic attempt at identifying the production function for Soviet industry without making the competitive relations assumption. It interprets the growth of Soviet industry in terms of the elasticity of substitution between capital and labor, and the rate of technical change.

Weitzman's main conclusions are the following: (i) the constant elasticity of substitution (*CES*) production function with constant returns to scale adequately represents postwar growth in Soviet industry; (ii) the estimated elasticity of substitution of .403 is significantly less than 1; and (iii) the estimated technical change parameter of .0205 is not different from the parameter value of .023 for American manufacturing in the recent period.

Given these parametric values, Weitzman reaches two major conclusions with respect to the actual performance of Soviet industry in the postwar period and its future growth. With respect to its actual performance, he concludes that by the late 1960's " . . . a low elasticity of substitution seems to imply that capital accumulation has outstripped labor growth by a wide enough margin that the drag due to diminishing returns is significantly cutting into output growth. In the mature Soviet economy, labor scarcity appears to be a reality" (p. 685). Furthermore, the rate of growth of technical change of about 2 percent per year " . . . is not nearly so significant a determinant of economic growth as in some other economies. The Soviet postwar record looks very much like a classical model of economic growth with high rates of capital accumulation serving as the prime mover" (p. 685).

As for the future implications of this scenario for Soviet industry, Weitzman concludes that "Instead of capital, labor and technical change will have to be increasingly relied upon as alternative sources of future economic growth" (p. 685). But since "the growth of industrial labor force cannot in the near future rise significantly above what it has averaged in the past five years" (pp. 685–86), the Soviets can achieve high rates of industrial growth by actively encouraging the residual element or technical change. "With in-

* Russian Research Center, Harvard University. In the course of working on this paper, I have profited from prolonged and frequent discussions with T. N. Srinivasan and valuable suggestions from Martin Weitzman. Useful comments were made on a penultimate draft by Zvi Griliches, Bent Hansen, Alan Manne, Thomas Marschak, Tom Rothenberg, and Robert Solow. Thanks are also due to Abram Bergson and Gregory Grossman for comments on an earlier version of the paper. The computer work involved in the paper was done with speed and expertise by Bronwyn Hall. The non-linear estimation program used has been developed by Robert Hall. The financial support provided by the Institute of International Studies at the University of California, Berkeley, during 1973–74, is gratefully acknowledged. An earlier version of this paper was discussed at the Stockholm School of Economics and presented at the Econometric Society meetings in San Francisco in December 1974.

creased λ [technical change], the Soviet growth scenario would resemble a little more closely the contemporary expansion of Japan and a few Western countries" (p. 686).

These results and conclusions are impressive enough to raise the critical question: how dependable are Weitzman's data, his specification of the production relationship for Soviet industry, and its theoretical underpinnings?

Weitzman relies exclusively on estimates of output, industrial productive fixed assets, and industrial man-hours available in Soviet sources. However, in the absence of corresponding data on raw materials, he is constrained to develop a "hybrid" output series, weighting the output indexes of Soviet branches by their estimated 1960 value-added shares, and to work with this hybrid series and the available capital and labor data.

Weitzman's hybrid series cannot really be interpreted as a value-added series. Weitzman himself is aware of the limitations of his hybrid index. Thus he writes:

> In pretending that industrial output is a function of capital and labor alone we are introducing an error by omitting industrial purchases of inputs from other sectors, principally transportation and agriculture. My distinct feeling is that such omissions turn out to be empirically irrelevant for industry as a whole. In any case it is difficult to obtain year to year input-output type data of the kind needed to test the importance of this omission. [p. 692]

The principal task of this paper, then, is to test the importance of this omission. In doing this, I have developed a data series of raw materials used in Soviet industry, utilizing a technique which has been set out at length elsewhere,[1] and which I sketch briefly in the Statistical Appendix. Section A of the Appendix shows how gross output, value-added, and raw materials in Soviet industry at current prices can be derived. The former are described as Desai estimates as they differ from the official Soviet indexes of gross output.[2] Since I need these indexes at constant prices, the necessary price deflators are developed in Section B of the Appendix.

The resulting Desai estimates of gross output, raw materials, and gross value indexes are presented alongside and compared with the Soviet output index and Weitzman's hybrid index in Section I. Next, in Section II, alternative production functions are specified for Soviet industry, using both gross value-added (Desai) and gross output (Soviet and Desai) as the dependent variables. While the Weitzman assumptions of Hicks-neutral, disembodied technical change, and a multiplicative error term are retained, and his use of nonlinear estimation technique is retained in preference to the use of competitive relations for estimating the production function, my specification of the production function in terms of gross output will allow for raw materials.

Section III presents the "best" estimates. Among them, in turn, the *CES* production function with constant returns to scale, *and* with raw materials specified, appears to give the best fit. While the elasticity of substitution between capital and labor continues to be significantly less than one, the Hicks-neutral technical change parameter increases substantially to 3.5 to 4 percent annually. This and other implications of the analysis, plus directions for further econometric analysis, conclude the paper.

## I. Statistical Series

The statistical methods set out in the

*Notes:* All figures in columns (1)–(8) and (13)–(14) are derived according to the method outlined in the Appendix. Figures in columns (9)–(10) are directly from Soviet sources. Figures in columns (11)–(12) are from Weitzman (p. 677). All figures in columns (2), (4), (6), (8), (10), (12), and (14) are the annual percentage growth rates of the corresponding figures in the preceding column.

Appendix result in the following (constant-price) indexes of importance in our estimation of a production function for Soviet industry: gross value-added; material usage; and gross output (Desai). These are listed in Table 1, together with the following additional indexes: Soviet gross output;[3] Weitzman's "hybrid";[4] and Desai's "hybrid" (using Weitzman's weighting procedure but Desai's estimated value-added weights).[5] The annual percentage rates of growth of each series are also presented in Table 1. A few remarks on the different series are in order before the estimation of production functions, based on these series, is described in the following sections.

It is clear now that the absolute levels of the indexes estimated by my methods (and presented in columns (1), (3), and (7)) are generally, but especially after 1960, higher than the indexes in columns (9), (11), and (13). The gross value-added index I estimated *via* the double deflation method is generally higher than all the alternative index series.[6] Secondly, the gross output index I estimated (column (7) of Table 1) and the index of gross output in Soviet sources (column (9) of Table 1) are not far apart, although the corresponding rates of growth show consider-

[3] This series is taken from the following sources: For 1955–57, *Promyshlennost' S.S.S.R.*, p. 36; for 1958–60, *Narkhoz* (1965, p. 125); for 1960–64, *Narkhoz* (1965, p. 126); for 1965–69, *Narkhoz* (1967 and 1969, pp. 189 and 147); for 1970, *Narkhoz* (1970, p. 136); for 1971, *Jubilee Volume*, p. 126.

[4] This series is taken from Weitzman, p. 677.

[5] The value-added figures in billion rubles, the corresponding Desai weights, and the Weitzman weights, p. 690, are shown in the Appendix, Table A3.

[6] Also the double-deflated value-added series show a rising trend with marked fluctuations. In my judgment, the fluctuations are a result of the method employed in deriving the series. On the other hand, they may reflect changes in inventories of materials. There is no way of tracking down these changes, if any, and adjusting for them on the basis of evidence on inventories in Soviet sources. Furthermore, a dip in the double-deflated value-added index in 1964 also seems to arise from the use of "inappropriate" price deflators for gross output and/or raw materials. Paul David (1962) has suggested that such dips can arise as a result of a change in the technique of production. Such a possibility, which is likely in the case of double-deflated value-added index number comparisons between two points of time which are far wide apart, can be ruled out in the present case where the comparison is between two consecutive years.

able divergence from year to year.[7]

The most striking observation is with respect to the Soviet gross output index (column (9)), the Weitzman hybrid index (column (11)), and the Desai hybrid index (column (13)). These three indexes and their growth rates are practically identical. The Weitzman index and the Desai index are identical, thus bearing out Weitzman's argument that "the industrial production index appears to be remarkably insensitive to changes in the value-added weights caused by somewhat different assumptions used in composing them" (p. 691).[8] Finally, in the estimation that follows in the next two sections, I used the Weitzman estimates of industrial manhours and his series on fixed assets to focus sharply on the differences introduced by my explicit consideration of raw materials in contrast to Weitzman's analysis.

## II. Specification of the Production Function

The specification of the production function and the underlying assumptions in the following analysis are essentially similar to those of Weitzman. The difference is that the dependent variable is defined here alternately in terms of gross output and gross value-added, and raw materials are explicitly considered. By contrast, Weitzman's dependent variable was a hybrid index (an overall industry output index where the branch *output* indexes are weighted by value-added-share weights), and raw materials were ignored among the explanatory variables. Furthermore, as noted in the previous section, Weitzman's hybrid index is almost identical to the Soviet gross output index for total industry. This being so, the omission of raw materials as one of the explanatory variables in the production relationship should distort Weitzman's parametric estimates.

The *CES* and Cobb-Douglas forms with variable and constant returns to scale were fitted to the time-series data. Two gross output series, Soviet and Desai, and Weitzman's hybrid series,[9] were used for estimating production functions defined on capital, labor, *and* raw materials. The two value-added series I derived, double-deflated and single-deflated, were used to estimate production functions defined on capital and labor alone.[10] Thus, given that

[7] The main reason for the divergence is that whereas I derive the gross output series first in current prices and then in constant prices by deflating the former with a suitable price index, the Soviet method is to derive the output series, beginning with the enterprise, by multiplying physical enterprise output with the product price of a given year. Incidentally, the average rates of growth of value-added (single deflated and double deflated) in columns (2) and (4) are higher than the average rates of growth of gross output, Desai and Soviet, in columns (8) and (10). The higher rate of growth of value-added in Soviet industry (with 1950 = 100 and for a slightly shorter period) as compared to that of gross output is also emphasized by Judith Thornton (1970).

[8] In my judgment, the industrial production index would remain "insensitive" not only because the value-added weights are spread over a range of .66 percent (for Desai weights) and .82 percent (for Weitzman weights) in Glass and ceramics and of 29 percent for both in Machinebuilding and metalworking but *also* because the spread in the branch *production* indexes themselves (to which the weights are applied), at least up to 1963, is not very large. For example, in 1963, the minimum production index is 109.64 in Soft goods and the maximum is 149.72 in Machinebuilding and metalworking, thus indicating a spread of 40.08 points.

[9] Weitzman's hybrid index may be treated as if it was an output index because it works with Soviet branch output indexes, merely using value-added for weights. Strictly speaking, the Weitzman index can be interpreted as a value-added index if materials are a fixed proportion of gross output in each branch throughout the period under consideration. This is, however, an extremely restrictive assumption and is not validated by an examination of the gross output and materials series employed in our analysis.

[10] It is relevant here to indicate the theoretical rationale for adopting either the single-deflated or the double-deflated value-added series in specifying the production function. David (1966) has shown that if observed payments to factors (i.e., value-added) result from profit maximization subject to the constraint of a linear homogeneous production function, under conditions of perfect competition in product and material markets, then the net output index can be obtained simply by deflating an index of current value-added by the index of the industry's product price. David thus provides a rationalization for using a single-deflated value-added index in the specification of a production function. He further argues that the double deflation

(in a three-factor production function) each *CES* form was tried with four alternative parametric restrictions on pairwise elasticities of substitution,[11] altogether 30 trials were made for the gross output production function and 8 for the value-added variety.

Of these 38 trials, the presentable results were (fortunately) confined to 5. All 5 were *CES*, none Cobb-Douglas, and none showed variable returns to scale. In essence, then, the following three forms of the *CES* production function were fitted with (varying degrees of) success:

(1) *CES (I): Constant returns to scale*

$$O_I(t) = A_I e^{\lambda_I t}[\alpha_I K_I(t)^{-\rho_I} + \beta_I L_I(t)^{-\rho_I} + (1 - \alpha_I - \beta_I) R_I(t)^{-\rho_I}]^{-1/\rho_I} e^{u_I(t)}$$

where

$$A_I > 0, \quad 0 \leq \alpha_I + \beta_I \leq 1, \quad \alpha_I \geq 0, \quad \beta_I \geq 0, \quad \rho_I \geq -1$$

and elasticity of substitution between

$$[K_I(t), L_I(t)] = [K_I(t), R_I(t)] = [L_I(t), R_I(t)] = 1/\rho_I + 1$$

(2) *CES (II): Constant returns to scale*

$$O_I(t) = A_I e^{\lambda_I t}[\alpha_I K_I(t)^{-\rho_I} + (1 - \alpha_I) L_I(t)^{-\rho_I}]^{-\gamma_I/\rho_I} R_I(t)^{(1-\gamma_I)} e^{u_I(t)}$$

where

$$A_I > 0, \ 0 \leq \alpha_I \leq 1, \ 0 \leq \gamma_I \leq 1, \ \rho_I \geq -1$$

and elasticity of substitution between

$$[K_I(t), L_I(t)] = \frac{1}{\rho_I + 1}$$

$$[K_I(t), R_I(t)] = 1$$

$$[L_I(t), R_I(t)] = 1$$

(3) *CES (I): Constant returns to scale*

$$Y_I(t) = A_I e^{\lambda_I t}[\alpha_I K_I(t)^{-\rho_I} + (1 - \alpha_I) L_I(t)^{-\rho_I}]^{-1/\rho_I} e^{u_I(t)}$$

where

$$A_I > 0, \quad 0 \leq \alpha_I \leq 1, \quad \rho_I \geq -1$$

In specifications (1) and (2), $O_I$ refers to gross output, and in specification (3), $Y_I$ refers to gross value-added. In all the specifications, $K_I$, $L_I$, and $R_I$ refer respectively to fixed productive assets, annual man-hours, and material usage.

## III. Results and Conclusions

### A. *"Best" Estimates*

In Table 2 the estimated parameters for trials, corresponding to the three production function forms just listed and corresponding to alternative estimates of the dependent variable, have been presented. All the parametric values satisfy the specified limits; but not all of them are statistically significant.

While some readers will find it possible to accept more than one of the five results presented in Table 2, my view is that the best result is for *CES* with gross output and identical elasticities of substitution

method requires no formal assumption, and "... because it makes no theoretical assumptions, it yields no more than hypothetical calculations which are not particularly appropriate for production function analysis" (p. 425). However, a rationale can be provided for the use of double-deflated value-added on the basis of further work by Kenneth Arrow and Bent Hansen. Thus Arrow has argued that if capital and labor are (weakly) separable from materials in production of gross output and if both the gross output and the "nested" production functions are homogeneous, then with further assumptions of profit maximization, it is possible to derive an index number of value-added up to a proportionality factor. Carrying the argument further, Hansen has argued that under the same assumptions, the Arrow index of value-added can be interpreted as a double-deflated value-added index. Hansen further argues that David's single-deflated value-added index differs from a double-deflated index by a term which can be interpreted as a terms-of-trade term (p. 10). It would, therefore, seem that under the assumptions of linear homogeneous production functions, profit maximization and separability, both the single-deflated and double-deflated value-added index series have a theoretical rationale for production function analysis.

[11] Thus, in the first variation of the *CES* form, the elasticity of substitution among the three factors taken two at a time is defined to be equal to, say, $\sigma$; in the remaining three variations, the elasticity of substitution between a given pair of factors is defined to be equal to $\sigma$, whereas the elasticity between the remaining two pairs of factors is specified to be equal to unity.

TABLE 2—PRODUCTION FUNCTION ESTIMATES FOR SOVIET INDUSTRY: 1955–1969[a]

| Form of equation (1)[b] | Dependent variable (2)[c] | Hicks-neutral technical change parameter (3)[d] | Elasticity of substitution[e] (4) | $\alpha$ (Capital coefficient) (5) | $\beta$ (Labor coefficient) (6) | $\gamma$ (7) | Returns to scale (8) | $R^2$ (9)[f] | $d$ (10)[f] | $SSR$ (11)[g] |

| | | (0.0187) | | (0.2270) | | | | | | (0.0449) |

[a] All the values in parentheses are the standard errors of estimates of the relevant coefficients. The standard errors of estimates of the elasticity of substitution coefficient $\sigma$ (where $\sigma=1/1+\rho$) have not been stated. The $t$-values of the estimated coefficients $\rho$ in each case indicate that at the 95 percent confidence interval, the values of the elasticities of substitution coefficients are statistically significant.

[b] All production functions are characterized by constant returns to scale. The forms of the equation in column (1) are spelled out in detail in the text.

[c] The dependent variables in column (2) in terms of indexes with 1960=100 are stated in Table 1.

[d] The equations in the text also specify the limits to the values of the parameters in columns (3) to (8).

[e] The elasticity of substitution in *CES (I)* is equal at $1/1+\rho$ for all pairs of factors. For *CES (II)*, the elasticity reported in the column is between capital and labor, whereas that for all other pairs is equal to unity.

[f] $R^2$ in column (9) is (correlation coefficients)$^2$, $d$ in column (10) is the Durbin-Watson statistic.

[g] $SSR$ in column (11) is the sum of squared residuals and the values in parentheses are the standard errors of the regression.

between each pair of factors in row (1). This can be argued as follows: since the $R^2$ is high and almost equally good in all cases, we can shift attention to the sum of squared residuals in column (11). It is seen that the last three production functions show a substantially higher sum of squared residuals; hence the first two, *CES* on gross output, would seem more acceptable on that account. Note also that for the last three equations, the standard errors of estimate for the technical change parameters are too high and make them statistically insignificant.

Hence the (first) two *CES* production functions with alternative specifications of the factor elasticities of substitution seem to be the best fits. However, among the two, we may further prefer the first form, with the elasticity of substitution between each pair of factors at approximately 0.28, over the second form which postulates an elasticity of substitution between capital and materials, and between labor and materials, at unity and thus in excess of the estimated elasticity of substitution between capital and labor only at approximately 0.20.

### B. *Economic Implications*

Regardless, however, which of the two *CES* forms on gross output is chosen as the more acceptable, my conclusions are similar to Weitzman's in two respects: the *CES* constant returns to scale production function adequately describes the production relationship in Soviet industry; and the elasticity of substitution between capital and labor is significantly less than one, thus indicating diminishing returns to factor proportions. An amusing consequence of this finding by Weitzman and myself is that the *imputed* (competitive) share of labor income in Soviet industry *rises* over time whereas the *actual* (Soviet) share of labor income has *fallen* over time. The Marxist-Leninist system would thus seem to be of dubious trendwise value to the industrial proletariat compared to labor's potential share under the capitalist-

competitive system![12]

However, in *contrast* to Weitzman's estimated Hicks-neutral technical change parameter of 2 percent, my analysis leads to a higher estimate of 3.5 or 4 percent. This finding is clearly of some importance in suggesting that the rate of Soviet technical change is significantly higher than that arrived at by Weitzman. The conclusion that the Soviet technical change is as high as 3.5 or 4 percent is, of course, fully consistent with the widespread view of the generally low *level* of Soviet technology and, in fact, may even complement that view if one attributes the high *rate* of technical change to a process of "catching up."[13]

[12] The difference between imputed and actual shares is referred to by Thornton (Section IV, in her important paper). However, she argues: "But the Cobb-Douglas form with fixed factor shares provides a poor approximation to the data for Soviet industry in this period when the share of capital shows a considerable increase," and "In his production function study, Weitzman found elasticities of substitution ranging in value from .274 to .403. In contrast, the data presented in this study in which a rise in the capital-labor ratio is associated with an increasing share of capital would seem to imply an elasticity of substitution greater than unity" (pp. 867–68). The imputed and actual shares can in this manner be discussed interchangeably only if the Soviet system has worked within a fully competitive framework during the period under consideration. This, however, would be an extraordinary assumption to make. It is precisely for this reason that both Weitzman and I have used the non-linear estimation technique for estimating the production function for Soviet industry and avoided using the competitive-relations estimation technique pioneered by Arrow et al.

[13] I might also add that, in a separate study in which I analyze the forms of the production function, the elasticities of substitution, the returns to scale, and the technical change parameters for various *branches* of Soviet industry in the postwar period (using identical estimation procedures to those used in this paper), I get the following values of the technical change parameters: Electricity: 1.69–3.15 percent; Ferrous metallurgy: 1.74 percent; Chemical and mining-chemical: 7.68 percent; Machinery and metalworking: 4.89 percent; Construction materials: 2.80–3.36 percent; Light industry: 2.16 percent; Food industry (i.e., mainly processed food items): 4.96 percent. Leaving out Fuel, Wood, woodworking and paper-cellulose, and Glass and ceramics, these branches nonetheless cover a preponderant amount of Soviet industrial output. The approximate average of these branch technical change parameters indicates an aggregate industry parameter closer to 3.5 to 4 percent than Weitzman's 2 percent.

However, a further comment on the contrast between the estimates by Weitzman and myself is in order. The higher estimate in my analysis which accounts for the material inputs omitted in Weitzman's analysis could well indicate that technical change in Soviet industry was material saving.[14] Since the estimated elasticity of factor substitution is also less than one, it may well be that an examination of factor-augmenting forms for the technical progress function may yield results that indicate biased technical change.[15] Since the coefficient of capital stock in my preferred function is statistically insignificant, it is also possible that the introduction of biased technical progress could change the situation in that regard as well. This is clearly the next analytical step to be taken in the interpretation of technical progress in Soviet industry.

## Statistical Appendix

### A. *Method of Deriving Gross Value of Output, Gross Value-Added, and Material Usage in Soviet Industry at Current Prices*

The method of deriving these three components in Soviet industry is stated at length elsewhere.[16] Here I briefly recapitulate the essential steps. Note first that:

$$D_I(t) = d_I(t) \cdot K_I(t) \tag{A1}$$

[14] This would also seem to be indicated by the fact that the technical change parameters for *CES* on value-added (double-deflated and single-deflated) are substantially lower (even below Weitzman's) while being admittedly statistically insignificant. The hypothesis of material-saving technical progress in Soviet industry also sound *prima facie* plausible to those who think, à la Kennedy-Weizsacker lines, that the scarcity and/or dearness of a factor tends to bias technical change in the direction of seeking new techniques to economize on its use. Clearly Soviet firms, like firms in developing countries with quantitative restrictions on imports of materials, tend to carry high inventories and may also be directing their technical *R* and *D* efforts toward "reducing the dependence" on the precarious supply of materials in a centrally planned economy.

[15] Recall that both Weitzman and I use the Hicks-neutral form of technical progress in our estimates.

[16] See my 1973 article. It also extends the method to a derivation of these components in various branches of Soviet industry and further breaks down the estimates

where $K_I(t)$ is defined as the average productive fixed assets in industry as a whole during year t in terms of 1955 prices, $d_I(t)$ is the rate of amortization in industry, defined as a ratio of $K_I(t)$, and $D_I(t)$ is the level of depreciation or amortization in industry during year t.

The second set of relationships below links $D_I(t)$ thus obtained to total expenditure in industry during t:

$$E_I(t) = \frac{D_I(t)}{m_I(t)} \tag{A2}$$

where $E_I(t)$ is defined as *total* expenditure during t in industry on raw materials, fuel and electricity, amortization, wages plus social security deductions and "other expenditures," and $m_I(t)$ are the parameters which express amortization during t in industry as a proportion of *total* expenditure in industry.

The *total* expenditures $E_I(t)$ derived in (A2) above are in current enterprise prices, i.e., these prices are net of taxes; however, these expenditures include the taxes on purchases (such as oil and raw materials of Light and Food industries) made by industry. Next, we define gross output:

$$O_I(t) = E_I(t) + P_I(t) \tag{A3}$$

where $P_I(t)$ are the levels of industry profits given in Soviet sources. Moreover we have the definition of value-added:

$$Y_I(t) = P_I(t) + D_I(t) + W_I(t) \tag{A4}$$

where $W_I(t)$ are wages in total industry and are derived below:

$$W_I(t) = w_I(t) \cdot E_I(t) \tag{A5}$$

and $w_I(t)$ are available in Soviet sources.

It is also clear from equation (A2) above that the method outlined here also gives expenditures on materials (including auxiliary materials), fuel and electricity in industry. We hereafter refer to these as material purchases. Note that according to Soviet practice, these material purchases include purchases from sectors such as Transport and Communications.[17]

## B. *Method of Converting Current-Price into Constant-Price Estimates*

The next task consists of converting these three series of gross output, gross value-added, and material purchases at *current* factor-cost prices into constant prices with 1960 = 100. The gross output series are deflated with the Soviet price index in industry and then converted into indexes with 1960 = 100. The resulting estimates are given in column (7) of Table 1.

As for gross value-added, the standard procedure for converting gross *value-added* series in Soviet industry into constant prices has been to use the single deflation method: i.e., to employ price indexes of gross *output*.[18] Adopting this procedure, the resulting index of this series with 1960 = 100 is presented in column (1) of Table 1.

However, we can also use the double deflation method by (a) first converting both the gross output and material purchases series into constant prices with their respective price deflators, and (b) then subtracting the material purchases series from the gross output series. The method of deriving a suitable price index for deflating the material purchases in industry, then, consists of the following three steps:

(i) On the basis of the information in the 1959 and 1966 input-output tables given in Soviet sources,[19] total material purchases

of gross output in total industry between Groups A and B (i.e., Heavy and Consumer Goods sectors in Soviet terminology). The total industry, branch, and group estimates are compared for reliability with the corresponding figures in Soviet sources. All the sources of data derived from applying the set of equations in the Appendix, their specific features and their limitations are discussed at length in the article, and are not recapitulated here.

[17] Both the input-output tables for 1959 (*Narkhoz* 1960, pp. 104–43) and for 1966 (*Narkhoz* 1967, pp. 64–111) include purchases by various sectors of industry from Transport and Communications, Trade and Supplies and Others.

[18] For example, see Thornton, pp. 865–66.

[19] See *Narkhoz* (1960, pp. 104–43) and *Narkhoz* (1967, pp. 64–111). These tables indicate that purchases by industry from sectors such as Agriculture, Transport and Communications, Supplies and Others are respectively 36 percent and 37 percent of total material purchases by industry in 1959 and 1966. In my judgment, these figures of extra-industry purchases by industry are substantial and contradict Weitzman's assumption

TABLE A1—ABSOLUTE PRICES AND PRICE INDEXES IN SOVIET AGRICULTURE; TRANSPORT AND COMMUNICATIONS[a]

| (i) | Price Per Tonne of Agricultural Output (ii) | Price Index in Agriculture (iii) | Price Per Tonne/km. of Transport and Communications Output (iv) | Price Index in Transport and Communications (v) |
|---|---|---|---|---|
| 1958 | 144.299 | 107.10 | .598 | 86.79 |
| 1959 | 153.273 | 113.76 | .639 | 92.74 |
| 1960 | 134.736 | 100.00 | .689 | 100.00 |
| 1961 | 142.847 | 106.02 | .678 | 98.40 |
| 1962 | 164.962 | 122.43 | .662 | 96.08 |
| 1963 | 182.350 | 135.34 | .647 | 93.90 |
| 1964 | 148.581 | 110.27 | .646 | 93.76 |
| 1965 | 180.112 | 133.68 | .651 | 94.48 |
| 1966 | 177.536 | 131.76 | .651 | 94.48 |
| 1967 | 177.690 | 131.88 | .658 | 95.50 |
| 1968 | 176.697 | 131.14 | .643 | 93.32 |
| 1969 | 195.387 | 145.01 | .643 | 93.32 |
| 1970 | 211.650 | 157.08 | .653 | 94.71 |
| 1971 | 226.360 | 168.00 | .660 | 95.79 |

[a] Column (ii) is shown in rubles, and column (iv) in kopecks.

*Notes:* Gross values of agricultural and transport and communications outputs for 1958, 1963, 1963, and 1964 are taken from *Narkhoz* (1964, p. 677 and p. 67); for 1960 and 1965–70, from *Narkhoz* (1970, p. 607 and p. 60); for 1971, from *Jubilee Volume*, p. 59.

For 1959, 1961, and 1962, the gross values of outputs in each sector are derived by applying the proportions of these for each year to the absolute levels of gross outputs in the economy as a whole. The relevant information is given in *Narkhoz* (1962, p. 64).

Physical outputs in Agriculture for 1958–70 are taken from *Narkhoz* (1970, p. 273); for 1971, from *Jubilee Volume*, p. 217. Physical outputs in Transport and Communications for 1960–71 are from *Jubilee* Volume, p. 293; for 1958 and 1959, from *Narkhoz* (1965, p. 457).

Columns (ii) and (iv) are derived by dividing the gross values of outputs in each sector by the corresponding physical volumes of outputs.

Columns (iii) and (iv) are derived from the corresponding entries in columns (ii) and (iv) with 1960=100.

by industry are allocated in the proportions of 0.68, 0.21, and 0.11 to industry itself, to Agriculture, Transportation and Communications, respectively.

(ii) The price indexes in Soviet Agriculture, Transport and Communications are derived by evaluating the gross output in each at current prices and dividing it by the physical volume of the corresponding output. The series of absolute prices and the corresponding price indexes in Agriculture, Transport and Communications derived from the use of the relevant information in Soviet sources are presented in Table A1.

(iii) Finally, the composite price index for deflating material purchases by industry is derived by applying a weight of 0.68 to the price index in industry itself, of 0.21 to the price index in Agriculture and of 0.11 to the price index in Transport and Communications. This composite price index is presented in Table A2.

that "... such omissions [of purchases by industry from Agriculture and Transportation] turn out to be empirically irrelevant for [Soviet] industry as a whole" (pp. 691–92). Furthermore, it is possible to compute the magnitudes of extra-industry purchases as a proportion of *gross value of output* in industry in the following manner: Applying the proportions of extra-industry purchases of 36 to 37 percent in 1959 and 1966 to the corresponding material purchases by industry of 78.609 billion and 173.998 billion rubles estimated via the method of Section A of the Appendix, one gets the values of 28.299 and 64.379 billion rubles as estimates of extra-industry purchases by industry in 1959 and 1966, respectively. Dividing these by the corresponding values of gross outputs in industry of 118.743 and 259.266 billion rubles in 1959 and 1966, again estimated in Section A of the Appendix, the percentages of extra-industry purchases by industry as proportions of *gross value of output* in industry turn out to be 24 percent in 1959 and 25 percent in 1966. These are by no means insignificant amounts.

TABLE A2—PRICE INDEX FOR DEFLATING MATERIAL PURCHASES BY INDUSTRY[a]

| (1) 1958 | (2) 1959 | (3) 1960 | (4) 1961 | (5) 1962 | (6) 1963 | (7) 1964 | (8) 1965 | (9) 1966 | (10) 1967 | (11) 1968 | (12) 1969 | (13) 1970 | (14) 1971 |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| 98.68 | 100.73 | 100.00 | 101.08 | 104.28 | 106.75 | 101.47 | 105.10 | 104.02 | 109.59 | 109.20 | 112.11 | 116.17 | 118.58 |

[a] The price deflator for 1958 is used for deflating material purchases during 1955–57.

TABLE A3—DATA UNDERLYING DESAI HYBRID INDEX[a,b]

| Branch (1) | Desai Gross Value-Added (2) | Desai Weights (3) | Weitzman Weights (4) |
|---|---|---|---|
| Electricity | 1.770 | 3.87 | 5.01 |
| Fuels | 5.489[c] | 11.99 | 14.73 |
| Ferrous metals | 2.784 | 6.08 | 7.47 |
| Nonferrous metals | 1.379[c] | 3.01 | 3.70 |
| Wood & paper products | 3.896 | 8.51 | 9.84 |
| Construction materials | 2.131 | 4.65 | 6.42 |
| Chemicals | 1.939 | 4.23 | 4.36 |
| Glass and ceramics | .304[c] | .66 | .82 |
| Machinebuilding and metal working | 13.207 | 28.84 | 28.89 |
| Soft goods | 6.420 | 14.02 | 10.35 |
| Processed foods | 6.473 | 14.14 | 8.41 |

*Source:* As explained in the text.

[a] The weights are applied to the branch gross output indexes available in Soviet sources, by both Weitzman and Desai.

[b] Column (2) is shown in billion rubles, and columns (3) and (4), in percent.

[c] Weitzman estimates.

The gross value-added figures in industry derived by using the double deflation procedure are converted into indexes with 1960=100 and presented in column (3) of Table 1. The indexes of material purchases with 1960=100 are presented in column (5) of the same table.

# Public Safety

By SERGE-CHRISTOPHE KOLM*

All measures taken by the public sector have some influence upon the occurence of human deaths and other bodily injuries. And to diminish these risks is the essential or unique aim of a number of them, which include both expenditures and regulations. What is the optimum for these measures? Is the present situation close to it?

A very strong negative answer to the latter question has often been suggested by the observation of the marginal costs incurred to save lives in various sectors by various measures (or, equivalently, of the marginal efficiency of life saving expenditures). The information is plentiful for several countries; in English, let me just mention the studies by William Gorham and Dan Usher and the references they give. The result is always of the same order of magnitude: according to sectors and measures, these marginal costs or efficiencies can be multiplied by factors up to thousands. Can we conclude that human life, the most important commodity, the only one which is an indispensable complement to the enjoyment of any other, is also the one produced with the grossest misallocation and waste?

Several arguments have been and could be advanced to justify discrepancies in these marginal costs and efficiencies. Their general presentation and discussion can be found in my paper (1975). One of them is by far more important than the others, and I focus on it here. It will give results such that, most of the time, the number of dollars spent to avoid a marginal casualty must be higher the more "collective," or "public," the danger is in some sense. And, it will turn out that computations from purely technical observable data can tell us whether safety has received too little or too much emphasis in any given sector.

* School for Higher Studies in the Social Sciences, and CEPREMAP, Paris. The present English (and abbreviated) version was presented at a conference on Public Economics organized by Israel's Scientific Research Council at Kibbutz Kiryat Anavim, June 1975.

## I. Assumptions

Unavoidably, a number of simplifications must be accepted. In some cases, my model and results will be directly applicable. In others, the model must be completed by other considerations, and the role of this study then is to show the way toward important phenomena and conclusions. The main simplifications are as follows. I shall explicitly consider only death, but the same analysis applies to other bodily injuries; more generally, it is the theory of optimum allocation of nontransferable consumptions produced by both private and public inputs (education and recreation are other cases). There is only one period, short enough so that everyone's probability of dying during this period is small. The main problem considered will be to allocate public safety funds between several uses, and the only valuable effect is to reduce casualties; I assume no effective nonnegativity constraints on these different amounts. Finally, there will be no externalities, an assumption which has four main applications here. 1) There are no Pareto-irrelevant (distributional) price externalities, which means that either the considered variations affect too small a sector of the whole economy to influence prices, or that price effects are compensated. 2) There is no externality in consumption: individuals are not directly affected by the consumption-work choices of others, be it through their tastes or their choices' nonbudget constraints. 3) As a special case of 2), individuals are not so affected by the probability of death of others. 4) The death probability of individuals is not affected by the others' choices, i.e., we exclude manslaughter. (Accidents as "congestion externalities" are analyzed in my book (1970).)

The last three cases require an explanation. For individuals' choices about consumption, work, safety, etc., for both the decision and the evaluation, the biological "individual" is not, in fact, the right social

unit. To consider "the family" as the unit would be far better. This term is, however, ambiguous. Every biological individual is the center of concentric circles of individuals who are more or less directly (i.e., not through markets) concerned by, and participating in, "his" choices: himself, the nuclear family, relatives, friends, acquaintances, etc. They, more or less, have a feeling for the individual's situation and influence the corresponding choices. Then, the absence of inter-individual externality means that, in some sense, their influence is "proportional to" their feeling. This participation in choice is through suasion, "reciprocity" exchange, vicarious choice, an individual's desire to please another, etc. This paper is not the place to develop this analysis. Let me just mention its application to the question of risks of death. Who is concerned by an individual's survival probability? First, himself. Then his closest family, first for affective reasons, often with the same intensity as the individual himself, and for material and economic reasons. Then his friends, relatives, etc. Then members of the social communities to which he belongs (neighborhood, church, region, nation, mankind), with a spectrum of degrees of intensity. We are assuming here that the influences on the individual's choices which affect his death probability (as well as on other aspects of his well being) internalize the corresponding feelings, especially at the intrafamily level where they would be impossible to ignore.

## II. Optimality Conditions

Turning now to traditional economic concepts, let $i$ be an individual, $p^i$ his death probability, $v^i$ his marginal willingness to pay for $p^i$, $s^i$ the social marginal value of his wealth. We assume "normal" individuals and society so that $v^i<0$, $s^i>0$, and all the $s^i$ are equal if "distribution is optimal." The term $y^i$ is the set of parameters describing $i$'s "situation" (commodities consumed, work, location, etc.); $x_j$ is the amount of public money spent to reduce risk of type $j$; and $x$ is the vector of $x_j$. From the assumptions, $p^i$ is a function of $x$ and $y^i$ only: $p^i=p^i(x, y^i)$, where $p^i_j=\partial p^i/\partial x_j$ is the "direct" marginal effect of $x_j$ on $p^i$; we shall normally have $p^i_j<0$. The individual $i$ chooses $y^i$ in a possibility set $Y^i$ (which includes in particular its budget constraint but does not directly depend upon $p^{i'}$, and $y^{i'}$ for $i'\neq i$), so as to maximize his utility function $u^i[y^i, p^i(x, y^i)]$. It is shown in the Appendix that an optimality condition for $x_j$ is that $\sum s^i v^i p^i_j$ is the same for all $j$. This condition holds if $\sum x_j$ is given, but it also holds if we explicitly consider how this sum is obtained, for instance through taxation of any kind, as long as the $x_j$ enter in the problem's constraints only by their sum. The result can be applied to any set of risks $j$ (containing at least two $j$'s).

## III. Direct and Indirect Effects

With given functions $u^i$ and $Y^i$, the $y^i$ chosen by individual $i$, $y^{i*}$, depends upon $x: y^{i*}=y^{i*}(x)$. We assume that this function is differentiable for the present exposition, although it is not necessarily so in this field (decisions to incur or shun some kind of risk). The sensitivity (total derivative) of $p^i$ for $x_j$ is

$$P^i_j = \frac{dp^i}{dx_j} = p^i_j + \sum_k \frac{\partial p^i}{\partial y^{i*}} \frac{\partial y^{i*}_k}{\partial x_j}$$

where the $y^i_k$ are the components of $y^i$. In the normal case $0>P^i_j>p^i_j$, meaning that the increment in income received by the gift in safety through an increase in $x_j$ is redistributed among several items of consumption, including some left in safety.

It is usually possible to distinguish for each $x_j$ a subset of $y^i_k$, say those with $k\in K_j$, which are parameters chosen by the individuals and having some influence on their risk which is affected by $x_j$; thus, $\partial p^i_j/\partial y^i_k=0$ for $k\notin K_j$; we then call

$$\pi^i_j = p^i_j + \sum_{k\in K_j} \frac{\partial p^i}{\partial y^{i*}_k} \frac{\partial y^{i*}_k}{\partial x_j}$$

The normal case seems to be such that $0\geq\pi^i_j\geq p^i_j$. The case $\pi^i_j=p^i_j$ generally implies that the individual has no influence on the risk affected by $x_j$. Ordinary behavior seems also to suggest that $\pi^i_j=P^i_j$ is not infrequent.

We now have three candidates for mea-

suring the marginal efficiency of $x_j$ in number of lives saved: $\sum_i |P_j^i|$, $\sum_i |\pi_j^i|$, and $\sum_i |p_j^i|$. The "right" one may seem to be the total marginal number of lives saved, $\sum_i |P_j^i|$. However, the one which is given by the above mentioned statistics is the number of lives saved in the considered activity, $\sum_i |\pi_j^i|$. One may consider the individuals' adjustments as their own responsibility, implying that the marginal efficiency which should count for allocating $x_j$ is the marginal number of lives "directly" saved, $\sum_i |p_j^i|$. According to which number of deaths we would like to minimize, it is the equality for all $j$ of one of these three numbers which are the corresponding first-order conditions. None is, however, a priori the true optimality condition.

### IV. When Must We Save As Many Lives As Possible?

There are, however, nonfortuitous cases when $\sum_i p_j^i = \sum_i p_k^i$ is the condition for optimal allocation between $x_j$ and $x_k$. One is when $x_j$ and $x_k$ are such that, necessarily, $p_j^i$ is the same for all $i$ and $p_k^i$ is the same for all $i$. We call the corresponding risks "pure public risks." Practically, this happens for risks which are common to the whole population under consideration. The case also practically requires that individuals cannot modify this risk for themselves, and thus that $p_j^i = \pi_j^i$ and $p_k^i = \pi_k^i$. In such cases, if statistics show $|\pi_j^i| \neq |\pi_k^i|$, or if engineering computation concludes that $|p_j^i| \neq |p_k^i|$ in the actual situation, there is misallocation and funds must generally be transferred from the less to the more efficient use.

Another case, at the extreme opposite, is when $x_j$ and $x_k$ actually affect the safety of only one and the same individual. That is, $p_j^{i'} = p_k^{i'} = 0$ for all $i' \neq i$. The corresponding risks are "purely private risks" for individual $i$. We then note that the condition $p_j^i = p_k^i$ does not depend upon the fact that individual $i$ may be more able to shun one risk than the other one by his own choices, i.e., does not depend upon the differences in individual responsibility in risks.

These two cases are subcases of the one where $x_j$ and $x_k$ affect in a purely public way the safety of the individuals of some subsociety, and do not affect the others. That is, there is a set $I$ of $i$ such that $p_j^i = p_k^i = 0$ for $i \notin I$, and $p_j^i$ are the same for all $i \in I$ and $p_k^i$ are the same for all $i \in I$.

A third case would be when all $V^i = v^i s^{i}$'s are equal: then $\sum_i p_j^i$ must be the same for all $j$. But this certainly does not hold. Even apart from inequalities in $s^i$, the $v^i$ are far from equal, due to differences in individuals' situations and tastes (some people never take a plane, others play Russian roulette).

In all these cases but the last, the result does not depend upon the $V^i$, and therefore not on the $v^i$ or $s^i$. Thus it is independent of the income distribution, of individual tastes, and of costs of raising public funds. The most significant of these cases is that of pure public risks: the allocation of safety funds among risks must save as many lives as possible.

### V. The Technological Optimality Condition

With $s^i v^i = V^i$, the optimality conditions are $\sum_i V^i p_j^i = \lambda$. We write $p_i$ for optimum $p_j^i$ when $j$ is a pure private risk for $i$. The condition gives $V^i p_i = \lambda$. Then, for any general risk $j$, the condition is $\sum_i p_j^i / p_i = 1$. The interest of this formula is that $p_j^i/p_i$ is the rate of substitution of purely private safety costs to $x_j$ in $p^i$. In particular, it may be a purely private safety expenditure in the same field where $x_j$ intervenes. Then, $p_j^i/p_i$ are often computable through engineering data or from casualty statistics. We would generally conclude that $x_j$ is too small or too large from the fact that $\sum_i p_j^i/p_i$ is larger or smaller than one.

### VI. Pure Public and Private Risks

Let us now call $p_0$ the optimum $p_j^i$ for any pure public risk $j$. The above optimality condition gives $1/p_0 = \sum 1/p_i$. Or, $n$ being the number of persons in the society,

$$\frac{1}{np_0} = \frac{1}{n} \sum \frac{1}{p_i}$$

$n|p_0|$ is the direct marginal efficiency of purely public safety in number of lives saved. It must thus be the harmonic mean of the like efficiencies of purely private safety, $|p_i|$. Thus, if $m = Min_i |p_i|$ and $M =$

$Max_i\,|p_i|$, $m \leq n|p_0| \leq M$ must hold. Furthermore, from an easy application of Cauchy's inequality, one must have $n\,|p_0| \leq (1/n)\sum |p_i|$, that is to say, one extra dollar must save more lives if it is equally shared between purely private safeties than if it is used for pure public safety; both allocations are "egalitarian" in some sense. It may seem surprising that equal sharing, which is arbitrary from efficiency viewpoints, is nevertheless the most efficient way of saving lives. Schweitzer's and Sisha-Mond's inequalities furthermore show that

$$\frac{1}{n}\sum |p^i| / n |p_0| \leq (M+m)^2/4Mm$$

and

$$\frac{1}{n}\sum |p^i| - n|p_0| \leq (M^{1/2} - m^{1/2})^2$$

The equalities hold everywhere if and only if all $p_i$ were equal, which is unlikely since it would also imply the equality of all $V^i$ at the optimum. Thus, if a nonpure public risk $j$ is close enough to a pure public risk in the sense that the dispersion of the $p_j^i$ is low enough, the same inequalities must hold when $\sum_i |p_j|$ replace $n|p_0|$. In particular, $\sum_i |p_j^i| \leq (1/n)\sum |p_i|$. It is, however, the comparison between general $\sum_j |p_j^i|$ and $n|p_0|$ which is the most interesting one: this is the topic of Section VIII.

## VII. Public or Private Provision

Before leaving purely private risks, we must note a difference between two kinds of safety expenditures according to who decides about them: the public sector or the individual. There are publicly provided pure private safety and privately provided pure private safety. We considered the former. For the latter, the individual's choice does not necessarily conform to the social optimum: if we call $p_i'$ the derivative of $p^i$ for any safety expenditure chosen by individual $i$, this choice is such that $v^i p_i' = 1$. This private choice would coincide with what would be the optimum one if the public sector were in charge of this decision if $s^i = \lambda$, giving $p_i' = p_i$ at optimum. This would happen if lump sum transfers between individual $i$'s wealth and the public safety fund $\sum x_j$ were possible. Otherwise, generally $p_i' \neq p_i$. More precisely, at optimum $p_i'/p_i = s^i/\lambda$, which means that the marginal rate of substitution of publicly provided to privately provided purely private safety funds for $i$ must be equal to the social marginal value of $i$'s wealth measured in public safety dollars. Now, statistics sometimes provide $p_i'$ more easily than $p_i$; for instance, in the case of road traffic safety, accident statistics based on cars (a private choice) give $p_i'$, whereas statistics based on the condition of roads (a public safety choice) give $p_j^i$. If "income distribution is optimal," $s^i$ is the same for all $i$ by definition, and the first-order optimality condition for the allocation of the $x_j$ is that $\sum_i p_j^i/p_i'$ is the same for all $j$. If, furthermore, there can be lump sum transfers between individuals' incomes and the public safety fund, these conditions become that $\sum_i p_j^i/p_i' = 1$ for all $j$. And the actual discrepancies between these values indicate how the $x_j$ must be reallocated.

## VIII. General and Pure Public Risks

Optimum allocation between purely public and general safety imply

$$p_0 = \sum_i \frac{V^i}{\sum V^i} p_j^i = \sum_i \frac{1/p_i}{\sum 1/p_i} p_j^i$$

and the marginal number of lives saved by $x_0$ is

$$n|p_0| = \sum_i \frac{V^i}{\overline{V}} |p_j^i|$$

where $\overline{V} = \sum V^i/n$ is the average $V^i$. Therefore $n|p_0| < \sum_i |p_j^i|$ if the $p_i$ and the $p_j^i$ are similarly classified by $i$, and the reverse inequality holds if they are inversely classified by $i$ (i.e., $(p_i - p_{i'})(p_j^i - p_j^{i'})$ for all pairs $i, i'$ is positive in the former case and negative in the latter one).

Let $\pi^{ij}$ be the probability that the cause of risk $j$ kills individual $i$. It is an additive part of $p^i$. It depends upon $x_j$ the amount of public money which diminishes this risk for all $i$, and upon $y_j^i$ the sum spent to diminish this risk for individual $i$ only, $x_j$ and $y_j^i$ influence $p^i$ through $\pi^{ij}$ only. We also assume that $\pi^{ij} = \pi^j(x_j, y_j^i)$; i.e., the only reason why

$\pi^{ij}$ depends upon $i$ is that the $y_j^i$ differ. This is a frequent situation which only means that the effect of $x_j$ and $y_j^i$ on $\pi^{ij}$ is a purely technical matter, general and not dependent upon other individual characteristics; $\pi^j$ is a decreasing function of both its arguments. But, being a probability, it is constrained by $\pi^{ij} \geq 0$. It is small by assumption, and in ordinary cases very small. We consider the situation at the optimum. We certainly have $\partial^2 \pi^j / \partial y_j^{i2} > 0$ because of $\pi^j$'s positivity and smallness; this indicates a point of decreasing returns to scale of $y_j^i$ expenditure on safety. But $\partial \pi^j / \partial y_j^i = p^i$ and $\partial \pi^j / \partial x_j = p_j^i$. Thus $p_i$ is an increasing function of $y_j^i$, and therefore $p_i$, $y_j^i$, $-\pi^{ij}$ are similarly ordered by $i$. Also $p_j^i$ is similarly ordered or, on the contrary, inversely ordered, by $i$, depending on whether it is an increasing or a decreasing function of $y_j^i$, i.e., on whether $\partial^2 \pi^j / \partial x_j \partial y_j^i$ is positive or negative, i.e., on whether $x_j$ and $y_j^i$ are substitutes or complements in providing safety.

To conclude, *a public expenditure on a general public safety must marginally save more or fewer lives than one on a pure public safety depending on whether it is a substitute or a complement to private safety measures* (i.e., the marginal cost of saving a life must be lower or higher in this manner than from pure public risks depending on this condition).

In most cases, public and private safety measures happen to be substitutes rather than complements. This is for instance the case for most road (public) and car (private) safety improvements, for firemen and private fire protection (extinguishers, use of fireproof material, exits), for police and private watchmen or systems preventing entry, for most home and hospital cures, for vaccination and public sanitation, for public air pollution prevention and private air filters, etc. There are however cases when they are complements: for instance, various aspects of health care, or car lights and road signals, or, generally, private alarm systems (things or men) and the public service they call (fire, police, accident rescue).

The most common case thus is $n|p_0| < \sum_i |p_j^i|$ at the optimum, i.e., an extra dollar must save fewer lives from a pure public risk than from nonpure public risks, or, we must pay more to save an extra life from a pure public risk than elsewhere. The reason for it as shown above is that the nonpure public safety measure saves on the average "cheaper" lives than the purely public one because the more valuable ones are more sheltered from this risk by specific protection—a discrimination which is not possible for purely public risks.

The difference in death's marginal costs may have to be substantial. If risk averters (i.e., high $|v^i|$ people) completely shun risk $j$ so that $p_j^i = 0$ for these $i$, whereas other people care little (low $|v^i|$), then $\sum_i (V^i/\overline{V})|p_j^i| = n|p_0|$ may be much smaller than $\sum_i |p_j^i|$.

## IX. General Risks

Now calling $\rho_j$ the correlation coefficient between $V^i$ and $p_j^i$, we have

$$\sum_i V^i p_j^i = \overline{V} \cdot (1 + \rho_j) \cdot \sum_i p_j^i$$

which shows that the marginal cost of saving a life by $x_j$ must be proportional to $1 + \rho_j$ ($\rho_j = 0$ for a pure public risk and the above argument is that $\rho_j < 0$ for most of the other cases). It is also possible to distinguish the factors in $V^i = s^i v^i$ and analyze the effect on the optimum marginal costs of life of the correlations between $s^i$ (income distribution), $v^i$ (individual risk aversion), and $p_j^i$.

## X. Conclusion

Given its importance, the economic value of human life has received little attention. It is hoped that this paper sheds some light on some of these important aspects, in particular on the question of the inequality of values for different sectors and decisions, especially public decisions. Among the results are the following: There generally must be inequalities. An exception is the case of purely public risks where as many lives as possible must be saved by the appropriate allocation of safety funds. For other safety measures, life must generally be cheaper or more expensive than for purely public safety

depending on whether this expenditure is a substitute or a complement to purely private safety; most often, it must be cheaper. Finally, it has been shown how statistical or engineering data may indicate whether safety is too low or too high in any given sector.

## Appendix

The usual notations are used for the derivatives for vectors and of vectors. We call $v^i_y$ the vector of individual $i$'s willingness to pay for the components of $y^i$ when $p^i$ is given. We note $p^i_y$ for $p^i_{y^i}$. Given $x$, individual $i$ chooses an $y^i$, $y^{i*}(x) \in Y^i$. Either $v^i p_y + v^i_y = 0$, or $y^{i*}(x)$ is on the border of $Y^i$ and the vector $v^i p_y + v^i_y$ for $y^i = y^{i*}(x)$ is within the cone of normals to $Y^i$ at this point. Thus, when $x$ differentially varies, we have

$$(v^i p^i_y + v^i_y)\Big|_{y^i = y^{i*}(x)} \cdot y^{i*}_x(x) \cdot dx = 0$$

Therefore, individual $i$'s marginal willingness to pay for a change $dx$ in $x$ is the value at $y^i = y^{i*}(x)$ of

$$[v^i p^i_x + (v^i p^i_y + v^i_y) y^{i*}_x] \cdot dx = v^i p^i_x \cdot dx$$

whence the mentioned optimality condition. The same result can be shown to hold when $y^{i*}(x)$ is not differentiable, a not unimportant case (choices to incur or not some risk—for instance, to take a plane or not).

# A State-Preference Approach to the Precautionary Demand for Money

*By* M. L. CROPPER*

Much attention has been devoted in the literature to the transactions demand for money and the asset demand for money. The precautionary motive for holding cash balances, however, is seldom analyzed. A notable exception is S. C. Tsiang's inventory-theoretic analysis, which integrates precautionary demand into an inventory model of the transactions demand for cash. Precautionary demand can, however, be approached as a problem in portfolio theory using a state-preference approach, as John Hicks (1967) once suggested.[1] The states of nature in this case represent the times at which an investor may, for reasons beyond his control, have to liquidate his portfolio. It is this uncertainty regarding future cash requirements, combined with the fact that some assets are neither readily nor costlessly convertible into cash, which gives rise to the precautionary demand for money.

Consider the situation of an investor who is allocating his wealth among assets of varying degrees of liquidity to maximize expected utility of wealth at the end of his horizon. The investor believes that certain events (outside of his control) may occur which will force him to liquidate his portfolio before the end of his horizon. If liquidation is not called for, the portfolio will be held until the end of the horizon and then sold. Whether or not liquidation will actually be required is not known until the time the cash is needed. Thus, if the portfolio must be sold before the end of the period, it must be sold on short notice. This means that the investor will be able to sell his less liquid assets only at a discount, the size of the discount varying inversely with the length of notice given before the asset is sold. The individual thus has an incentive to hold liquid assets, say, cash, to reduce losses which may possibly be incurred if he must suddenly liquidate his portfolio. Money held for this purpose may be labelled precautionary cash balances. An increase in the probability that the investor will have to liquidate his portfolio in the near future should increase this demand.

The remainder of this paper investigates the precautionary demand for money in the framework outlined above. Using two concepts of liquidity, I derive conditions under which an increase in the probability of having to liquidate one's portfolio on short notice will increase the precautionary demand for money; that is, conditions are obtained under which a well-behaved precautionary demand for money, in the above sense, can be said to exist.

In Section I the concept of liquidity is discussed at some length. This discussion is necessary before liquidity can be formally incorporated into a portfolio selection model. The formal model is presented in Section II.

## I

A liquid asset according to J. M. Keynes' definition is one which is " . . . more certainly realizable on short notice without loss" (p. 67). This is usually interpreted to mean that *il*liquid assets are either not realiz-

* Assistant professor of economics, University of California, Riverside. I gratefully acknowledge helpful comments from two anonymous referees.

[1] I have not however followed the model outlined by Hicks (1967, pp. 31–34). In that model, an illiquid asset is one which incurs high transactions cost, e.g., brokerage fees, whenever it is traded, *regardless* of the length of notice given before the transaction takes place. (This use of the term liquidity deviates somewhat from that followed by Keynes and Tsiang.) The longer the investor's horizon, the more incentive he will have to invest in illiquid assets since transactions costs will decline as a percentage of asset yield as the holding period is lengthened. Put somewhat differently, Hicks is saying that it will pay to invest in illiquid assets only if they can be held long enough to compensate for their high transactions costs. Precautionary demand enters when the planned date of realization is uncertain.

able with certainty or that they can be converted into cash on short notice, only at a loss. The size of the loss incurred is assumed to vary inversely with the length of notice given before the asset is sold. This is the common interpretation of the term liquidity (see Hicks, 1962; Tsiang); however, a little reflection indicates that this interpretation is not meaningful in all market situations. In a perfectly competitive capital market, for example, there is no obvious reason why the price at which an asset is sold should vary directly with the length of notice given before the asset is sold. Therefore, before liquidity can formally be incorporated into a portfolio selection model, some further discussion is clearly required. To give the term more meaning, I shall discuss two sources of uncertainty in capital markets.

Uncertainty in most portfolio selection models is uncertainty about which state of nature will occur at some future time t.[2] Investors are assumed to know security prices contingent on the state of the world at that time. Because an investor is uncertain exactly what the state of the world will be, he has a subjective probability distribution over asset prices. Once time t has arrived, however, the state of the world is known and there is a single known asset price. (Capital markets are assumed to be perfect in all respects other than knowledge of the future.)

In the above model the individual believes that the price of each security at time t is determined by forces external to him, for example, political conditions in the United States, the world demand for steel, etc. Once the outcome of these forces is known a unique price is determined for each security. The investor has no reason to believe that this price will be altered should he have to sell the security at time t. Thus there is no reason to believe that the investor's distribution over future asset price should be affected by the length of notice given before an asset is sold. By this reasoning, the "realizable on short notice without loss" aspect of the term liquidity really has no meaning in a portfolio model in which uncertainty is only of a state-of-nature variety. One asset can be more liquid than another in this context only if it is "more certainly realizable" regardless of the length of notice given before it is sold. Thus, in standard portfolio selection models, "more liquid" must be synonymous with "less risky," and a perfectly liquid asset must necessarily be a riskless asset.

Keynes' definition of liquidity is meaningful, however, in markets in which investors are imperfectly informed about opportunities to buy and sell securities. In markets in which information is imperfect there will usually be a distribution of prices for any security at any time, rather than a single equilibrium price.[3] In such a market an investor has a subjective distribution over asset yield (price) because he is uncertain about the actual price at which he will sell a security. The moments of the subjective distribution will generally depend on the amount of price information the individual can obtain by sampling bids of prospective buyers.

Assuming that sampling takes time, one may argue that an investor who does not have time to search out potential buyers, for example, because he must sell his assets on short notice, will most likely have to sell his assets at a lower price than an investor who has time to acquire a larger sample of bids. Reasoning in this way, one may interpret "realizable on short notice without loss" to mean that illiquid assets can be sold on short notice only at a discount. This discount arises because the individual does not have time to obtain more price information, and it should therefore vary inversely with the length of notice given before the asset is sold. This aspect of liquidity is usually re-

[2] The uncertainty in Markowitz-Tobin portfolio selection models is implicitly of the state-of-nature variety. In these models investors have probability distributions over security prices at some time in the future, which are by assumption independent of current prices. These distributions may be regarded as having been derived from a knowledge of state-contingent returns and a probability distribution over states when the number of states is infinite. It should be emphasized that state-of-nature uncertainty can exist even when capital markets are perfect, in the sense that each asset has a single known equilibrium price.

[3] The uncertainty in recent job-search models is of this variety.

ferred to as marketability.

In the model below we are interested not in the price at which an illiquid (imperfectly marketable) asset is actually sold, but in the effect that having suddenly to liquidate the asset will have on the investor's subjective distribution over asset yield. That is, we wish to know how the belief that an illiquid asset must be sold on short notice will alter the investor's subjective probability distribution over yield. If an investor believes that by increasing the size of his sample he will reduce the variability of the distribution and increase its mean, it follows that the subjective distribution should have greater variability (a more precise definition of greater variability is given below) and a lower mean if the investor must sell the security on short notice than if he has more time to sample potential buyers.[4] With this interpretation of liquidity in mind, we turn to the formal model.

## II

Assume that an investor must divide his initial wealth $W_0$ between two securities: money, a perfectly liquid asset paying zero return with certainty, and an illiquid asset, the return on which is a random variable. One of two possible events which may be thought of as states of nature must occur before the end of the investor's horizon. The first event, which we shall call state 1, is the occurrence of some emergency which requires immediate cash payment. If state 1 occurs the investor must sell his portfolio at once. State 2 is the absence of such an emergency. If state 2 occurs the portfolio will be held to the end of the horizon and then sold.

Money, because it is a perfectly liquid asset, pays a certain return (of zero) in both states.[5] The return on the illiquid asset is $r_1$ in state 1 and $r_2$ in state 2. It is assumed that this asset is illiquid because it is imperfectly marketable. Thus the distribution over $r_1$ should be more variable and should have a lower mean than the distribution over $r_2$, since the investor will not have as much time to sample price information in state 1 as he will if state 2 occurs.[6] It is further assumed that $r_1$ and $r_2$ must lie in the interval $[-1, \infty)$. This implies that the investor's wealth can never fall below 0.[7]

The investor's objective is to set $a$, the fraction of $W_0$ invested in the illiquid asset, to maximize expected utility of wealth at the time his portfolio is liquidated. Thus the investor seeks to

$$\max_a \{pE[U(W_1)] + (1-p)E[U(W_2)]\},$$

$$W_1 = W_0(1 + ar_1) \tag{1}$$
$$W_2 = W_0(1 + ar_2)$$

where $p$ is the subjective probability that state 1 will occur and $(1-p)$ is the subjective probability attached to state 2. The investor's utility function is assumed to be identical in both states and to obey

$$U' > 0 \quad \text{and} \quad U'' < 0 \tag{2}$$

Because we are interested only in a solution for which $0<a<1$, I shall make the following assumptions which guarantee an interior solution to (1).

$$U'(0) = \infty \tag{3}$$

$$E(r_1) > 0, \qquad E(r_2) > 0 \tag{4}$$

First-order and second-order conditions for a maximum are, respectively,

$$pW_0E[r_1U'(W_1(a))] + (1-p)W_0E[r_2U'(W_2(a))] = 0 \tag{5}$$

[4] This is a tricky point. The investor is making a judgment in the present, before any sample is taken, about what the shape of his subjective distribution will be in the future, after the sample has been taken. The belief before the sample is taken that the variability of the distribution can be reduced by taking a larger sample corresponds to what in Bayesian terminology is referred to as preposterior analysis.

[5] The analysis may be extended with little difficulty to the case where money pays a nonzero return with certainty by reinterpreting $r$ as the yield differential between liquid and illiquid assets. As this does not significantly affect the results, I present only the case where the return on money is zero.

[6] Any other sources of uncertainty, e.g., state-of-nature uncertainty, by assumption do not differ between the two states.

[7] It also implies that the limits of integration in equations (6) and (7) below are independent of $r$; hence, differentiation is permissible within the integral sign.

$$\frac{da}{dp} = \frac{-W_0\{E[r_1U'(W_1(a))] - E[r_2U'(W_2(a))]\}}{pW_0^2E[r_1^2U''(W_1(a))] + (1-p)W_0^2E[r_2^2U''(W_2(a))]} \tag{7}$$

$$pW_0^2E[r_1^2U''(W_1(a))] + (1-p)W_0^2E[r_2^2U''(W_2(a))] < 0 \tag{6}$$

We now wish to see whether an increase in $p$, the probability that the investor must suddenly liquidate his portfolio, will increase the demand for money. This is, of course, equivalent to determining whether $da/dp$ is in fact negative. Applying the implicit function theorem to (5), an implicit function of $a$ and $p$, yields equation (7), shown above.

The denominator of (7) must be negative if the second-order condition for a maximum, equation (6), is satisfied. Thus $da/dp \gtreqless 0$ as $E[r_2U'(W_2)] \gtreqless E[r_1U'(W_1)]$. We can make statements about the sign of the numerator of (7) under alternative assumptions about the distribution functions $F_1(r_1)$ and $F_2(r_2)$. For reasons elaborated in the previous section, I argue that $F_2(r_2)$, the distribution function over the yield on the illiquid asset in state 2, should have higher mean and lower variability than $F_1(r_1)$.

We consider first the case where $r_2 = r_1 + k$, $k > 0$, so that for every possible value of $r_1$ there is a corresponding value of $r_2$ which is greater by $k$ and has the same probability occurrence. This implies that $F_1(r_1)$ and $F_2(r_2)$ are identical distributions, but that the mean of $F_2(r_2)$ is greater than the mean of $F_1(r_1)$. In this case the sign of $da/dp$ depends on whether the gain in utility from investing an additional dollar in the illiquid asset, $rU'[W_0(1+ar)]$, is increasing or decreasing in $r$.

From the assumption that $r_2 = r_1 + k$ it follows that

$$\int r_1U'[W_0(1+ar_1)]dF_1(r_1) \gtrless \int r_2U'[W_0(1+ar_2)]dF_2(r_2) \tag{8}$$

as

$$\frac{\partial}{\partial r}\{rU'[W_0(1+ar)]\} \lessgtr 0 \tag{9}$$

From equation (7) we know that the sign of the inequality in (8) determines whether the fraction of initial wealth invested in the illiquid asset increases or decreases as the probability of having suddenly to liquidate the portfolio increases. Thus, assuming that the illiquid asset has lower expected return if the portfolio must be sold on short notice, the proportion of $W_0$ invested in this asset will increase if $\partial/\partial r\{rU'(W)\} < 0$ and will decrease if $\partial/\partial r\{rU'(W)\} > 0$. That is, an increase in the probability of having suddenly to liquidate the portfolio will cause an investor to put a smaller proportion of his wealth in the less liquid asset and will increase his precautionary demand for money, provided

$$\frac{\partial}{\partial r}\{rU'[W_0(1+ar)]\} > 0 \tag{10}$$

It is easily shown that (10) is equivalent to $U' + W_0arU'' > 0$. This condition can more meaningfully be stated in terms of the relative risk-aversion index $R = -WU''/U'$. Thus

$$\frac{\partial}{\partial r}\{rU'[W_0(1+ar)]\} = U'\left(1 - \left[\frac{ar}{1+ar}\cdot R\right]\right) \tag{11}$$

A necessary and sufficient condition for the right-hand side of (11) to be positive is that $R < (1+ar)/ar$. I argue that this is in fact likely to be the case. Since $a$ is a fraction and $r$, the single-period rate of return on the risky asset, is presumably also a fraction, it is very likely for $r > 0$ that $(1+ar)/ar > 2$. Thus a sufficient condition for an increase in $p$ to reduce the demand for the illiquid asset and to increase the demand for precautionary cash balances is that $R$, the relative risk-aversion index, be less than two. The literature on the theory of risk aversion suggests that this condition is indeed likely to be

satisfied.[8] Thus for most utility functions an increase in the probability of having to liquidate one's portfolio on short notice should increase the precautionary demand for money if liquidity is defined in terms of differences in the means of $F_1(r_1)$ and $F_2(r_2)$.

Let us now consider a different interpretation of the term liquidity. Above it was assumed that only the mean of the subjective probability distribution was affected by forced sale of the portfolio. We now assume that the distribution over $r_2$ has the same mean as the distribution over $r_1$, but less variability. This is justified on the grounds that obtaining a larger sample can be expected to reduce the dispersion of the distribution over $r$.

Variability will be defined in the manner suggested by Michael Rothschild and Joseph Stiglitz (1970), viz.,

$$r_1 \underset{d}{=} r_2 + Z \tag{12}$$

where $E(Z|r_2)=0$. This should be read "$r_1$ has the same distribution as $r_2$ plus noise." Using this definition of variability we can apply the following theorem (pp. 237–38) to make statements about the sign of the numerator of equation (7).

THEOREM (Rothschild and Stiglitz): *The following statements are equivalent*:

$$Y \underset{d}{=} X + Z, \qquad E(Z|X) = 0 \tag{13}$$

$$EU(X) \geq EU(Y), \qquad U'' < 0 \tag{14}$$

As Rothschild and Stiglitz suggest (p. 67), this theorem can be applied to problems of expected utility maximization in which an agent seeks to

$$\max_{\alpha} \int U(X, \alpha)dF(X) \tag{15}$$

The optimal $\alpha$ must satisfy

$$\int \frac{\partial U(X, \alpha)dF(X)}{\partial \alpha} = EU_\alpha(X, \alpha) = 0 \tag{16}$$

If $U_\alpha$ is monotone decreasing in $\alpha$ and if $U_\alpha(X, \alpha)$ is a concave function of $X$, then an increase in riskiness in the sense of (13) will by the theorem stated above imply

$$EU_\alpha(X, \alpha) \geq EU_\alpha(Y, \alpha) \tag{17}$$

In order to apply this result in the present case, we must see under what conditions $g(r)=rU'[W_0(1+ar)]$ is concave in $r$. (That $g(r)$ is a decreasing function of $a$ is implied by equation (2).) For all utility functions for which $g(r)$ is concave, it will be true by (12) and (17) that $E[r_2U'(W_2)]\geq E[r_1U'(W_1)]$. Hence for all utility functions which imply $g(r)$ concave, $da/dp<0$, and a well-behaved precautionary demand for money can be said to exist.

A necessary and sufficient condition for $g(r)$ concave is

$$\begin{aligned} g''(r) &= aW_0(aW_0rU'''+2U'') \\ &= aW_0[(W-W_0)U'''+2U'']<0 \end{aligned} \tag{18}$$

Following Rothschild and Stiglitz, the term in brackets can be written in terms of the expressions for relative and absolute risk aversion, yielding

$$\begin{aligned} g''(r) = aW_0[U''(1 - R + W_0A) \\ + U'(W_0A' - R')] < 0 \end{aligned} \tag{19}$$

where $R=-WU''/U'$ denotes relative risk aversion and $A=-U''/U'$ denotes absolute risk aversion. Equation (19) along with previous assumptions implies that a sufficient condition for $g(r)$ concave is that the investor's utility function exhibit nonincreasing absolute risk aversion, nondecreasing relative risk aversion, and a relative risk-aversion index less than $1+W_0A$.

Arrow (ch. 3) has convincingly argued that nondecreasing relative and nonincreasing absolute risk aversion are reasonable conditions to impose on the utility function. If absolute risk aversion is decreasing, investors are willing to risk larger amounts as their wealth increases, a prediction which

[8] Arrow (ch. 3) for example argues that $R$ should be in the neighborhood of one. His argument is based on the fact that if $U(W)$ is bounded from below, then $R$ cannot approach a limit *above* one as $W$ approaches 0, while if $U(W)$ is bounded from above, $R$ cannot approach a limit *below* one as $W$ approaches infinity. From this Arrow concludes that "... broadly speaking, the relative risk aversion must hover around 1, being, if anything, somewhat less for low wealths and somewhat higher for high wealths" (p. 98).

agrees with casual observation. Nondecreasing relative risk aversion implies that the wealth elasticity of demand for cash balances is greater than or equal to one. As Arrow notes (p. 103), this prediction agrees with empirical findings by Milton Friedman, Richard Selden and others.

The condition that $R$ be less than $1+W_0A$ does not easily admit of an intuitive interpretation; however, it can be shown that this condition is satisfied by many of the utility functions in the constant relative and constant absolute risk aversion classes. Utility functions which satisfy this property include the logarithmic utility function, $U(W)=log\ W$, and all constant relative risk-aversion utility functions, $U(W)=(1-b)W^{(1-b)}$, for which $0<b=R<(1+ar)/ar$.[9] As I have argued above for $R>0$ $(1+ar)/ar$ is very likely to be $\geq 2$. Therefore all constant relative risk-aversion utility functions for which $R<2$ will most likely satisfy the requirement that $R<1+W_0A$. The constant absolute risk-aversion utility function $U(W)=-e^{-bW}$, $b>0$, satisfies the property $R<1+W_0A$ provided $b<1/arW_0$.[10] Since $a$ is a fraction and $r$ is likely to be a fraction also, the condition $b<1/(arW_0)$ does not appear unduly restrictive. These considerations suggest that for a large class of utility functions, the present framework leads to a well-defined precautionary demand for money when liquidity is used in the sense of "less variability."

Before concluding, note that the model developed above yields another implication which agrees with intuition. Assuming that the utility function exhibits nondecreasing relative risk aversion, it can be shown (see the Appendix) that the proportion of initial wealth invested in liquid assets for precautionary purposes should increase as wealth increases.

## III

The purpose of this paper is three-fold: 1) to indicate how the precautionary demand for money can be incorporated into a portfolio selection model, albeit an extremely simplified portfolio selection model, using the notion of states of nature; 2) to give a possible interpretation to the term liquidity in the context of such a model; 3) to determine precisely what restrictions must be placed on an investor's utility function for a well-defined precautionary demand for money to exist.

I have argued that in a market in which there is a distribution of prices for any security rather than a single equilibrium price, it is reasonable to assume that an investor will perceive the distribution of prices with which he is faced as being more variable if he must sell the security on short notice than if he has more time in which to sample potential buyers. If this is the case, the investor will under the assumptions made above have a positive precautionary demand for money. Furthermore, an increase in the probability that his portfolio will have to be sold on short notice will increase the proportion of the portfolio invested in liquid assets, if the investor has a utility function which exhibits nonincreasing absolute and nondecreasing relative risk aversion and has a relative risk-aversion index which is less than $1+W_0A$. It can in addition be shown that the proportion of initial wealth invested in liquid assets for precautionary purposes should increase as wealth increases, provided that the utility function exhibits nondecreasing relative risk aversion.

## Appendix

The purpose of this Appendix is to show that the proportion of initial wealth invested in liquid assets for precautionary purposes will increase as wealth increases if the investor's utility function exhibits nondecreasing relative risk aversion. To demonstrate this, it is sufficient to show that

[9] For the logarithmic utility function, $R=1$ and $A=W^{-1}$; hence $W_0A=W_0W^{-1}$. The condition $R<1+W_0A$ is always satisfied since by assumption $W$ can never become negative. For the utility function $U(W)=(1-b)W^{(1-b)}$, $1+W_0A=1+bW_0W^{-1}$. The desired property $R<1+W_0A$ is equivalent to $b<1+bW_0W^{-1}$ in view of the fact that $R=b$. This will hold only if $b<1/(1-W_0W^{-1})$, which is equivalent to $b<(1+ar)/ar$ after substitution from $W=(1+ar)W_0$.

[10] In the case of the constant absolute risk aversion utility function $U(W)=-e^{-bW}$, $R=bW$, and $A=b$. The condition $R<1+W_0A$ is thus equivalent to $bW<1+bW_0$, which implies $b<(W-W_0)^{-1}$. Using the fact that $W=(1+ar)W_0$ this condition becomes $b<(arW_0)^{-1}$.

$$\text{(A2)}\quad \frac{da}{dW_0} = -\frac{pE[r_1U'(W_1)]+(1-p)E[r_2U'(W_2)]+pE[r_1W_1U''(W_1)]+(1-p)E[r_2W_2U''(W_2)]}{pW_0^2E[r_1^2U''(W_1)]+(1-p)W_0^2E[r_2^2U''(W_2)]}$$

$$\text{(A1)}\qquad R' \geq 0 \Rightarrow \frac{da}{dW_0} \leq 0$$

Implicit differentiation of the first-order condition for a maximum (equation (5)) with respect to $a$ and $W_0$ yields equation (A2). The denominator of (A2) is negative if the second-order condition for a maximum is satisfied. The first-order condition for a maximum implies that the first two terms in the numerator of (A2) equal zero. Hence to establish (A1) it is sufficient to show that

$$\text{(A3)}\quad R' \geq 0 \Rightarrow pE[r_1W_1U''(W_1)] + (1-p)E[r_2W_2U''(W_1)] \leq 0$$

This is easily demonstrated following a method of proof due to Arrow (p. 120).

If relative risk aversion is nondecreasing then $R(W_1)\geq R(W_0)$ for $r_1>0$ and $W_1= =W_0(1+ar_1)$. By definition $R(W_1)= -W_1U''(W_1)/U'(W_1)$, hence

$$\text{(A4)}\quad r_1W_1U''(W_1) \leq -R(W_0)U'(W_1)r_1$$

This same inequality also holds for $r_1\leq 0$. Taking the expectation of (A4) with respect to $r_1$,

$$\text{(A5)}\quad E[r_1W_1U''(W_1)] \leq -R(W_0)E[U'(W_1)r_1]$$

Because a similar inequality holds for $R(W_2)$ we have

$$\text{(A6)}\quad pE[r_1W_1U''(W_1)] + (1-p)E[r_2W_2U''(W_2)] \leq -R(W_0)\{pE[U'(W_1)r_1] + (1-p)E[U'(W_2)r_2]\}$$

But the first-order condition for a maximum implies that the term in braces is zero; hence the right-hand side of (A6) is also zero and (A3) has been shown to hold.

# Inflationary Expectations and Momentary Equilibrium

By LEWIS JOHNSON*

By introducing the Fisherian distinction between real and nominal rates of return into a conventional static macro-equilibrium model, Robert Mundell illustrated how macro theory could be modified to analyze the impact of inflationary expectations on equilibrium. Although details of the analysis permit considerable elaboration of the model studied by Mundell, the basic analytical framework has become standard. This framework maintains the usual specification of asset market equilibrium: that in momentary equilibrium all agents must be satisfied with the current composition of their portfolios.[1] This may be called a *portfolio balance* (*PB*) specification of asset market equilibrium.

It is with this adaptation of the *PB* model to an analysis of inflationary expectations that I wish to take issue. Unless transacting in asset markets is costless, wealth holders will not instantaneously adjust imbalances in the composition of their portfolios. But the introduction of inflationary expectations means that they must anticipate that the real value of their cash balances will be declining over time due to inflation. Wealth holders will plan to readjust their portfolios over time, taking into account this anticipated outflow of real balances. In Section I, a stock adjustment model of portfolio behavior is proposed. Asset markets are defined to be in equilibrium when the adjustment plans of individual wealth holders are consistent for the current moment. This will be called a portfolio adjustment (*PA*) model of asset market equilibrium. The *PB* model emerges as a special case in which portfolios are instantaneously adjusted. In Section II, the comparative statics of an increase in the expected rate of inflation are analyzed for full employment and rigid wages versions of both *PA* and *PB* models. It is shown that these alternative specifications of asset market equilibrium can lead to qualitatively different comparative statics results.

It is legitimate to ask why we should concern ourselves with this issue between two static theories. After all, static analysis is inherently incomplete as it is not possible to account for the impact of steadily accumulating capital (arising from nonzero investment) in a static framework. To discuss "long-run" equilibrium properties of an economy in a static framework is highly tenuous, at best. Nonetheless, the static framework is invaluable in defining positions of momentary equilibrium which partly determine the system's position at each moment in time. The comparative statics analysis of the momentary equilibrium will determine in part how variables will move as the parameters of the momentary model change in accord with the equations of motion of the dynamic system. In particular, in a model in which inflationary expectations are learned adaptively, the amount by which prices must change (in momentary equilibrium) in response to an autonomous rise in the expected rate of inflation will be critical for the stability of the dynamic system. The implications of the *PB* and *PA* models for this problem of dynamic stability will be discussed in Section III.

## I. A Portfolio Adjustment Model of Momentary Equilibrium

Implicit in the analysis of a monetary economy is the acknowledgement that frictions and uncertainties exist, for these provide the rationale for holding money balances. The existence of costs of transacting

* Economist, special studies section, Division of Research and Statistics, Federal Reserve Board. I am indebted to my colleagues Stephen LeRoy, Steven Salop, Roger Waud, and to an anonymous referee for helpful comments and suggestions, but I am solely responsible for any remaining errors. The views expressed herein are solely my own and do not necessarily represent the views of the Board of Governors of the Federal Reserve System.

[1] The term momentary equilibrium will be used to mean that the markets under discussion are (momentarily) cleared.

in capital and bond markets implies that wealth holders will formulate plans determining an optimal (time) rate of acquisition of money balances, titles to capital, and bonds in the face of a divergence between desired and actual holdings. Only in the extreme case of zero transactions costs (implying that it is *feasible* to make instantaneous transactions) will wealth holders always instantly adjust actual to desired holdings.

Clearly, the plans of many independent agents are not in general going to be consistent. It is the role of markets to adjust prices until the plans for current action are made consistent. Momentary equilibrium is a state in which the plans for the current moment are consistent over all agents. This does not require that each agent intends to hold his portfolio in its current composition. It merely requires that those who enter the market to dispose of stocks at some (time) rate find buyers wishing to acquire stocks at that same rate. Aggregate flow excess demand must be zero in momentary equilibrium. For a full employment model, then, we may characterize equilibrium by the condition that the flow excess demand for goods and the flow excess demand for money are both zero.

Consider first the flow excess demand for money. As the simplest case, assume that desired holdings of real balances $m$ are a function of real income $y$ and the nominal rate of interest $r$. Assume also that the chosen plan for accumulation is to acquire real balances at a rate proportional to the discrepancy between desired and actual holdings. Then the desired flow of real balances $Dm^d$ may be written:[2]

$$(1) \qquad Dm^d = \lambda(L(y, r) - m)$$

It is not necessary, however, for the individual wealth holder to enter the market to the extent indicated by (1) to achieve the desired adjustment. He may anticipate an inflow of real balances in the form of a) a share of government transfers and b) appreciation of his current money balances due to deflation. This anticipated inflow of real balances $Dm^e$ will partially accommodate his desired adjustment. Consequently, the market flow excess demand for real balances is:

$$(2) \quad Dm^d - Dm^e = \lambda(L(y, r) - m) - Dm^e$$

By definition:

$$Dm^e = (\theta - q)m$$

where $$\theta = \left(\frac{DM}{M}\right)^e, \qquad q = \left(\frac{Dp}{p}\right)^e$$

Consequently, momentary equilibrium implies:

$$(3) \quad \lambda(L(y, r)) - (\lambda + \theta - q)m = 0$$

This constitutes a portfolio adjustment specification of asset market equilibrium, at least in this case with the goods market assumed to be simultaneously cleared. This is quite distinct from the conventional liquidity preference ($PB$) model which requires that the stock of real balances equal the (stock) demand for real balances:

$$(3') \qquad L(y, r) - m = 0$$

For the analysis of most comparative statics problems it is assumed that $\theta$ and $q$ are both zero (or at least equal). In this case it is evident that the $PA$ and $PB$ models are the same. Since wealth holders (in this case) expect no flow supply of real balances, equilibrium requires that flow demand be zero, which will only occur if actual stock holdings equal desired stock holdings. Obviously, this requirement must be satisfied in long-run equilibrium (steady state). Thus the distinction can only arise in the analysis of momentary equilibrium. Also, it is clear that in the case that $\lambda$ tends to infinity there must be stock equilibrium (3′) to satisfy flow equilibrium (3). Again the models are identical.

However, if we wish to admit the existence of transactions costs in securities markets ($\lambda$ finite) and at the same time attempt to analyze the impact of an *autonomous* change in inflationary expectations (as in the articles by William Gibson, Robert Mundell, Edmund Phelps, Frank Steindl, and Roger Waud), it is evident that the standard $PB$ model is inadequate. Since the expectation

[2] The symbol $D$ will be used to denote the operator $d/dt$.

of inflation implies an anticipated depreciation of the real value of money holdings (a negative flow "supply"), the *PA* model must be used to describe equilibrium.

Goods market equilibrium is characterized by the condition that planned investment equal planned savings:

$$I(\rho) - S(y, \rho, m) = 0 \tag{4}$$

with $I'(\rho) < 0$, $S_1 > 0$, $S_2 \geq 0$, $S_3 \leq 0$; where $I(\rho)$ is planned investments, $S(y, \rho, m)$ is desired savings, and $\rho$ is the real rate of interest: $\rho = r - q$. Equations (3′) and (4) are the standard *PB* model of momentary equilibrium, and equations (3) and (4) constitute the proposed *PA* model. The impact of inflationary expectations will be analyzed for each of these models for two extreme cases: a) full employment ($y$ fixed) and b) variable real income (money wage fixed).

## II. The Impact of Inflationary Expectations on Momentary Equilibrium

### A. *Full Employment*

Consider first the effects of an autonomous increase in the expected rate of inflation on the full employment *PB* model. The simplest version of this analysis is as follows. At the initial nominal rate, the anticipation of inflation reduces the real cost of investing and simultaneously lowers the inducement to save. The resulting excess demand for goods forces prices to rise, lowering the existing stock of real balances. Wealth holders attempt to sell bonds in order to acquire cash balances which forces up the nominal rate of interest. In the absence of wealth effects ($S_3 = 0$), only the initial real rate is consistent with equilibrium in goods markets. Consequently, the nominal rate must rise by the amount of anticipated inflation and prices must rise sufficiently to reduce real balances to the level demanded at this higher nominal interest rate.

If there is a significant wealth effect ($S_3 < 0$) it is only necessary to note that the reduction of real balances (due to higher prices) has an effect on the goods market, insofar as it stimulates savings (the real balances effect). This requires a somewhat lower real rate of interest to clear the goods market. Thus the real rate falls, and the nominal rate rises by less than the expected rate of inflation. These are the results derived Mundell.

Analytical expressions for the impact of inflationary expectations on the interest rates and on prices may be obtained by differentiating (3′) and (4) with respect to $q$ and solving for $dr/dq$, $d\rho/dq$, and $(1/p) \cdot (dp/dq)$.[3] The solutions are:

$$\frac{dr}{dq} = \frac{-(I' - S_2)}{L_2 S_3 - (I' - S_2)} > 0 \tag{5}$$

$$\frac{d\rho}{dq} = \frac{dr}{dq} - 1 = \frac{-L_2 S_3}{L_2 S_3 - (I' - S_2)} < 0 \tag{6}$$

$$\frac{1}{p}\left(\frac{dp}{dq}\right) = \frac{L_2(I' - S_2)}{m[L_2 S_3 - (I' - S_2)]} > 0 \tag{7}$$

Consider the impact on prices. Prices must rise in order to reduce the level of real balances to that which will be desired at the new higher nominal rate of interest. But suppose that portfolios are not instantly readjusted. Then the expectation of inflation implies that people expect the real value of their cash balances to dwindle over time. If the period of adjustment is of precisely the right length, individual wealth holders need not enter the market at all to readjust their portfolios because their holdings of real balances will be reduced automatically by inflation. Consequently, no "once over" rise in prices will be required to maintain equilibrium. This anticipation effect is accounted for by the *PA* model. For this model, differentiate (3) and (4) with respect to $q$, and solve to get:

$$\frac{dr}{dq} = \frac{-[S_3 m + \lambda(I' - S_2)]}{\lambda[L_2 S_3 - (I' - S_2)]} > 0 \tag{8}$$

$$\frac{d\rho}{dq} = \frac{dr}{dq} - 1 = \frac{-S_3(m + \lambda L_2)}{\lambda[L_2 S_3 - (I' - S_2)]} \gtrless 0 \tag{9}$$

$$\frac{1}{p}\left(\frac{dp}{dq}\right) = \frac{(I' - S_2)(m + \lambda L_2)}{m\lambda[L_2 S_3 - (I' - S_2)]} \gtrless 0 \tag{10}$$

[3] For convenience of exposition, it will be assumed that the initial rate of monetary expansion and the initial expected rate of inflation are both zero.

According to (8) the nominal rate of interest must rise, as in the *PB* model. As may be seen from (9) and (10), however, although prices must again move in the opposite direction from the real rate (so long as $S_3 \neq 0$), they may either rise, fall, or remain unchanged. Thus the anticipation effect may be sufficiently strong to reverse the qualitative results predicted by the standard (*PB*) model.[4] The initial real interest rate and prices will be just maintained in the new equilibrium if

$$m + \lambda L_2 = 0$$

or

$$1/\lambda = -\frac{L_2}{m}$$

For convenience, define the interest elasticity of demand for money $\epsilon$ to be $-L_2/m$, despite other usage. Thus, if the average adjustment period $1/\lambda$ is equal to the elasticity of demand for money, the expected inflation will lead wealth holders to anticipate that their cash balances will be automatically adjusted at the desired rate. The elasticity of demand may be interpreted as the length of time expected for inflation to reduce the real value of cash balances to the level that would be desired if the nominal rate rises by exactly the rate of inflation. If this equals the desired lag in adjustment $1/\lambda$, prices and real rates will be unchanged. If people plan to make the adjustment in less time than $\epsilon$, then the standard *PB* model's results will be qualitatively correct: prices must rise and the real rate will fall. If they plan their adjustments to require more time than $\epsilon$, then prices will fall, and the real rate will rise. Thus the two models may have qualitatively different predictions.

## B. *The Variable Income Model*

In response to the demonstration by Phelps that anticipated inflation necessarily reduces "feasible" welfare, Waud argued that if the system were initially in a position of less than full employment (due to rigid money wages), anticipated inflation would provide a stimulus to aggregate demand, resulting in a higher equilibrium level of income; consequently anticipated inflation might well increase welfare. This increase in output is possible because a rise in prices reduces the real wage given the money wage. The analysis is much the same as that for the full employment case except that any movement in prices is accompanied by a change in income in the same direction. Thus for the *PB* model, an increase in anticipated inflation implies a rise in the nominal rate of interest, prices, and income and a fall in the real rate of interest (even in the case $S_3=0$, since income has risen).

In the *PA* version of the variable employment model, these results may not hold. The reasoning is the same as for the full employment case. Individual agents perceive that the inflation is reducing their real balances over time, and if the desired reduction is achieved rapidly enough, the system will remain in equilibrium at the initial level of prices. In fact if the reduction is proceeding too rapidly, prices may actually fall. Income is positively related to the price level because of the fixed-money wage, so income will rise (as in Waud's analysis) under the same conditions that prices will rise; specifically, income will rise due to inflationary expectations if and only if the average period of portfolio adjustment $1/\lambda$ is less than the interest elasticity of demand for money $\epsilon$. The reader may readily confirm these results algebraically.

## III. Stability

If the model implies a "once over" rise in prices in response to inflationary expectations, the question of how much they rise may be crucial for the stability of the system. Although it is tenuous to discuss stability without specifying a complete dynamic model, we can perhaps arrive at a few tentative conclusions. Suppose that expectations are revised adaptively such that the current error between expected and actual rates of inflation is corrected at a rate proportional (by a factor of $\beta$) to that error, i.e.:

[4] It should be noted that this perverse case strains the interpretation of the finite rate of adjustment arising from the existence of transactions costs in asset markets. A more thorough analysis than is currently available of portfolio behavior with transactions costs and inflationary expectations would be desirable.

$$(11) \qquad Dq = \beta(Dp/p - q)$$

It is readily possible that this adaptive expectations process will permit a self-sustaining expectations inflation, since an increase in the expected rate of inflation may itself cause prices to rise. To avoid instability, the rise in prices must not be sufficiently great to validate the increased inflationary expectations. Specifically, equation (11) will be a stable process if and only if:

$$(12) \qquad \frac{\partial(Dp/p)}{\partial q} < 1$$

The left-hand side of this inequality may be obtained by differentiating $p = p(q, M)$ with respect to time, substituting from (11) for $Dq$ and solving for the rate of inflation. Taking the partial with respect to $q$ of the resulting expression for $Dp/p$, inequality (12) may be arranged to yield:

$$(13) \qquad \frac{1}{p}\frac{dp}{dq} < \frac{1}{\beta}$$

This is the necessary and sufficient condition for stability of the expectations process. The gradual readjustment of actual portfolio composition to desired composition in the *PA* model will reduce the amount by which prices must rise in response to an increase in anticipated inflation, thus tending to stabilize the system. To see this, examine the "stability condition" (13) for both models.

Substituting from equation (7) into (13), the condition for stability of the PB model becomes:

$$(\beta L_2 + m)(I' - S_2) - mL_2S_3 < 0$$

As the wealth effect on savings is usually thought to be small, an interesting sufficient condition for this inequality to be satisfied is obtained by requiring that the first term be negative, which implies:[5]

$$(14) \qquad -\frac{L_2}{m} \equiv \epsilon < \frac{1}{\beta}$$

Similarly, (by (10) and (13)) the condition for stability of the PA model may be shown to be:

$$\beta[(m + \lambda L_2) + m\lambda][I' - S_2] - m\lambda S_3L_2 < 0$$

and the sufficient condition corresponding to (13) is:

$$(15) \qquad \epsilon < \left(\frac{1}{\beta}\right) + \left(\frac{1}{\lambda}\right)$$

Gradual portfolio adjustment clearly tends to stabilize the system, entering in precisely the same way as the average lag in expectations formation. For any values of $\epsilon$ (finite) and $\beta$, the system will be stable if portfolio adjustment is sufficiently slow. This is clear from equation (10) alone, since $\lambda$ may be small enough for prices to fall (in momentary equilibrium) in response to an increase in inflationary expectations.

A related point to the difference of the stability requirements of the two models is the efficacy of stabilization policy via the rate of monetary expansion $\theta$. It is evident by inspection of (3′) and (4) that tying $\theta$ inversely to the anticipated rate of inflation will have no impact on stability of the system in the *PB* model.[6] This is not true of the *PA* model however. In particular, the immediate impact of an increase in $\theta$ on the equilibrium price level is:

$$\frac{1}{p}\frac{dp}{d\theta} = \frac{(I' - S_2)}{\lambda[L_2S_3 - (I' - S_2)]} > 0$$

If $S_3$ is small, this is approximately $1/\lambda$. Thus it would be possible to design a stabilization policy by tying $\theta$ to $q$ if the length of time economic agents choose to readjust their portfolios is appreciable. The derivation of such a policy for a completely specified dynamic model is shown in my forthcoming paper.

[5] This is precisely the stability criterion first derived by Phillip Cagan for the single equation model discussed here and later proved to be necessary for stability of an equilibrium monetary growth model by Miguel Sidrauski. To see how this condition is modified in a model with gradual price adjustment, see the paper by Michael Hadjimichalakis (1971).

[6] As shown by Hadjimichalakis (1973), an alternative specification of monetary policy may be effective. Also, Robert MacKay has demonstrated that policy may be effective if asset market equilibrium accounts for the flow of nominal money, a step in the direction of the *PA* model.

## IV. Summary and Conclusions

The conventional *IS-LM* apparatus with a portfolio balance model of asset market equilibrium is adequate for the analysis of most problems in momentary equilibrium. It is, however, ill-suited for the analysis of the impact of an autonomous change in expectations on momentary equilibrium, except in the extreme case in which portfolios are instantaneously (costlessly) readjusted. The standard model ignores the anticipation effect: that wealth holders perceive that the real value of their cash balances will be declining over time, thus assisting them in readjusting their portfolios toward smaller money holdings. The portfolio adjustment theory of asset market equilibrium does take account of this effect and results in qualitatively different conclusions in the analysis of momentary equilibrium.

In addition to pointing out the different comparative statics results of a model incorporating gradual portfolio adjustment, the model was extended to examine stability and stabilization policies for an adaptive expectations process. While this framework does serve its purpose to illustrate clearly the nature and significance of the issues involved, it is evident that the assumed dynamics are somewhat implausible. In particular, it would seem to be farfetched to assume that portfolio adjustment requires an appreciable interval of time while goods markets are assumed to adjust instantaneously. However, the important result that gradual portfolio adjustment tends to stabilize the system (to the same degree as does gradual expectations formation) is retained when the portfolio adjustment process is imbedded in a general monetary growth framework, as is shown in my forthcoming paper.

# The Borrower-Lender Relationship, Competitive Equilibrium, and the Theory of Hedonic Prices

*By* ERNST BALTENSPERGER*

In a series of recent articles, Vernon Smith (1972b; see also 1971a, b, 1972a) has presented a very interesting analysis of the lender-borrower relationship, which emphasizes that the debtor's equity capital plays the role of an external economy to the lender, with the result that the traditional competitive equilibrium solution is not Pareto optimal. Smith considers a situation where a lender with initial wealth $w_0$ has the option of either buying government bonds with a certain return $r$, or giving a risky loan $z$ at a contractual rate of interest $r^*$ to an individual borrower or firm. The borrower uses his loan to finance a risky investment project yielding an uncertain return $\theta$ (assumed independent of the amount invested). The borrower also has an initial wealth $W_0$, which he invests partly in his risky investment project (his "firm") and partly in the form of riskless government securities at rate $r$. Since the borrower's risky investment activity (his firm) is assumed to be incorporated with limited liability, so that his private holdings of riskless bonds are protected from lender claims, the lender's expected utility from extending a loan clearly becomes dependent on the debtors' equity decision, i.e., on the way in which the debtor divides his personal wealth $W_0$ into investment in the risky project $y$ (his equity in his firm) and investment in riskless bonds (his personal, nonliable assets). The higher $y$, the lesser is (given the size of the loan $z$) the risk that the debtor will default on his loan, and thus the higher is the lender's expected utility. The debtor's equity capital acts, as Smith expresses it, as an external economy to the lender. The existence of this external effect implies that the standard competitive equilibrium solution, as summarized by his (1972b) equations (12) and (13), is not Pareto efficient. Therefore, he suggests that free competitive negotiations between borrowers and lenders may produce arrangements which look quite different from what is normally expected to characterize a "competitive equilibrium." More specifically, he links his analysis to the discussion about credit rationing (see Dwight Jaffee-Franco Modigliani, 1969, and Jaffee, 1971), and points out that a quota or rationing system can generate a solution which is consistent with the conditions for Pareto efficiency, if the quotas are set such that their shadow values are equal to the appropriate tax or subsidy. But he does not have a theory which explains how these quotas are determined as the outcome of a market process.

Fundamental to Smith's whole analysis is the behavioral assumption that both lender and borrower optimize based on the premise that the borrower's interest payment to the lender is independent of the debtor's equity capital $y$, and thus of his risk of default. The borrower takes the contractual interest rate $r^*$ as a datum and optimizes based on the assumption that he can obtain any amount of credit at this rate. The borrower has no inducement to increase his equity capital $y$ towards the Pareto optimal level, since his interest payment $r^*z$ depends, for any parametrically given value of the price $r^*$, on $z$ only, independent of $y$.

This paper discusses a model of the competitive process based on an alternative assumption about competitive behavior, one which is in my opinion more justified, and which leads to a Pareto-efficient solution. In contrast to Smith's rationing scheme, this solution is perfectly consistent with "what is usually expected to characterize a competitive equilibrium." In the context of a credit market system as discussed here, the assumption that the transactors optimize subject to a parametrically given contractual

* Associate professor of economics, Ohio State University.

interest rate $r^*$ does not seem justified, even in an atomistic environment. The assumption of price taking is, of course, a very standard behavioral assumption in economic theory, usually used as equivalent with "competitive behavior," and normally justified by assuming that the seller or buyer in question is but one among a large number of transactors, so that his individual behavior does not appreciably affect the market as a whole nor the market price. Clearly, this justification for price taking, if applied to the contractual interest rate $r^*$ as in Smith's model, is invalid. Every borrower, however small and insignificant he is relative to the market as a whole, knows that, given his equity capital $y$, he cannot borrow unlimited amounts at the same (contractual) interest rate, since an increase in his loan (or, alternatively, a change in his equity capital), *ceteris paribus*, will change his risk of default and therefore the "quality" of the loan. Recognition of this has nothing to do with presence or absence of competition. Even in an atomistic environment, a borrower is not reasonable if he does not take into account that the contractual rate $r^*$ must contain a risk premium which reflects the characteristics and riskiness of the individual borrower, and thus his equity decision, rather than general demand and supply conditions for the market as a whole. A credit transaction has two dimensions or "characteristics": dollar amount (or "quantity") and riskiness (or "quality," depending on $y$, relative to $z$). Both parties are perfectly well aware of this (and they know that the other side is aware of it), and thus should not be expected to optimize on the premise that the other side is *not* aware of it. Consequently, I suggest that the loan should be treated as a "good" with two characteristics. There is a perfect formal analogy between the problem under discussion here and the model of hedonic prices employed by Sherwin Rosen to discuss product differentiation in a competitive environment (which is based on the well-known work on consumer theory by Kelvin Lancaster, Gary Becker, and Hendrik Houthakker, where goods are treated as collections of utility generating characteristics).

Thus, I object to Smith's description of the conventional competitive model, since it is equivalent to assuming that the market participants optimize based on the assumption that price is independent not only of quantity, but also of quality. There is nothing in the traditional competitive model requiring this. It is shown that if this assumption is abandoned, and the loan is treated as a good with two characteristics, a competitive (atomistic) environment can be expected to produce a Pareto-efficient solution quite consistent with what is usually expected to characterize a competitive equilibrium (in other words: a situation where the appropriate "charges" or "subsidies" are imposed quite naturally as the outcome of a market process).

In Section I below, Smith's model will be briefly summarized. In Section II, a competitive model which does take account of the preceding discussion will be presented. Section III contains a brief summary.

## I

In the Smith model, the borrower's terminal wealth $W$ is

$$(1+r)(W_0-y) + (1+\theta)(y+z) - (1+r^*)z$$

in the event of nondefault. This occurs when $(1+\theta)(y+z)$, the end of period value of his investment project (or firm), exceeds his debt to the lender $(1+r^*)z$, or in other words,

$$\theta > [(1+r^*)z/(y+z)] - 1 \equiv \theta^*$$

On the other hand, in the event of default, the end of period value of his personal holdings of nonliable bonds equals $(1+r)(W_0-y)$, i.e., $\theta<\theta^*$.

The borrower is assumed to maximize his expected utility

$$(1)\quad B = \int_{\theta^*}^{\infty} U[(1\,r)(W_0-y) + (1+\theta)(y+z) - (1+r^*)z]f(\theta)d\theta + \int_{-1}^{\theta^*} U[(1+r)(W_0-y)]f(\theta)d\theta$$

where $U(W)$ denotes his (strictly concave) utility function for terminal wealth, and $f(\theta)$ his subjective probability density over the rate of return $\theta$. Maximizing $B$ with respect to $y$ and $z$, for given $r^*$, $r$, and $W_0$, determines the borrower's optimal equity capital $y$ and his loan demand $z$, as a function of $r^*$, $r$, and $W_0$.

The lender's terminal wealth $w$, on the other hand, is equal to

$$(1 + r)(w_0 - z) + (1 + r^*)z$$

in the event of nondefault ($\theta > \theta^*$), but only

$$(1 + r)(w_0 - z) + (1 + \theta)(y + z)$$

in the case of default ($\theta < \theta^*$).[1] The lender is assumed to maximize his expected utility

$$(2) \qquad L = \int_{\theta^*}^{\infty} V[(1 + r)(w_0 - z) + (1 + r^*)z]g(\theta)d\theta + \int_{-1}^{\theta^*} V[(1 + r)(w_0 - z) + (1 + \theta)(y + z)]g(\theta)d\theta$$

where $V(w)$ denotes his utility function for terminal wealth, and $g(\theta)$ his subjective density function over $\theta$. Maximization of $L$ with respect to $z$, subject to given values of $r^*$, $r$, $w_0$, and $y$, yields the lender's optimal loan supply $z$.

Clearly, a parametric change in $y$ changes the value of the lender's expected utility $L$:

$$(3) \qquad \frac{\partial L}{\partial y} = \int_{-1}^{\theta^*} V'(\cdot)(1 + \theta)g(\theta)d\theta > 0$$

and thus leads, *ceteris paribus*, to a change in the lender's loan supply. "The borrower's equity in an investment is an external economy to the lender," as Smith expresses it (his Proposition 1, p. 479, 1927b). The existence of this external effect leads to the conclusion that the traditional competitive market equilibrium is not Pareto efficient, as noted in the introduction.

## II

Smith's result is obtained because of the special (and, as argued here, objectionable) way in which the behavior of the market participants is specified. More specifically, because it is assumed that both borrower and lender optimize based on the premise that the contractual interest rate $r^*$ and thus the borrower's interest payment to the lender, is independent of his equity capital $y$, and thus of his risk of default. This is equivalent to assuming that price is independent of quality, and does not seem justified, even in an atomistic environment. I may expect that I can buy "any" amount of Coca Cola in the supermarket (i.e., any amount within a very large range around my current purchase, say, 100 bottles instead of my normal purchase of 1) without exerting any noticable effect on the market price, because I am but one of millions of purchasers of Coca Cola. However, even if I am but one among millions of (similar) credit takers, I will never expect that I can get "any" amount of credit at an unchanged contractual rate of interest, unless I keep default risk (the "quality" of the loan) constant by appropriately adjusting equity capital $y$ (or in some other way).[2] To assume competitive behavior in the sense of having many relatively small market participants whose behavior taken individually does not appreciably affect total market excess demand ("general market conditions") should not be equated with price taking in the sense of accepting $r^*$ as a datum (independent of $y$).

This paper suggests treating the loan as a good with two characteristics, $z$ and $y$ (size and quality). Consequently, we specify a price function $R = R(z, y)$, which relates the borrower's payment to the lender $R$ (defined as including the repayment of capital) to the

[1] To simplify the presentation, it is assumed that the lowest possible value of $\theta$ is not below $-1$, i.e., the lowest possible terminal value of the lender's investment project not less than zero. If lower values for $\theta$ were admitted, we would have to include a third term in (2), since in this case the lender's terminal wealth would be given by $(1+r)(w_0-z)$ alone (because he is not liable for the borrower's debt to somebody else).

[2] For example, via putting up otherwise nonliable wealth as collateral. This would be an obvious extension of the model.

characteristics $z$ and $y$.[3] At any point in time, the market reveals an $R(z, y)$ function, which can be inferred from observed prices for different $z/y$ packages. Presumably, $R_z>0$ and $R_y<0$: an increase in $z$ implies a larger total payment $R$, while an increase in $y$, given $z$, represents an increase in the quality of the loan, and thus implies a lower compensation $R$. The transactors treat this price function as parametric to their decisions. This is the meaning of competition in this context. In other words, each transactor is small enough relative to the market as a whole that his individual actions have no recognizable effect on the $R(z, y)$ function exhibited by the market. An equilibrium price function is determined by market forces in the same way as equilibrium price is determined in the usual competitive model: an equilibrium value for $R(z, y)$ is reached if buyers and sellers are perfectly matched at each $z/y$ combination. For a discussion of the determination of such an equilibrium price function, see Rosen and Louis Court.

The borrower's and lender's expected utility functions now are

$$(4)\quad B = \int_{\theta^*}^{\infty} U[(1+r)(W_0 - y) + (1+\theta)(y+z) - R(z,y)]f(\theta)d\theta + \int_{-1}^{\theta^*} U[(1+r)(W_0 - y)]f(\theta)d\theta$$

and

$$(5)\quad L = \int_{\theta^*}^{\infty} V[(1+r)(w_0 - z) + R(z, y)]g(\theta)d\theta + \int_{-1}^{\theta^*} [V(1+r)(w_0 - z) + (1+\theta)(y+z)]g(\theta)d\theta$$

where $\theta^* = [R(z, y)/(y+z)] - 1$ again is the value of $\theta$ below which the borrower defaults on his loan.

Treating $R(z, y)$ parametrically, the borrower determines his optimal $z$ and $y$ (size and quality of loan). His optimality conditions are

$$(6)\quad \frac{\partial B}{\partial z} = \int_{\theta^*}^{\infty} U'(\cdot)[1+\theta - R_z]f(\theta)d\theta = 0$$

$$(7)\quad \frac{\partial B}{\partial y} = \int_{\theta^*}^{\infty} U'(\cdot)[\theta - r - R_y]f(\theta)d\theta - \int_{-1}^{\theta^*} U'(\cdot)(1+r)f(\theta)d\theta = 0$$

Similarly, the lender determines, conditional upon $R(z, y)$, his desired values of $z$ and $y$, i.e., the size and quality of the loan he would like to make, given the market's $R(z, y)$:[4]

$$(8)\quad \frac{\partial L}{\partial z} = \int_{\theta^*}^{\infty} V'(\cdot)[R_z - 1 - r]g(\theta)d\theta + \int_{-1}^{\theta^*} V'(\cdot)[\theta - r]g(\theta)d\theta = 0$$

$$(9)\quad \frac{\partial L}{\partial y} = \int_{\theta^*}^{\infty} V'(\cdot)R_y g(\theta)d\theta + \int_{-1}^{\theta^*} V'(\cdot)(1+\theta)g(\theta)d\theta = 0$$

A competitive market equilibrium is reached if the $R(z, y)$ function is such that there results complete consistency between borrowers and lenders. See Rosen for a discussion of the price function as the joint envelope of a family of indifference surfaces for borrowers and lenders. Of course, the existence of a whole equilibrium price *function*, i.e., the coexistence of different $z/y$ combinations in equilibrium, requires the existence of heterogeneity among borrowers and/or lenders (for example, a distribution of $U$-functions, and/or distribution of $V$-functions). If all borrowers as well as all lenders were identical, all borrowers and all

[3] Note that $z$ and $y$ together determine $\theta^*$, the critical value of $\theta$ below which the debtor defaults on his loan. The "quality" of the loan, of course, also depends on the density functions over $\theta$, which we treat as given here. In principle, we can think of the parameters of these functions as additional characteristics of the loan.

[4] In addition, the appropriate second-order conditions for a maximum must be satisfied.

lenders would always end up with identical decisions, so that there would be only one equilibrium $z/y$ combination. Consequently, the market then could not provide the information necessary to infer a complete $R(z, y)$ function. A discussion of how an equilibrium price function is reached, starting from a disequilibrium situation, is clearly beyond the scope of this paper. However, it can easily be seen that such an equilibrium, if obtained, satisfies all the conditions for Pareto optimality. Using the shorthand notation employed by Smith (1972b, p. 481), we can rewrite the borrower's and lender's objective functions (4) and (5) as $B=B(u, z, y/R(z, y), r)$ and $L=L(v, z, y/R(z, y), r)$, with $u=W_0-y$ and $v=w_0-z$. Independent maximization by both sides yields the following marginal conditions (equivalent to (6)–(9))

$$B_u = B_y, \qquad B_z = 0 \tag{10}$$

and

$$L_v = L_z, \qquad L_y = 0 \tag{11}$$

which is perfectly consistent with the condition for Pareto efficiency (as summarized by Smith's (14), 1972b, p. 481).

## III

I have discussed a competitive model of the credit market which does explicitly take into account that the credit transaction has two characteristics: size and riskiness, or "quality." It has been argued that it is reasonable to assume that market participants do explicitly take this into account in their optimization procedures; and it has been shown that a model of the competitive process where this is the case does lead to a Pareto-efficient solution which is perfectly consistent with what is usually expected to characterize a competitive equilibrium (in contrast to the competitive model discussed by Smith).

# The Borrower-Lender Relationship

*By* VERNON L. SMITH*

One frequently encounters the belief that there are pervasive "imperfections in the capital market" (see George Stigler), and the widespread practice of lender rationing in loan markets is often implicated as providing the evidence in support of this proposition (see Dwight Jaffee and Franco Modigliani). I have long thought this to be a simplistic proposition, and my papers on the borrower-lender contract are an attempt to interpret the phenomenon of lender or capital rationing as an instance in which competitive markets were doing their job but where the "commodity" had unusual or nonstandard properties. The loan contract has the nonstandard characteristic that the lender's gain from the exchange depends upon a host of borrower controlled activities. Thus the lender wants to know how the proceeds of the loan are to be invested, the level of borrower equity, and the amounts and terms of any other loans contracted.

A formal way to treat such a commodity is to enrich its price expression to correspond to its enriched space of characteristics. There are several well-known examples of this formalism. By treating externalities as commodities and giving them prices, one recovers the competitive efficiency properties otherwise lost. Efficiency in the presence of uncertainty is no problem, formally, if one simply invents state-contingent claims. In this spirit, a natural way to treat the loan contract is to let its market price (the nominal interest rate) be a function of the borrower's equity, or any other relevant characteristics, as well as the amount of the loan. This approach is so natural that I did it myself in several pages of the working notes for the papers cited by Ernst Baltensperger. The published version did not develop this line of analysis because I thought it finessed the issue of capital rationing in the borrower-lender contract which was my principal interest. Also we know that, in general, competitive loan markets could improve on the Baltensperger price function if borrowers would issue state-contingent claims. The proper full formal treatment of the loan contract is to see that it has as many dimensions as contingent states, $\theta$, and that claims contingent on each such state must have a market price. The problem with either the full treatment, or the compromise treatment, is that they do not represent what bankers or borrowers do. Bankers do not buy state contingent claims from borrowers, and they do not issue price schedules relating interest charged to borrower's equity and amount lent. As indicated in my papers, bankers do set up major loan categories with different interest rates and rationing rules for each category, and my formulation of the problem was intended to minimize the violence done to these stylized facts. One of my main points was that if we think of the borrower as rationing equity size to the lender, and the lender as rationing loan size to the borrower, these quotas would have implicit prices. This defines implicitly an enriched price space which, if examined more carefully, might not look so imperfect as it does at first blush.

I do not know why bankers and other lenders do not fine-tune interest rates to the conditions of every loan. A legitimate hypothesis is that the costs of information, monitoring, negotiating, and transacting do not make it worthwhile. Rationing and qualification rules, laid down by bank management, can be applied routinely by minor officers. Also it takes a certain amount of sophistication for a borrower to understand that there are defensible reasons why his mortgage rate would be higher than his neighbor's, and bankers might like to avoid having to make explanations. So "if you want to buy a house here is the rate, and,

* University of Arizona.

providing you qualify, we will loan not more than 80 percent of market value." I am not yet prepared to say that this scenario represents either an imperfect (except by an irrelevant definition of "perfect") or inefficient market. I confess to frustration at not having a competitive process that leads to this result as an equilibrium, but I think some form of direct modeling of observed institutions is an important source of insight. Models based upon more idealized institutions can be useful if they help us to understand observed institutions, but for me they are sterile if they lead merely to the conclusion that real markets are "incomplete."

# Labor Supply and the Payroll Tax

By C. DUNCAN MACRAE AND ELIZABETH CHASE MACRAE*

In a recent issue of this *Review*, the debate between John Brittain and Martin Feldstein regarding the incidence of the social security payroll tax focused on the effect of the payroll tax on labor supply. Both authors conclude that the tax will have an effect only if supply is wage elastic. Their analyses, however, are carried out only in terms of aggregate supply and ignore the ceiling on taxable earnings.[1]

The purpose of this note is to demonstrate that the social security payroll tax will have an effect on aggregate labor supply even if individual labor supply is wage inelastic, as long as there are individuals with earnings above the ceiling. Moreover, we will also show that the tax can be labor market neutral in the sense that it does not have an effect on aggregate labor supply, only if individual supply is wage elastic. Hence, an incidence analysis which does not take into account both the existence of the ceiling and the composition of aggregate supply can be misleading.

To see the effects of the payroll tax we employ the traditional income-leisure model of individual labor supply. The individual is assumed to supply labor so as to maximize utility from income and leisure subject to a budget constraint that specifies the tradeoff between income and leisure given the wage rate and the level of unearned income. Figure 1 shows the boundary of the individual's constraint set as the broken line $ABF$ when $Y^n$ is the level of unearned income and the (negative) slope $W$ of the line $AB$ is the wage rate. For given levels of $W$ and $Y^n$, the individual will supply a quantity of labor which corresponds to the point on the line $AB$ which lies on the highest possible indifference curve. The individual's labor supply curve, which simply shows the wage-labor combinations for some given level of unearned income ($Y^n$), with no payroll tax, appears as curve $S$ in Figure 2. Assuming

MacRae's research was supported by funds from the Office of Research and Development, Manpower Administration, U.S. Department of Labor under Grant No. 21-11-74-09 to the Urban Institute. Opinions expressed are our own and do not necessarily represent the views of the Department of Labor, The Urban Institute or its sponsors.

[1] See Feldstein, fn. 8, p. 738, however, for a recognition that the analysis should be carried out in terms of individual supply and take the ceiling into account, although he does not do so.

that leisure is a superior good, a decrease in $Y^n$ will increase the amount of labor supplied at any wage rate and thus shift the curve to the right, perhaps with a change in shape.

Now let us introduce a payroll tax composed of a ceiling $E$ on taxable earnings and a tax rate $t$. As shown by line $CDB$ in Figure 1, if the individual does not perceive the tax as an intertemporal transfer to himself, the tax corresponds to a percentage reduction in the wage rate of $100t$ for earnings below the ceiling level $E$ and a constant reduction in income of $tE$ for earnings above $E$ with no reduction in the wage rate. The lowered slope of the budget line segment $DB$ for earnings below $E$ means that a given amount of labor will now be forthcoming only at a higher market wage rate. In Figure 2, this is shown as an upward shift in the labor supply curve in the area below the $WL=E$ hyperbola, which will decrease labor supply unless the income effect dominates. The $WL=E$ hyperbola shows the combination of wage rates and hours of labor equal to the ceiling amount of taxable earnings. The downward shift in the budget line segment $CD$ for earnings above $E$ amounts to a fixed reduction in unearned income in the amount of the tax paid, $tE$. Consequently, the labor supply curve $S'$ in Figure 2 is shown shifted to the right in the area above the $E$ hyperbola so that labor supply will definitely increase in this area if leisure is a superior good.

Since the budget line after the imposition of the payroll tax is no longer convex, there is a "jump" in the labor supply curve in the neighborhood of $E$. That is, there is some wage rate, shown as $W'$ in Figure 2, at which the individual is indifferent between supplying enough labor to generate earnings above $E$ and supplying less labor to generate earnings below $E$. Under the payroll tax, there is no combination of $W$ and $Y^n$ for which the individual will choose to earn exactly the ceiling amount $E$, since he can always increase utility by earning more or less than $E$.

The conclusion to be drawn from the foregoing analysis is that while for individuals with earnings below the ceiling the payroll tax acts to reduce their wage rate and, therefore, reduces their work incentive if supply is wage elastic, for individuals with earnings above the ceiling the tax acts solely to reduce their unearned income and, therefore, increases their work incentive if leisure is a superior good. Therefore, if individual supply is wage inelastic, the effect of the payroll tax is solely to increase the work effort of those with earnings above the ceiling and, hence, unequivocably to increase aggregate labor supply. However, if individual supply is elastic, then it is possible for the increase in supply by those above the ceiling to be cancelled out by the decrease in supply by those with earnings below ceiling. Only then will the social security payroll tax not affect aggregate labor supply, if individuals perceive it truly to be a tax and not a subsidy to themselves.

# On the Regulated Price-Setting Monopoly Firm with a Random Demand Curve

By Stylianos Perrakis*

The development of a substantial body of literature dealing with probabilistic microeconomics (see, for instance, Hayne Leland, John McCall, and Kenneth Smith) has imposed the necessity to reexamine certain classical results in the theory of the firm under deterministic conditions. One such category of results is derived from the analysis of the behavior of a monopoly firm under a regulatory constraint by, among others, Harvey Averch and Leland Johnson, William Baumol and Alvin Klevorick, and Akira Takayama. In view of their importance for regulatory policy these results have generated a substantial amount of controversy and discussion.[1] The question that poses itself, therefore, is to what extent is the behavior of a monopoly firm modified if the demand curve facing the monopolist is not fixed (as it was assumed until now), but fluctuates randomly according to a known probability distribution.

The general conceptual framework for the theory of the firm with uncertain demand was established recently by Leland. His study distinguishes two types of monopoly behavior, depending upon the time span of the "static" period considered and the degree of latitude allowed to the firm in order to vary the price of its output within this period. The quantity-setting firm makes its pricing decisions after the value of the random demand is known, while the price-setting firm must set the price in advance. The resulting profit-maximizing behavior is, of course, substantially different for these two classes of firms.

In an earlier study I examined the behavior of a quantity-setting monopoly firm under rate of return regulation using a fairly general set of assumptions. Focus was placed upon the well-known result of the deterministic case that the capital stock of the regulated monopolist (when the regulatory constraint is effective) is larger than the capital stock of the same firm in the absence of regulation.[2] It was shown that this result was not in general true for a monopoly firm facing a random demand curve in the absence of additional restrictions upon the shape of the probability distribution of the random factor, the monopolist's utility function, and/or the firm's revenue function. This conclusion, in turn, invalidated a number of other related results that were based on the so-called Averch-Johnson effect of overcapitalization.

In this paper I examine the behavior of a price-setting monopoly firm with random demand that is institutionally constrained to satisfy all demand for its product. As in my earlier study, one important deterministic result is not true in this more general model. This result is best described by quoting from Johnson: "Only in the unusual circumstance where the marginal physical product of capital falls below zero would the firm be led to gold-plate or to hold capital strictly idle . . . " (p. 91).[3] In fact, it is shown below under quite plausible assumptions that the regulated price-setting monopoly firm will maximize its profits by operating its capital

* Faculty of Management Sciences, University of Ottawa. I wish to thank John Zerbinis and the referee for helpful advice and comment.

[1] See, for instance, the exchange between Mohamed El Hodiri and Takayama and Israel Pressman and Arthur Carol.

[2] The most rigorous and general proof of this is in El Hodiri and Takayama. The importance of the result lies in the fact that it may be used as the basis for the proof of the so-called Averch-Johnson effect of overcapitalization (see Averch and Johnson, and Baumol and Klevorick), which is that rate of return regulation leads to a larger capital-labor ratio of the regulated firm than the one corresponding to minimum cost production at the chosen output.

[3] A proof of Johnson's statement is given by Edward Zajac.

stock at less than full capacity for an entire range of values of the random factor in the demand curve.

I shall first derive the profit-maximizing conditions for an unregulated monopolist. Next, after adding the rate of return constraint, two important propositions will be proved that define the profit-maximizing behavior of the regulated monopoly firm. Finally, the results will be extended to two special cases of random demand curves, the additive and the multiplicative random factors. In all cases the results will be proved for both expected profit and expected utility maximizing firms, hereafter referred to as risk neutrality and risk aversion, respectively.

## I. The General Model

As usual, $F(uK, L)$ denotes the monopolist's production function ($K$ capital, $L$ labor), with $F_K \equiv \partial F/\partial(uK) > 0$, $F_L \equiv \partial F/\partial L > 0$,[4] for $uK$, $L$ in a given region in the nonnegative orthant that contains the origin. The term $u$ is a linear scale variable with $0 \leq u \leq 1$, as in Smith, and Perrakis and Izzet Sahin. The usual second-order conditions are assumed to hold for $F(uK, L)$. The monopolist's demand curve is given by $D(p, x)$, where $p$ is the price and $x$ the random factor. It is assumed that $-\infty < \underline{x} \leq x \leq \bar{x} < +\infty$, and that $g(x)$, the subjective probability density function of $x$, exists and is known and continuous for $x \in X$, where $X$ denotes the closed set $[\underline{x}, \bar{x}]$. It is also assumed, following Leland, that $D_x$ is continuous and positive for all $x \in X$, and that $D_p < 0$ for all $p > 0$.

The monopolist selects the *ex post* controls $u$ and $L$ given $p$, $K$, and $x$. The *ex ante* controls $p$ and $K$ are chosen by maximizing expected utility, which is a function of profit that is linear (risk neutral) or strictly concave (risk averse). The monopolist is institutionally constrained to satisfy all demand for his product,[5] which means that:

$$F(uK, L) = D(p, x) \tag{1}$$

Given this constraint the choice of the *ex post* controls for the unregulated monopolist is made by maximizing the utility of profit $U(\pi)$ where $U' > 0$, $U'' \leq 0$, and

$$\pi(x) = pD(p, x) - wL - rK \tag{2}$$

where $w$ and $r$ are input prices. It is easy to see that the maximum utility given $p$, $K$, and $x$ is achieved by choosing the minimum $L$ satisfying (1), which is given by the choice of controls:

$$u = 1, \qquad L = \bar{L}(p, K, x) \tag{3}$$

where $\bar{L}(p, K, x) > 0$ is the (assumed unique) solution of (1) if $u = 1$.[6] The assumed restrictions on the partial derivatives of $F$ and $D$ guarantees the existence of the partials of $\bar{L}$ which are as follows:[7]

$$\bar{L}_p \equiv \frac{\partial \bar{L}}{\partial p} = \frac{D_p}{F_L}, \quad \bar{L}_x \equiv \frac{\partial \bar{L}}{\partial x} = \frac{D_x}{F_L}, \quad \bar{L}_K \equiv \frac{\partial \bar{L}}{\partial K} = -\frac{F_K}{F_L} \tag{4}$$

Hence, the *ex ante* controls $p$ and $K$ are now chosen by maximizing $E[U(\pi(x))]$ with respect to $p$ and $K$. The derivation of the necessary conditions is as follows:

$$\max_{p,K} E\{U(pD(p, x) - w\bar{L}(p, K, x) - rK)\} \tag{5}$$

$$E[U'[pD_p + D - w\bar{L}_p]] = 0 \tag{6a}$$

$$E[U'[-w\bar{L}_K - r]] = 0 \tag{6b}$$

where $U' \equiv U'(\pi(x))$, and $\pi(x)$ is given by (2) with $L = \bar{L}(p, K, x)$. If (4) is taken into account then (6a) and (6b) become:

$$E[U'D] = E\left[U'D_p\left(\frac{w}{F_L} - p\right)\right] \tag{7a}$$

[4] Hereafter subscripts will denote partial derivatives with respect to the variable(s) in the subscript.

[5] If this assumption is not introduced then the model must provide for product rationing, storage, and/or disposal.

[6] It is easy to see that the existence of an $L > 0$ satisfying (1) is guaranteed by the condition $F_L > 0 \forall L > 0$.

[7] It should be noted in (4) that the partial derivatives of $\bar{L}(p, K, x)$ are *ex ante* random variables, since $x$ enters the expressions either explicitly or implicitly through $L$.

$$E\left[U'\frac{F_K}{F_L}\right]=\frac{r}{w}E(U') \tag{7b}$$

In the case of risk neutrality $U'$ is a constant and disappears from both sides of (7a) and (7b).

Now let $(p_A, K_A)$ denote the solution of system (7a) and (7b), and assume that $(p_A, K_A)$ is unique and satisfies the second-order maximization conditions. The assumed conditions on $F$ and $D$ in turn guarantee the existence of an open neighborhood $\Omega$ of $(p_A, K_A)$ in $p$–$K$ space, in which $\bar{L}(p, K, x)$ as defined by (3) is $>0\ \forall\ x\in X$. Hereafter, it will be assumed that all pairs $p$–$K$ in our discussion fall within $\Omega$.[8]

## II. The Rate of Return Constraint

If $s>r$ is the allowable regulatory upper limit on the rate of return then we must have:

$$sK \geq pD(p, x) - wL \tag{8}$$

and the *ex post* controls are found by defining $u\in[0, 1]$ and $L>0$ satisfying (1) and (8) and maximizing $\pi(x)$ for given values of $p$, $K$, and $x$. Equation (8) may be written as:

$$L \geq \frac{pD(p, x) - sK}{w} \tag{9}$$

It is obvious now that if $\bar{L}(p, K, x)$ is $\geq$ the right-hand side of (9) then the constraint is inoperative for this particular value of $x$ and the *ex post* controls are given by (3). If, on the other hand, the right-hand side of (9) is greater than $\bar{L}(p, K, x)$, then the optimal choice is given by:

$$L=\frac{pD(p, x) - sK}{w} \tag{10}$$

$$F\left[uK, \frac{pD(p, x) - sK}{w}\right] = D(p, x)$$

the solution of the second part of (10) yielding the value of $u\in(0, 1)$. Since this value of $u$ is $<1$ it follows that for this class of values of $x$ the firm will operate *below full capacity.*

Now let $(p_B, K_B)$ be the solution of the constrained problem. Assume again that $(p_B, K_B)$ is the unique solution of the corresponding first-order necessary conditions that satisfies also the second-order conditions for a maximum. The derivation of these conditions follows from (5), with (10) replacing $\bar{L}(p, K, x)$ where appropriate. Two sets of values of $x$ may be defined as follows:

$$\omega_1 = X\cap\left\{x: sK_B \geq p_B D(p_B, x) - w\bar{L}(p_B, K_B, x)\right\} = X\cap\left\{x: F\left[K_B, \frac{p_B D(p_B, x) - sK_B}{w}\right] \leq D(p_B, x)\right\} \tag{11}$$

$$\bar{\omega}_1 = X\cap\left\{x: F\left[K_B, \frac{p_B D(p_B, x) - sK_B}{w}\right] > D(p_B, x)\right\} \tag{12}$$

and the *ex post* controls are now (3) for $x\in\omega_1$ and (10) for $x\in\bar{\omega}_1$. We may now prove the following:

PROPOSITION 1: *If the regulation is effective,*[9] $\bar{\omega}_1$ *cannot be empty for either the risk-neutral or the risk-averse monopolist.*

PROOF:

If $\bar{\omega}_1$ were empty then at $(p_B, K_B)x\in\omega_1 \Leftrightarrow x\in X$. This means that (3) is the solution of the *ex post* problem for all $x\in X$ and, hence, that (7a) and (7b) are the necessary conditions for the *ex ante* controls. However, it was assumed earlier that $(p_A, K_A)$ was the unique solution of the unconstrained problem, hence the only possibility is $(p_A, K_A) = (p_B, K_B)$. This means that the constraint (8) does not affect the choices of the monop-

[8] If $F(uK, L)$ is defined for all $(uK, L)$ in the nonnegative orthant, and if $D(p, x)$ is defined and $>0$ for all $p>0$, then $\Omega$ consists of the entire positive orthant in $p-K$ space.

[9] An effective regulation (or effective constraint) is defined here as a constraint that changes the input and/or scale choices of the monopolist for some $x\in X$.

olist for any value of $x \in X \Rightarrow$ regulation is not effective since the expected profit and/or utility are unchanged. Hence, if the regulation is effective $\bar{\omega}_1 \neq \phi$.

COROLLARY 1: *The effectively regulated price-setting monopoly firm will always operate below full capacity for some range of values of the random demand.*

As mentioned earlier, this result is drastically at variance with the deterministic results of Zajac and Baumol-Klevorick. We also note that this holding of idle capital does not happen in the unregulated monopoly with random demand, as seen by (3). Finally, nothing is implied here about the effect of the regulatory constraint on the relative size of capital stocks, prices, and/or input ratios.

The profit function of the regulated firm is now given by:

$$\text{(13a)} \quad \pi(x) = p_B D(p_B, x) - w\bar{L}(p_B, K_B, x) - rK_B, \qquad x \in \omega_1$$

$$\text{(13b)} \quad \pi(x) = (s - r)K_B, \qquad x \in \bar{\omega}_1$$

On substituting (13a) and (13b) into (5) we get:

$$\text{(14)} \quad \max_{p,K} \left\{ \int_{\omega_1} U[pD(p, x) - w\bar{L}(p, K, x) - rK]g(x)dx + \int_{\bar{\omega}_1} U[(s - r)K]g(x)dx \right\}$$

It is easy to see that the maximization procedure together with (4) yields, instead of (7a) and (7b):

$$\text{(15a)} \quad \int_{\omega_1} U'\left[pD_p + D - \frac{wD_p}{F_L}\right] g(x)dx = 0$$

$$\text{(15b)} \quad \int_{\omega_1} U'\left[\frac{wF_K}{F_L} - r\right] g(x)dx + (s - r)U' \int_{\bar{\omega}_1} g(x)dx = 0$$

where $U' \equiv U'(\pi(x))$ and $\pi(x)$ is defined by (13a) and (13b). Alternatively, (15a) and (15b) may be written as:

$$\text{(16a)} \quad \int_{\omega_1} U'Dg(x)dx = \int_{\omega_1} U'D_p\left(\frac{w}{F_L} - p\right) g(x)dx$$

$$\text{(16b)} \quad \int_{\omega_1} U' \frac{wF_K}{F_L} g(x)dx + sU' \int_{\bar{\omega}_1} g(x)dx = r\left[\int_{\omega_1} U'g(x)dx + U' \int_{\bar{\omega}_1} g(x)dx\right] = rE[U'(\pi(x))]$$

In the case of risk neutrality, (16a) and (16b) become:

$$\text{(17a)} \quad \int_{\omega_1} Dg(x)dx = \int_{\omega_1} D_P\left(\frac{w}{F_L} - p\right) g(x)dx$$

$$\text{(17b)} \quad \int_{\omega_1} \frac{wF_K}{F_L} g(x)dx + s\int_{\bar{\omega}_1} g(x)dx = r$$

The following proposition helps us characterize the solution of (16a) and (16b) and/or (17a) and (17b).

PROPOSITION 2: *$\omega_1$ possesses a relative interior for all risk-neutral and risk-averse monopolists and all distributions $g(x)$.*

PROOF:

Proposition 2 basically says that $sK_B > p_BD(p_B, x) - w\bar{L}(p_B, K_B, x)$[10] for some ranges of values of the random variable $x$. To prove it we note that the necessary conditions (16b) or (17b) are violated if $\omega_1 = \phi$, since $s$ is $> r$ by assumption. Hence we must eliminate the possibility that $\omega_1 = \{x: sK_B = p_BD(p_B, x) - w\bar{L}(p_B, K_B, x)\} \cap X$. If this is true, then $\omega_1$ is either countable or contains a compact subinterval of values of $x$ in $X$. Within such a subinterval we must have:

$$\text{(18)} \quad sK_B = p_BD(p_B, x) - w\bar{L}(p_B, K_B, x)$$

[10] Or, alternatively, that $F(K_B, (p_BD(p_B, x) - sK_B)/w) < D(p, x)$.

Differentiating (18) and taking (4) into account, we get:

$$p_B D_x = w \frac{D_x}{F_L} \tag{19}$$

and, since $D_x > 0$, we must have:

$$\frac{p_B}{w} = \frac{1}{F_L} \tag{20}$$

where

$$F_L \equiv F_L\left[K_B, \frac{p_B D(p_B, x) - sK_B}{w}\right] \tag{21}$$

Equation (20) implies that $F_L$ is constant with respect to $x$, which implies that $\partial F_L/\partial x = 0 \Rightarrow F_{LL}(p_B D_x/w) = 0$, impossible for a positive $p_B$, since $D_x > 0$ and $F_{LL} < 0$.[11] Therefore, since (18) cannot hold for a compact subinterval of values of $x$ in $X$, $\omega_1$ either contains values of $x$ in $X$, for which $sK_B > p_B D(p_B, x) - w\bar{L}(p_B, K_B, x)$, or consists entirely of a countable set of single points, on which (18) holds. The latter case would violate the necessary conditions (15b) or (17b), since the first integral on the left-hand side would be zero because of the continuity of $g(x)$. The only remaining possibility is that $sK_B > p_B D(p_B, x) - w\bar{L}(p_B, K_B, x)$ for some $x$ in $X$ and the continuity of $D$ and $\bar{L}$ insures that the above inequality will hold strictly for a range of values of $x$ in $X$.

Propositions 1 and 2 imply that there exist at least two compact intervals of values of $x$ in $X$, in which constraint (8) holds with equality and with strict inequality respectively. The consequences of this may be expressed by the following:

COROLLARY 2: *The expected rate of return on invested capital for the regulated price-setting monopolist is strictly less than the regulatory upper bound s.*[12]

[11] For a neoclassical production function with convex isoquants $F_{LL}$ must be $<0$.

[12] Corollary 2 is also valid for the quantity-setting regulated firm, as can be seen from my earlier study. This is a consequence of the regulatory assumptions of both studies, which imply that the regulators would enforce the regulatory constraint at every observable state of nature, and the firm knows this and acts accordingly. A different model, requiring a multiperiod formulation would be more appropriate if it is assumed that the regulators restrict the *average* rate of return over a number of observed realizations of the random demand.

## III. Some Special Cases

Two important special forms of the random demand curve are those with additive and multiplicative random terms. Specifically:

$$D(p, x) = D(p) + x > 0 \quad \text{for additive} \tag{22a}$$

$$D(p, x) = xD(p), \quad x > 0 \quad \text{for multiplicative} \tag{22b}$$

We may assume without loss of generality that $E(x) = 0$ in (22a) and $E(x) = 1$ in (22b).

The solution of the problem of the constrained price-setting monopolist involves, among others, the definition of the subspaces $\omega_1$ and $\bar{\omega}_1$. For this we need to find the roots in $x$ of the equation

$$\frac{F[K, pD(p, x) - sK]}{w} = D(p, x) \tag{23}$$

This is simplified in both additive and multiplicative cases by the following:

PROPOSITION 3: *For random demand curves with additive or multiplicative random factors $\omega_1$ is compact and* (23) *has either one or two roots in X.*

PROOF: Define $\Lambda(x)$ as follows:

$$\Lambda(x) = \frac{F[K, pD(p, x) - sK]}{w} - D(p, x) \tag{24}$$

It is easy to see by repeated differentiation that $\Lambda''(x) < 0$ when $D(p, x)$ has the forms (22a) or (22b). Hence, $\Lambda(x)$ is strictly concave and the equation $\Lambda(x) = 0$ has at most two roots in $X$. Since $\bar{\omega}_1$ is defined by $\Lambda(x) > 0$ the strict concavity of $\Lambda(x)$ insures that if $\hat{x}_1 < \hat{x}_2$ are the two roots of (23), then $\bar{\omega}_1 = (\hat{x}_1, \hat{x}_2) \cap X$, which is compact.

The fact that $\omega_1$ must possess an interior implies that at least one of the subspaces $[\underline{x}, \hat{x}_1] \cap X$, $[\hat{x}_2, \bar{x}] \cap X$ must possess an interior. It is easy to show that it is not

possible to have $\omega_1 = [\hat{x}_2, \bar{x}] \cap X$. To see this we observe that at $(p_B, K_B)$ the point $x_m$, at which $\Lambda(x) = max$ is given by the solution of $\Lambda'(x) = 0$, which yields $pF_L/w = 1$; obviously, if $x_m \in X$ then $x_m \in \bar{\omega}_1$. It follows that $\hat{x}_2 > x_m$ and, if $\omega_1 = [\hat{x}_2, \bar{x}]$, $\Lambda'(x) < 0 \ \forall \, x \in \omega_1$, implying in turn that $w/F_L - p > 0 \ \forall \, x \in \omega_1$ and the necessary condition (16a) can have no solution since the left-hand side is $>0$ and the right-hand side $<0$ always. Hence, for these two important special forms of the random demand curve we must have either:

$$\omega_1 = [\underline{x}, \hat{x}_1], \qquad \bar{\omega}_1 = (\hat{x}_1, \bar{x}) \tag{25}$$

or

$$\omega_1 = [\underline{x}, \hat{x}_1] \cup [\hat{x}_2, \bar{x}], \quad \bar{\omega}_1 = (\hat{x}_1, \hat{x}_2) \tag{26}$$

where $\hat{x}_1$ and $\hat{x}_2$ are the two roots in $x$ of (23) for the optimal *ex ante* controls $(p_B, K_B)$.

## IV. Conclusions

The combination of demand uncertainty, price-setting behavior, and rate of return regulation for a monopoly firm has as a result the operation of the firm's capital stock below full capacity for at least one entire range of realizations of the random demand at the optimally chosen price and capital. This is true for all types of probability distributions and all utility functions with nondecreasing marginal utility, which includes of course, risk-neutral monopolists. Further, the expected *ex ante* rate of return is strictly less than the maximum allowed by the regulators, while the observed *ex post* rate of return is equal to the maximum allowed whenever the firm operates its capital stock below full capacity, and vice versa.

These results are direct consequences of the adopted assumptions about firm objectives and regulation, which are natural extensions to the uncertain demand case of the Averch-Johnson model of firm behavior. The firm must satisfy *ex post* (i.e., after the value of the random demand becomes known) both the rate of return constraint and the demand constraint (1). At some "states of nature," it must increase its labor above a certain minimum in order to stay within the allowed rate of return. This, however, forces it to underutilize the invested capital in order to meet demand exactly. These states of nature will occur with a positive probability whenever the firm choooses *ex ante* the output price and capital stock by maximizing expected profit (or expected utility of profit). Needless to say, the conclusions of this paper will have to be modified if other firm objectives or methods of regulation are considered (as in the article by Elizabeth Bailey and John Malone for the deterministic case).

As a final remark it should be noted that, although numerical solution of (23) and (16a) and (16b) should present no problems, analytical results are difficult to obtain. Proposition 3 offers some help in this direction for the two important cases of demand curves with additive or multiplicative random terms, since it shows that the solution of (23) is equivalent to finding the zeros of a strictly concave function. However, even in the simple case of a Cobb-Douglas production function and a constant elasticity demand curve with a multiplicative random factor it is not possible to solve (23) explicitly. Barring restrictive assumptions, therefore, there is very little that can be said about relative size of capital stock, price, expected output, etc.

# Money, Income, and Causality: The U.K. Experience

*By* DAVID WILLIAMS, C. A. E. GOODHART, AND D. H. GOWLAND*

In a recent paper, Christopher Sims developed a statistical technique for testing whether there was evidence of unidirectional causality within a two-variable system. He applied this technique to an examination of the relationship between movements in nominal incomes and in the money supply, in order to throw light on the question whether there was evidence of clear-cut unidirectional causality running from changes in the money stock to changes in nominal incomes, or vice versa. He concludes that: "The main empirical finding is that the hypothesis that causality is unidirectional from money to income agrees with the postwar *U.S.* data, whereas the hypothesis that causality is unidirectional from income to money is rejected" (p. 540). Accordingly,

> . . . one clearly should not estimate a demand for money relation from these data [of *GNP* and money stock], treating *GNP* as exogenous with money on the left-hand side; no evidence appears to contradict the common assumption that money can be treated as exogenous in a regression of *GNP* on current and past money. [p. 550]

This is an important, indeed sweeping, conclusion, which could if generally upheld have a major influence on monetary economics. One way of examining the strength of these results is to replicate the exercise in other contexts and using differing data and time periods. In this paper we undertake a closely similar exercise using *U.K.* data.

There were a number of reasons for doubting whether Sims' results would hold within a *U.K.* context. Unlike the United States, the United Kingdom is a relatively small, open economy which during the observation period maintained a regime of fixed exchange rates. Under such circumstances the private sector can more easily adjust their money holdings to their incomes by transfers of funds over the exchanges (subject to exchange control), than in a virtually closed economy such as the *U.S.* Furthermore the conduct of monetary policy during the 1960's was influenced by the precepts of the Radcliffe Committee Report that "The authorities thus have to regard the structure of interest rates rather than the supply of money as the centre-piece of the monetary mechanism" (p. 135). In so far as the authorities primarily aim to regulate the structure of interest rates, movements in the money stock can be expected to respond to movements in nominal incomes.

Because of the various differences in context the finding that in the United Kingdom the relationship between money and income appears different from that found by Sims for the United States in no way casts any doubt on the validity of Sims' own results. Sims, in fact, comments (pp. 542–43) that the results are peculiar to his sample. A recent study by Thomas Sargent and Neil Wallace[1] investigates the direction of causality between money and prices during periods of hyperinflation for certain European countries using an approach similar to Sims. They show that there is evidence to suggest that the causality is from prices to money. Hence, the implication is that the form and direction of these relationships do depend on the institutional context, and that Sims' results do not have a general validity in all economies. In particular it may be hazardous to extrapolate findings obtained in a virtually closed economy such as the *U.S.*, also to smaller, open economies.

* Bank of England. Our thanks are due to our colleagues in the Economic Section of the Bank for their general help and to a referee of an earlier version of this paper for some specific advice and suggestions. In addition, we have benefited by having the chance to read as yet unpublished papers on this topic by E. L. Feige of the University of Wisconsin and K. Wall of Queen Mary College, London. The errors and shortcomings, however, remain our responsibility.

[1] We are grateful to a referee for bringing this reference to our attention.

## I. Methodology and Content

Following an approach initially developed by C. W. J. Granger Sims sets out and proves the theorem that when the jointly covariance-stationary pair of stochastic processes $X$ and $Y$ . . .

> . . . has an autoregressive representation, $Y$ can be expressed as a distributed lag function of current and past $X$ with a residual which is not correlated with any values of $X$, past or future, if, and only if, $Y$ does not cause $X$ in Granger's sense. . . . Only in the special case where causality runs from $X$ to $Y$ can we expect that no future values of $X$ would enter the regression if we allowed them. [p. 544–45]

So if $X$ causes $Y$, a regression of $Y$ on past, current, and future values of $X$ should exhibit significant coefficients for past and current values but insignificant coefficients on future values. Again if $X$ causes $Y$, a regression of $X$ on past, current, and future values of $Y$ should exhibit significant coefficients on future values of $Y$ (and may, or may not, exhibit significant coefficients on present and past values). As Sims states, this method "does rest on a sophisticated version of the *post hoc ergo propter hoc* principle," but he argues strongly that this "method is not easily fooled" (p. 543).

Essentially, therefore, the method involves regressing $X$ on current, past, and *future* values of $Y$, and then reversing the process regressing $Y$ on $X$. Causality, in this sense, then appears to be unidirectional from $X$ to $Y$, if future values of $X$ are insignificant, but current and past values of $X$ are significant in the regression of $Y$ on $X$, while future values of $Y$ are significant when regressing $X$ on $Y$. These tests will only indicate the presence of what may be called proper causality, i.e., the causal effect takes at least one time period to manifest itself. Contemporaneous causality can be tested by including the present with the future lags when carrying out the tests. However, we followed Sims in only testing for proper causality.

Sims noted (p. 543) that there are two situations when the results of these tests can be misleading:

(i) The first situation concerns the possible existence of a third variable which, say, affects $X$ quicker than $Y$. In this case the future lags of $Y$ will be significant when explaining $X$ even though $X$ and $Y$ themselves may not be causally related. We will never know whether this situation has obtained without formulating a more comprehensive model. This is something of a vicious circle since these causality tests are to be used as a preliminary to any model building.

(ii) The second situation arises when the factors affecting one variable, say $Y$, include the expected future values of the other variable $X$ and yet there is no causal relationship from $Y$ to $X$. In the event of the expectations being accurate, the future values of $X$ may be significant when explaining $Y$ owing to the autocorrelation of $X$. This situation should rarely occur in practice because of the assumption that there is no causal relationship from $Y$ to $X$. However Michael Rozeff, in a recent study analyzing the relationship between money and stock market prices in the United States, has suggested that investors do correctly anticipate the future path of monetary expansion although there is supposedly no causal relationship from stock market prices to money.

For this exercise, examining the direction of causality between incomes and money, the standard *U.K.* series for nominal incomes is the quarterly series for *GDP* at current prices. This series can be divided into its real (*RGDP*) and price components (*PGDP*), which are additive on the logarithmic scale. This series is available on a consistent basis from 1958-I till 1971-III, the period of observation for this exercise. Complete monetary data, covering all the banks, are only available from 1963-I onwards, so, in order to obtain a longer period of observation, proxy series were used. Two monetary series were used: (i) notes and coin plus current accounts with the London clearing banks, subsequently termed narrow money ($M_N$); (ii) $M_N$, plus deposit accounts with the London clearing banks, subsequently termed broad money ($M_B$).

The first may be regarded as a proxy for $M_1$, and the second for $M_3$ as currently defined (Bank of England). These monetary aggregates based on London clearing bank deposits formed a declining proportion of the total money stock, especially in the case of the broader definition in the later years. However, the London clearing banks account for a very large proportion of the *U.K.* banking sector, and throughout the period maintained a dominant share of current accounts, over 80 percent. Therefore, $M_N$ is probably a better proxy for $M_1$, than is $M_B$ for $M_3$. It should, however, also be noted that the clearing banks tended to bear the brunt of the authorities' direct interventions in the banking system (for example, ceilings on lending). These monetary series were available monthly and were converted into a consistent quarterly series by averaging. Since these variables are only proxies, then, only to a limited extent are they measuring the theoretical concepts which they are representing. This is typically an instance of errors in variables. These errors will tend to reduce the significance of the coefficients in the Sims regressions and so causality is less likely to be detected, and might be distorted. However, there is no reason to expect these measurement errors in money to be correlated with incomes, unlike the case cited by Sims (p. 543) where "animal spirits" of bankers and businessmen could affect money quickly but *GNP* only with a distributed lag.

Sims noted (p. 546) that if different seasonal adjustment procedures are used on money and incomes then "spurious" seasonality can be induced into the relationship. We used the same seasonal adjustment procedure on both sides of the regression equation, and could therefore dispense with seasonal dummies. However, we tested the residuals from each fitted regression for fourth-order autocorrelation and found it to be absent in every case (see below).

Before computing his regressions, Sims applied a filter to all his variables of the form $(1-\frac{3}{4}B)^2$ where $BX_t = X_{t-1}$. The object of this filter was to ensure that the residuals were approximately white noise. Marc Nerlove considered filters of the type $(1-kB)^p$ applied to seasonally adjusted series. His objective was to remove the trend, and he judged this successful if the resulting spectrum was relatively flat, thereby simulating white noise. He found empirically that flat spectra could be achieved in quite a number of economic time-series with $k=\frac{3}{4}$ and $p=1$, 2, or 3.

As noted by Sims (p. 544), the derivation of the regression tests between two economic processes $X$ and $Y$ requires that these series are jointly covariance stationary processes each with zero mean. Since they are growing through time, both the money and income series are nonstationary. This is true for both the *U.S.* and the *U.K.* Sims assumes that the nonstationary behavior can be modelled by a deterministic linear time trend plus a stationary stochastic residual. We preferred the more general assumption of stochastic nonstationarity.[2] G. E. P. Box and G. M. Jenkins (p. 85) suggest that such nonstationarity can be eliminated by an appropriate degree of differencing, i.e., using a filter $(1-\mathrm{B})^d$ with $d$ usually equal to 1 or 2.

Like Sims, we assumed that the relationship, if any, between money and income was linear on the logarithmic scale. Using the methodology of Box and Jenkins the transformed series of both money and income can be made stationary by taking first differences. To ensure a zero mean, each stationary series should be mean corrected by subtracting the appropriate sample mean. This is equivalent to including a constant term in the regressions, which is what we did.

In specifying his regressions, Sims used 4 future and 8 past lags and also included a time trend. Before estimation he used the filter $(1-\frac{3}{4}B)^2$. Our specification can be thought of as being the same as Sims' except that we used the filter $(1-B)$ which reduces the time trend to a constant. However the

[2] This means that the parameters of the linear time trend are assumed to be stochastic. However, the data were such that only the intercept parameter could be considered stochastic. It will be seen below that, following a referee's suggestion, the assumption of stochastic nonstationarity was tested and justified empirically.

purpose of Sims' filter was to produce an uncorrelated error structure in each of the regressions whereas our filter was to produce covariance stationary processes. Hence, we possibly need a further filter to cope with autocorrelation in the error structure. Autocorrelation may be present because the chosen lag length is arbitrary and so further relevant lags are included in the error term. In order to assess the magnitude of this autocorrelation, we have made the standard assumption that it can be modelled by an autoregressive process, since this can be dealt with using regression techniques. So, instead of only applying a single filter to each regression before estimating the lag profile, we adopted the following procedures:

(i) apply *OLS* to the first-differenced specification;

(ii) investigate the autoregressive properties of the fitted residuals, $e_t$, from step (i) by regressing $e_t$ on $e_{t-1}, \ldots, e_{t-4}$. We found that $e_{t-1}$ and $e_{t-2}$ at most had significant coefficients giving a filter of the form $(1-a_1B-a_2B^2)$. The lagged error $e_{t-4}$ was used to check for residual seasonality and was found to be insignificant in every case;

(iii) apply the estimated filter from step (ii) to the first-differenced specification and, using *OLS*, estimate the lag profile.

Ideally, this procedure should be iterated using the fitted residuals from step (iii) and repeating steps (ii) and (iii). However, since it is necessary to use the same autoregressive filter in estimating the lag profile both with and without the future lags, and this common filter is estimated by averaging the two independently estimated filters, one iteration was considered sufficient. With first-differencing and the autoregressive filter, the combined filter which is applied to each variable is of the form $(1-B)(1-a_1B-a_2B^2)$ for the more complicated second-order autoregressive filter. This may be compared and contrasted with Sims' filter $(1-\frac{3}{4}B)^2$.

In our approach, the filter $(1-B)$ is assumed to be necessary. A referee suggested that it would be possible to check this assumption empirically as follows:

(i) form the appropriate specification between the unfiltered variables, i.e., with or without the future lags, and also include a time trend in the specification;

(ii) apply an initial filter to the specification, for example, either $(1-B)$ or $(1-\frac{3}{4}B)^2$, and estimate the lag profile using *OLS*;

(iii) using the estimated coefficients from step (ii), evaluate the residuals in the original specification. If the filter $(1-B)$ has been used then these residuals will not have zero mean;

(iv) investigate the autoregressive properties of these residuals $e_t$ by regressing $e_t$ on $e_{t-1}, \ldots, e_{t-4}$ and including a constant term if necessary;

(v) use the estimated filter from step (iv) instead of the initial filter and repeat step (ii).

We extended the referee's suggestion by iterating the procedure and then averaged the two final estimated filters for the specification with and without the future lags to derive a common filter which is therefore equivalent to the combined filter mentioned above. A comparison of the filters using the two approaches is shown in Table 1. With the referee's approach, four of the filters have a factor $(1-B)$ (assessed by the algebraic sum of the coefficients being zero) and half of the remaining filters have a factor close to $(1-B)$ (assessed by algebraic sum of the coefficients being less than 0.2). This suggests that our assumption of $(1-B)$ is justified. In fact, the regression results of the two approaches were similar and the conclusions identical. Consequently only the results of our approach are reported since we believe that our combined filter having a factor of $(1-B)$ is theoretically more satisfying.

## II. Empirical Results

The crucial empirical issue is whether future values appear significant when each series is regressed on a distributed lag of past, present, and future values of the other series. Sims found "... Future values of *GNP* were highly significant in explaining the *M* dependent variable, but future values of *M* were not significant in explaining the

TABLE 1—COMPARISON OF COMBINED FILTERS

| Regression | Our Approach[a] | Referee's Approach[a] |
|---|---|---|
| **Nominal Income** | | |

[a] See text.

$GNP$ dependent variable" (p. 546). An $F$-test was used to check the significance of the future values. Although not as significant, our results using $U.K.$ data suggested the opposite relationship particularly with the narrow definition of money $M_N$. The situation was less clear-cut with the broad definition of money $M_B$. In Table 2, our results and those presented by Sims (in his Table 3) are shown and contrasted. None of our $F$-ratios are significant at the 5 percent level.[3] However, the future lags for $GDP$ on $M_N$ are almost significant at the 5 percent level whereas those for $M_N$ on $GDP$ are definitely nonsignificant. This suggests at least the possibility of unidirectional causality from $GDP$ to $M_N$.

In Table 3, we present the $R^2$ for the various regressions, which show that there is still a sizeable proportion of unexplained variance. A test of whether or not $R^2$ is significantly different from zero is assessed by an $F$-ratio. These are also given in Table 3. Only two ratios are significant at the 5 percent level, viz., $M_N$ on $GDP$ without future lags and $GDP$ on $M_N$ with future lags. These are the two ratios that would a priori have

[3] The significance level quoted in all the tables is for the case of a second-order autoregressive filter since this gives the minimum degrees of freedom and hence the maximum value of the $F$-ratio.

been expected to be significant on the assumption of unidirectional causality from *GDP* to $M_N$. The coefficients of the regressions themselves are given in Table 4. Caution should be exercised in interpreting both the sizes and patterns of the coefficients since unrestricted estimation is unlikely to give an efficient estimate of the lag profile.

Sims then proceeded to examine the relationship between money and the real and price components of income separately. He found that the relationship between money and the real component of *GNP* (*RGNP*) was much the same as the relationship between *M* and nominal income, but, with the price component of *GNP* (*PGNP*), none of the *F*-ratios testing the future coefficients were significant. We undertook a similar exercise and the *F*-ratios testing the future coefficients are presented in Table 5. None of these *F*-ratios for *RGDP* is significant. However with *PGDP*, that with $M_N$ as the dependent variable is almost significant at the 5 percent level. This suggests a possibility that there might be unidirectional causality from money to prices.

Again, we have estimated the significance of the $R^2$ in the various regressions. These results are presented in Table 6. None of them is significant at the 5 percent level.

TABLE 5—*F*-TESTS ON FOUR FUTURE QUARTERS' COEFFICIENTS

| Regression | *F*-ratio |
|---|---|
| $M_N$ on *PGDP* | 2.73 |
| $M_B$ on *PGDP* | 2.07 |
| *PGDP* on $M_N$ | 1.26 |
| *PGDP* on $M_B$ | 0.56 |
| $M_N$ on *RGDP* | 0.45 |

| *RGDP* on $M_B$ | 0.27 | 0.76 | 0.24 | 1.12 |
| $M_N$ on *RGDP* | 0.32 | 0.94 | 0.27 | 1.25 |
| $M_B$ on *RGDP* | 0.19 | 0.48 | 0.12 | 0.47 |
| *PGDP* on $M_N$ | 0.34 | 1.04 | 0.21 | 0.90 |
| *PGDP* on $M_B$ | 0.39 | 1.29 | 0.34 | 1.72 |
| $M_N$ on *PGDP* | 0.49 | 1.92 | 0.28 | 1.26 |
| $M_B$ on *PGDP* | 0.32 | 0.99 | 0.11 | 0.44 |
| 5 percent significance level | | 2.12 | | 2.21 |

This is further evidence that the relationship between movements in money and in prices and real incomes in the *U.K.* is not very close.

### III. Conclusion

The evidence indicating the direction of causality between money and income in the *U.K.* is much less clear-cut than that which Sims found in his examination of *U.S.* data. As remarked above, the tests carried out by both Sims and ourselves are for proper causality, i.e., with a lag of at least one period. A negative result still leaves open the possibility of simultaneous causality. Sims found evidence of unidirectional causality running from money to nominal income, especially from money to real income. We found for the *U.K.* some evidence of unidirectional causality running from nominal incomes to money but also some evidence of unidirectional causality running from money to prices. Taken together, this evidence suggests, perhaps, a more complicated causal relationship between money and incomes in which both are determined simultaneously.

# The Neoclassical Production Function: Comment

By P. GAREGNANI*

In an article recently published in this *Review*, Lowell Galloway and Vishwa Shukla (hereafter G-S) consider an economy where two commodities, 1 and 2, are produced in separate industries and in annual cycles by means of labor and a circulating capital made up of the commodities themselves. Two alternative methods are assumed for the production of commodity 2 and there are, therefore, two alternative "systems" of production, each formed by taking the method of production of commodity 1 together with one of the methods for commodity 2; moreover, both commodities are basic in each of the systems.[1]

## I. A Nonreswitching Theorem

Galloway and Shukla claim that if each system gives a relative price of the two commodities which is "positive and finite for any positive value of the interest rate" (p. 349), then reswitching between them cannot occur; i.e., the system which has become less profitable than the other because of a change in the rate of interest $r$ cannot revert to being more profitable as $r$ changes further in the same direction.

There are two points to be made about this claim. The first is that the claim is false: under the conditions stated by G-S reswitching is possible. A numerical example showing this is given in the Appendix together with an indication of the error in their attempted proof.

The second point is that, contrary to what readers of the article might have been led to think, the G-S condition of a positive price "for any positive value of the interest rate" has no apparent economic justification.

## II. The Maximum Rate of Interest

In their article, G-S refer to numerical examples which various authors, myself included, had given in order to disprove an earlier nonreswitching "theorem,"[2] and write "... in all fairness to the counterexamples it should be noted that $p_1$ and $p_2$ [the prices of the two commodities] are positive within the range of $r$ encompassing the switch points. However at other values of $r$, either $p_1$ or $p_2$ is negative" (p. 350, fn. 10). They, however, do not specify that the "other values of $r$," at which the relative price of the two commodities[3] is negative in the counterexamples, are values of $r$ larger than the "maximum rate of interest," i.e., are rates of interest for which the wage and the relative price of the two commodities cannot both be positive.[4]

When, therefore, G-S, later in the text, write of the "Failure of ... counterexamples of reswitching to meet the basic assumption of positive and finite commodity prices for all $r>0$ ..." (p. 351), the reader may be induced to think that the examples in question are in contradiction to the usual assumption of positive prices (for rates of in-

* Professor of economics, University of Rome.

[1] The G-S assumption of "indecomposable production systems" (p. 349) is equivalent to assuming that each of the two commodities is basic, i.e., enters directly or indirectly in the production of both itself and the other commodity (see Piero Sraffa, p. 8).

[2] The nonreswitching theorem was given by David Levhari, and the counterexamples by Michio Morishima; Michael Bruno, Edwin Burmeister, and Eytan Sheshinsky; the author (1966).

[3] The price equations can only determine relative prices, and therefore, in a two-commodity system, they determine a single relative price.

[4] In any system of production which is "viable," (i.e., capable of yielding a surplus over the replacement of the means of production) and includes only basic commodities, the rise from zero of the rate of interest $r$ makes the wage in terms of any commodity fall continuously from a value $w_{max}$ for $r=0$, down to the level zero, reached for a finite "maximum rate of interest" $r_{max}$, at which the whole national income goes to profits. Further, for $0 \leq r \leq r_{max}$ all prices are positive. These properties, well known since Sraffa, are ignored by G-S, though they were restated by myself (1966) in the article to which they refer. The additional proposition that the wage and prices cannot all be positive for $r>r_{max}$ is demonstrated in paragraph 3 of the Appendix below.

terest up to the maximum) "basic" to all economic theory, and not in contradiction solely to the special assumption made by G-S of positive prices even beyond the maximum rate of interest.

Galloway and Shukla's own assumption will become basic for economic theory only after they have explained what importance we are to attach to positive prices when the wage is negative. The failure of their nonreswitching theorem may, however, exempt them now from this task—which is made less easy by the fact that later in the article, they themselves repeatedly dismiss the range of $r$ larger than the maximum, as "outside the pertinent range of the factor price contour."[5]

### III. The Convexity of the Wage Curve

Finally, a remark on a property to which G-S seem to attach considerable importance, namely the convexity to the origin of the "wage curve," (the curve relating the wage and the rate of interest within a given system of production). This convexity implies that in the integrated production of the wage commodity, the value of capital per worker in terms of that commodity falls as the rate of interest rises.[6]

Galloway and Shukla maintain that the constraints ensuring a positive relative price of the commodities at all positive rates of interest also ensure the convexity of the wage curve (see pp. 349; 357–58). This is misleading. Those constraints will not prevent the wage curves from being concave, once their other assumption of a wage advanced at the beginning of the annual production cycle is abandoned in favor of a wage paid post factum.[7]

The convexity of the G-S wage curves is therefore primarily due to the assumption of an "advanced wage" which makes the wage an element of capital, additional to the means of production: as the rate of interest rises this (additional) wage element of capital falls, and thus makes for a fall in the value of capital per worker, i.e., makes for the convexity of the wage curve. The G-S constraints ensuring positive prices play only a subordinate role in this respect: the role of preventing the value of the means-of-production element of capital from rising so much, relative to the wage commodity, as to more than compensate the fall in the wage.[8]

## APPENDIX

### 1. *A Numerical Example*

Consider the following alternative two-commodity systems of production, *I* and *II*:

$$\text{System } I \begin{cases} a_{01} = 1, & \overset{I}{a}_{02} = 1 \\ m_1 = \dfrac{1}{12}, & \overset{I}{m}_2 = \dfrac{1}{6} \\ n_1 = \dfrac{1}{3}, & \overset{I}{n}_2 = \dfrac{1}{6} \end{cases}$$

[5] One such passage reads "However, the second switchpoint lies beyond $r_0$ [the lower of the maximum rates of interest for the two systems concerned] and, therefore, is at a value of $w$ . . . which is negative. Thus it lies outside the pertinent range of the factor price contour" (p. 354; see also pp. 355 and 357).

[6] See the author (1970, p. 419).

[7] This possibility of concave wage curves can be easily seen if we start from the fact that with a wage paid post factum, any indecomposable two-commodity system which gives a convex wage curve when $w$ is in terms of one commodity, say 1, will give a concave curve when $w$ is in terms of the other commodity. Indeed, a convex $w_1(r)$ curve implies a fall in $p_2$, the price of 2 in terms of 1, as $r$ rises: only the fall of $p_2$ can make the given aggregate of the two commodities used as capital in the integrated production of 1 fall in value relative to 1. But, then, a convex $w_1(r)$ implies a rise in $1/p_2$, the price of 1 in terms of 2—and, hence, a rise in the value relative to 2 of the given aggregate of commodities 1 and 2 used as capital for the integrated production of 2; i.e., a convex $w_1(r)$ implies a concave $w_2(r)$ curve. Returning now to G-S constraints on each system of production (see the Appendix) we can note that they are independent of which commodity is used for measuring the wage and prices. What we have seen above then implies that if the constraints are compatible with a convex wage curve, they are by that very fact compatible with a concave curve.

[8] Their constraints on each system of production imply: (a) that each commodity is used in a lower proportion to labor for the production of itself than for the production of the other commodity; and, hence, (b) that the production of one commodity cannot require both means of production in a higher ratio to labor than the production of the other commodity (see fn. 9 below). Both these conditions make for a smaller change in the relative value of the two commodities in the face of any given change in $r$.

$$\text{System } II \begin{cases} a_{01} = 1, & \overset{II}{a_{02}} = \dfrac{92}{91} \\ m_1 = \dfrac{1}{12}, & \overset{II}{m_2} = \dfrac{137}{546} \\ n_1 = \dfrac{1}{3}, & \overset{II}{n_2} = \dfrac{19}{273} \end{cases}$$

where $a_{0i}$, $m_i$, and $n_i$ are, respectively, the inputs of labor, commodity 1, and commodity 2, required to produce a unit of commodity $i$, $(i=1, 2)$. The two systems, which are indecomposable and differ only in the method of production of commodity 2, satisfy Galloway and Shukla's constraints (5) and (6), (p. 349),[9] since:

$$I \begin{cases} a_{01}\overset{I}{m_2} - \overset{I}{a_{02}}m_1 = \dfrac{1}{12} > 0 \\ \overset{I}{a_{02}}n_1 - a_{01}\overset{I}{n_2} = \dfrac{1}{6} > 0 \end{cases}$$

$$II \begin{cases} a_{01}\overset{II}{m_2} - \overset{II}{a_{02}}m_1 = \dfrac{1}{6} > 0 \\ \overset{II}{a_{02}}n_1 - a_{01}\overset{II}{n_2} = \dfrac{73}{273} > 0 \end{cases}$$

From the price equations of each system, we obtain the following relations between $w$ and $r$:

$$\text{(A1)} \quad w^I = \frac{1 - \dfrac{1}{4}(1+r) - \dfrac{1}{24}(1+r)^2}{(1+r) + \dfrac{1}{6}(1+r)^2}$$

$$\text{(A2)} \quad w^{II} = \frac{1 - \dfrac{167}{1092}(1+r) - \dfrac{85}{1092}(1+r)^2}{(1+r) + \dfrac{73}{273}(1+r)^2}$$

Equalizing the right-hand sides of equations (A1) and (A2) we obtain the values $r_1 = 1/3$ and $r_2 = 1/2$ of the rate of interest for which the wage rates in the two systems are the same (i.e., $w_1^I = w_1^{II} = 4/11$; $w_2^I = w_2^{II} = 17/60$). Since for $r=0$, $w^I > w^{II}$, the above result implies that producers will adopt system $I$ for $0 \leq r \leq 1/3$, will then switch to system $II$ for $1/3 \leq r \leq 1/2$, and will finally revert to system $I$ as $r$ increases up to the maximum admissible in the economy $r^I_{max} \cong 1.75$.

## 2. *The Error in Galloway and Shukla's "Proof"*

The coefficients of production of the above numerical example place it in the category which Galloway and Shukla discuss at some length (pp. 355–57) as the third possible under the hypotheses of "Panel B" in their Figure 3. They write the $w$ functions as $w^I = f(r)/\phi(r)$, $w^{II} = f_1(r)/\phi_1(r)$ and discuss the possibility of reswitching in terms of the intersections between the $N = f(r)/f_1(r)$ and $D = \phi(r)/\phi_1(r)$ curves, rather than directly in terms of the intersections between the $w^I$ and $w^{II}$ curves. The decisive error in their argument occurs in the discussion of the curves $\phi(r)$ and $\phi_1(r)$ (the denominators of functions (A1) and (A2), respectively, in the above numerical example), when they fail to notice that for $r=1$, the two curves are tangent to one another (because the two derivatives are $\phi'(-1) = \phi_1'(-1) = a_{01}$) and therefore do not intersect as shown in their Figure 6, p. 356.[10] It follows that the $D = \phi(r)/\phi_1(r)$ curve decreases in the entire interval $r'_{od} < r < -1$ and does not have the minimum shown by G-S in Figures 6 and 7. Accordingly, when $r'_{od} > r'_{on}$, the $D$ curve need

[9] The above constraints on each system can be written as:

$$\frac{m_1}{a_{01}} < \frac{m_2}{a_{02}}; \quad \frac{n_2}{a_{02}} < \frac{n_1}{a_{01}}$$

confirming what was asserted in fn. 8.

[10] Figure 6 is confusing because the points for $r = -1$ of the several functions $\phi(r)$, $\phi_1(r)$, $D$, are all represented as if they occurred in correspondence of point zero of the axis named $r$; moreover, the vertical axis in the figure is incorrectly named $w$ (the same oversights occur in Figures 5 and 7). A more substantial slip occurs in the discussion and representation of curve $N$ as having a single stationary point (p. 355 and Figures 5, 7), whereas the quadratic nature of its derivative should have made clear that if $N$ has one stationary point, then it must have two. Under the hypotheses for which Figures 5 and 7 are drawn, the second stationary point is a maximum occurring for $r > r_{on}$.

not intersect the $N$ curve in the negative range of $r$, and the two curves can intersect twice in the relevant positive interval $0<r<r_{on}$, as happens in my numerical example. (In the G-S notation $r_{on}$, $r'_{on}$ are, respectively, the positive and the negative value of $r$ for which the function $N$ is zero; $r_{od}$, on the other hand, is the (negative) value of $r$ for which $D$ is zero.)

### 3. *The Wage and Prices Cannot be All Positive for $r>r_{max}$*

This proposition can be easily demonstrated for any system with a number $n$ of commodities of which at least one is basic, and each is produced in a separate industry. We can resort to Sraffa's "standard system" where the $n$ industries appear with the unique nonnegative multipliers[11] which ensure that both the net product and the aggregate means of production consist of the same composite "standard commodity." In the standard system the maximum rate of interest compatible with the system of production appears as the ratio between the net product and the aggregate means of production, both measured as quantities of the standard commodity. It follows that for $r>r_{max}$ the amount of profits will consist of a quantity of the standard commodity exceeding the standard net product, and, therefore, the wages in the standard system will be negative together with the wage rate $w_s$ in terms of the standard commodity. If then we refer to the wage $w_i$ in terms of any other commodity $i$, say commodity 1, the equation $w_1=w_s p_s$ shows that $w_1$ will be positive only if $p_s$, the price of the standard commodity in terms of commodity 1, is negative. And since $p_s$ is a weighted average of the prices of the basic commodities in the system, with weights all positive, a negative $p_s$ implies the negativity of at least one of those prices.

In conclusion, for $r>r_{max}$, either the wage will be negative in terms of the chosen value unit or, if positive, at least one of the $(n-1)$ prices will be negative. In either case it will be impossible that both the wage and all prices will be positive.

[11] The multipliers will be positive for the industries producing basic commodities and will be zero for the other industries. (See Sraffa, chs. 4 and 5.)

# The Neoclassical Production Function: Comment

*By* KAZUO SATO*

The reswitching phenomenon brought to light the fact that the neoclassical production system need not be well behaved. This means that the central proposition in neoclassical production theory, namely the monotonic relation between the round-aboutness of production and the interest rate, need not always hold. There are two ways to cope with this situation. One is to accept what is true, however cumbersome it may be. The other is to look for conditions which rule out "perverse" phenomena in the hope that such conditions are empirically acceptable.

Lowell Gallaway and Vishwa Shukla (abbreviated as G-S henceforth) have taken the second approach and claimed to have discovered a new sufficient condition that rules out the reswitching of techniques in a neoclassical production system, a condition which may be called the capital-intensity condition. Unfortunately, their claim is unfounded; their analysis is faulty. Rather than showing where it has gone astray, I shall present a counterexample that satisfies their capital-intensity condition and yet permits reswitching.[1] Though there are conditions that warrant the neoclassical production system to be well behaved, the capital-intensity condition is not among them.

### I. A Two-Sector Model

Take a well-known two-sector model of a closed economy with the following production structure:

| Sector | | Outputs 1 | Outputs 2 |
|---|---|---|---|
| inputs | labor | $a_{01}$ | $a_{02}$ |
| | 1 | $m_1$ | $m_2$ |
| | 2 | $n_1$ | $n_2$ |

Assume that all inputs are consumed entirely within each unit period and that wages are paid before the period begins. Then, the price equations are given by

$$(1)\quad \begin{cases} p_1 = (1+r)(m_1 p_1 + n_1 p_2 + a_{01} w) \\ p_2 = (1+r)(m_2 p_1 + n_2 p_2 + a_{02} w) \end{cases}$$

where $p$ is prices, $w$ is wage rate, and $r$ is interest rate. Equation (1) is solved to yield equation (2) shown at top of following page, and $w$ may be eliminated by taking the relative commodity price:

$$(3)\quad \frac{p_2}{p_1} = \frac{a_{02} + (a_{01}m_2 - a_{02}m_1)(1+r)}{a_{01} + (a_{02}n_1 - a_{01}n_2)(1+r)}$$

### II. Assertions of Gallaway and Shukla

There are four major assertions, one in each corresponding section of Gallaway and Shukla:

(i) The commodity prices are positive and finite for all positive values of $r$ if and only if:

$$(4)\quad \begin{cases} a_{01}m_2 - a_{02}m_1 > 0 \\ a_{02}n_1 - a_{01}n_2 > 0 \end{cases}$$

(ii) Equation (4) is violated by those counterexamples against nonreswitching in the literature.

(iii) Within the constraints of (4), reswitching cannot occur.

(iv) The factor-price frontier is convex to the origin when (4) prevails.

Equation (4) may be rewritten as

$$(5)\quad n_1/n_2 > a_{01}/a_{02} > m_1/m_2$$

which states that each sector is less capital-intensive in the use of its own product. In this sense, we may call it the capital-intensity condition.[2]

* Professor of economics, State University of New York, Buffalo. I wish to thank Murray Brown for raising an initial suspicion that the main proposition of Gallaway and Shukla is wrong.

[1] A more formal disproof of their "general nonreswitching theorem" is presented in the Appendix.

[2] If $m_1 = m_2 = 0$, the first half of (5) alone is relevant. This truncated capital-intensity condition plays a critical role in this special two-sector growth model as is well known in works of Hirofumi Uzawa and others.

$$(2)\qquad \begin{pmatrix} p_1/w \\ p_2/w \end{pmatrix} = \frac{1}{\left(\frac{1}{1+r} - m_1\right)\left(\frac{1}{1+r} - n_2\right) - m_2 n_1} \begin{bmatrix} \left(\frac{1}{1+r} - n_2\right) a_{01} + n_1 a_{02} \\ \left(\frac{1}{1+r} - m_1\right) a_{02} + n_2 a_{01} \end{bmatrix}$$

### III. The Positivity of Prices

The assertion (i) of G-S is stated in a way that confuses the issue. What they have looked at is the positivity of the relative price $p_2/p_1$. We note two rather obvious points below.

First, as the price system is subject to homogeneity of the first degree, economically relevant prices are $(p_1/w, p_2/w)$ or their reciprocals. What must be positive are these, not their ratio. When they are nonpositive, the technique[3] is not economically viable even though the price ratio is positive. As is well known, with each technique is associated the maximum feasible interest rate $(r^*)$ or the Frobenius root of the technique at which the real wages fall to zero.[4] When $r$ exceeds $r^*$, prices $(p_1, p_2)$ become negative for any positive money wages. They can be made positive only by paying negative wages to workers—an economic impossibility.

Second, when choices are made among alternative techniques, all elements of $(w/p)$ become simultaneously zero for the optimum technique when $r$ reaches the Frobenius root of the entire system. Beyond this point, there is no single technique that keeps all commodity prices positive unless, again, negative wages are paid.

Note that the capital-intensity condition is entirely irrelevant to this analysis and, hence, to the positivity of commodity prices.

### IV. A Counterexample

In their assertion (ii), G-S observed that all counterexamples, so far proposed in the literature, do not satisfy the capital-intensity condition. Suspecting that this failure may be the cause of reswitching, they took great pains to give "a general proof that within the constraints [of (4)] reswitching cannot occur" (p. 351). The proof is wrong. There is nothing better than presenting a counter-example to demolish a faulty proof. I give one such example below.[5]

TABLE 1—TWO TECHNIQUES GIVING RISE TO RESWITCHING

| | I | | | II | | |
|---|---|---|---|---|---|---|
| Sector | 1 | 2 | Ratio | 1 | 2 | Ratio |
| $a_0$ | 1 | 1.5 | .667 | 1 | 1.55 | .645 |
| $m$ | .2 | .4 | .500 | .2 | .5205 | .384 |
| $n$ | .4 | .2 | 2.000 | .4 | .08 | 5.000 |

As everybody (including G-S) has done, take two techniques in which one of the sectors employs the same activity. My example is given in Table 1. Observe that the capital-intensity condition is satisfied in each of the techniques. Taking the first good as the numeraire[6] and writing $y=1/(1+r)$, we obtain the wage-interest equations

$$(6)\quad w/p_1 = \begin{cases} \dfrac{(y-0.6)(y+0.2)}{y+0.4} \\ \text{for technique } I \text{ with } y^*=0.6 \\ \dfrac{y^2-0.28y-0.1922}{y+0.54} \\ \text{for technique } II \text{ with } y^*=0.6002 \end{cases}$$

where $y^*=1/(1+r^*)$. Compute $w/p_1$ for each of the techniques by changing $y$ from 1 to

[3] What I call a technique is referred to as a production system by G-S.

[4] Let $y=1/(1+r)$ and take $g(y)=y^2-(m_1+n_2)y-(m_2n_1-m_1n_2)$, which is the denominator on the right-hand side of (2). By assumption, $g(1)>0$ (i.e., real wages are positive at the zero interest rate). As $g(m_1)<0$ and $g(n_2)<0$, there is one solution $y^*$ to $g(y)=0$ such that $1>y^*>\max(m_1, n_2)$. The corresponding value of $r^*=(1-y^*)/y^*$ is the maximum feasible interest rate.

[5] How such counterexamples can be constructed is shown in the Appendix.

[6] The nonsubstitution theorem ensures that it does not matter which good is chosen as the numeraire.

TABLE 2—WAGE AND INTEREST RATES FOR THE TWO TECHNIQUES

| $y=\frac{1}{1+r}$ | $r$ | $w/p_1$ I | $w/p_1$ II | Dominated by |
|---|---|---|---|---|
| 1.0 | 0 | .3429 | .3427 | Technique *I* |
| .963 | .038 | .3097 | .3097 | Technique *II* |
| .90 | .111 | .2538 | .2540 | |
| .80 | .250 | .1667 | .1670 | |
| .70 | .429 | .0818 | .0821 | |
| .627 | .595 | .0217 | .0217 | |
| .61 | .639 | .0080 | .0079 | Technique *I* |
| .6002 | .666 | .00016 | 0 | |
| .6 | .667 | 0 | — | |

$y^*$. Table 2 shows that the two values are equated at $y=0.963$ and $0.627$ ($r=0.038$ and $0.595$). Technique *I* recurs at the high and low interest rates. Thus, the satisfaction of the capital-intensity condition does not guarantee the nonrecurrence of a technique, definitely disproving the assertion (iii) of G-S.[7]

Table 2 also shows that the two wage-interest curves are almost identical. It is clear that when the production structure is similar across sectors as the capital-intensity condition suggests, techniques tend to have wage-interest curves which are very close to each other. This is the main reason why those who earlier concocted counterexamples all opted for cases that violate the capital-intensity condition. Otherwise, their demonstration would have lost most of its dramatic impact. G-S misread this into their assertion (iii). We may, however, note that when satisfied, the capital-intensity condition definitely reduces the possibility of reswitching.

## V. Further Remarks

In closing,[8] two further remarks may be made. First, are there sufficient conditions that rule out reswitching in the present model? The answer is in the affirmative. For instance, if the capital goods and labor are substitutes in the techniques available, there is no reswitching. (The capital goods themselves may appear as complements with one another.) One of the capital goods has to be complementary with labor to yield the reswitching phenomenon in the model under study. This observation suggests that substitution-complementarity relationships are much more fundamental to the nonperversity of a neoclassical production system than conditions like the capital-intensity condition.

Second, our analysis can be conducted more appropriately when there are more techniques than two. The reswitching phenomenon loses its significance because no single technique is likely to recur (see Michael Bruno et al.). But this does not mean that perverse behavior is absent in the neoclassical system when techniques are continuously available. On the contrary, it is perfectly possible. I have shown elsewhere that sufficient conditions for ruling out perversity in this general case depend also on substitution-complementarity relationships between capital and labor.[9] The capital-intensity condition is not fundamental at all.

[7] This example points to where G-S's mathematics have gone astray. In the form employed by G-S, our two equations (6) can be written as

$$w/p_1 = \begin{cases} \dfrac{f(r)}{\phi(r)} = \dfrac{1-0.4(1+r)-0.12(1+r)^2}{(1+r)+0.4(1+r)^2} \\ \text{for technique } I \\ \dfrac{f_1(r)}{\phi_1(r)} = \dfrac{1-0.28(1+r)-0.1922(1+r)^2}{(1+r)+0.54(1+r)^2} \\ \text{for technique } II \end{cases}$$

An inspection of the four functions given above shows that our example is exactly the case studied in their Panel B of Figure 3 and, in particular, its third possibility that G-S examined at some length. Take $f(r)\phi_1(r) = f_1(r)\phi(r)$. Dividing it through by $(1+r)^2$, we obtain a quadratic equation in $(1+r)$, whose roots are the switching points. G-S assert that one of the roots is outside the range between $r=0$ and $r^*$, which is the root of $f_1(r)=0$, so that there is no reswitching possibility. My example indicates that G-S arrived at this erroneous conclusion through their faulty mathematical reasoning. (G-S, in their Section III, decided that two cases are possible candidates for reswitching: (A) $\phi(r)>\phi_1(r)$ and $f(r)>f_1(r)$ in $0<r<r^*$; (B) $\phi_1(r)>\phi(r)$ and $f_1(r)$ cuts $f(r)$ from above in $0<r<r^*$. This reasoning is mathematically defective. Because techniques *I* and *II* are interchangeable, if (A) is to be inspected, then (A′) $\phi_1(r)>\phi(r)$ and $f_1(r)>f(r)$ cannot be rejected in the way G-S did in a footnote. The same applies to (B).)

[8] The assertion (iv) is examined by others and need not be discussed here.

[9] When all capital goods depreciate at an equal rate, the neoclassical production system can be perverse only if there are some capital goods that are complementary with labor and relatively less labor intensive. This condition is sufficient but not necessary.

## Appendix

### *A General Reswitching Theorem*

This Appendix presents a (somewhat tedious) mathematical demonstration that the capital-intensity condition does not eliminate reswitching. Following G-S, consider "two production systems [techniques] that have in common the technique [activity] for producing commodity one" (p. 351). Let us distinguish them by putting primes to corresponding parameters and variables. We assume that at least one of $n_1$ and $m_2$ is nonzero.[10] Below, let $n_1>0$. We set $w=1$. There are two sets of price equations:

$$\text{(A1)} \quad \begin{aligned} p_1 &= (1+r)(m_1p_1 + n_1p_2 + a_{01}) \\ p_2 &= (1+r)(m_2p_1 + n_2p_2 + a_{02}) \end{aligned}$$

$$\text{(A2)} \quad \begin{aligned} p_1' &= (1+r)(m_1p_1' + n_1p_2' + a_{01}) \\ p_2' &= (1+r)(m_2'p_1' + n_2'p_2' + a_{02}') \end{aligned}$$

Define $\bar{p}_i = p_i' - p_i$, $i=1, 2$. Subtract the corresponding equations of (A1) from (A2) and rearrange terms to obtain

$$\text{(A3)} \quad \bar{p}_2 = \frac{\dfrac{1}{1+r} - m_1}{n_1} \bar{p}_1$$

$$\text{(A4)} \quad \bar{p}_1 = \frac{n_1}{\left(\dfrac{1}{1+r} - m_1\right)\left(\dfrac{1}{1+r} - n_2'\right)} \cdot [(m_2' - m_2)p_1 + (n_2' - n_2)p_2 + (a_{02}' - a_{02})]$$

We observe that reswitching takes place if $\bar{p}_1$ becomes zero more than once between $r=0$ and its maximum feasible value. Note that $\bar{p}_2$ is automatically zero at the same time.

When $\bar{p}_1=0$, we have

$$\text{(A5)} \quad (m_2' - m_2)p_1 + (n_2' - n_2)p_2 + (a_{02}' - a_{02}) = 0$$

Write[11]

$$\text{(A6)} \quad X_1 = -\frac{m_2' - m_2}{a_{02}' - a_{02}} \qquad X_2 = -\frac{n_2' - n_2}{a_{02}' - a_{02}}$$

and $y=1/(1+r)$. Substitute equation (2) in the text into (A5), which is then reduced into a quadratic equation

$$\text{(A7)} \quad h(y) = y^2 - Ay - B = 0$$

where

$$\text{(A8)} \quad \begin{aligned} A &= m_1 + n_2 + a_{01}X_1 + a_{02}X_2 \\ B &= (m_2n_1 - m_1n_2) \\ &\quad + (a_{02}n_1 - a_{01}n_2)X_1 \\ &\quad + (a_{01}m_2 - a_{02}m_1)X_2 \end{aligned}$$

Now assume the capital-intensity condition. If both $X_1$ and $X_2$ are nonnegative, we have $A>0$ and $B>0$, the latter by virtue of that condition. In this case, (A7) has only one positive root. As there is only one switching point at most, no reswitching occurs. Note that both capital goods appear as substitutes for labor between the two techniques.

For reswitching to occur, one of $X_1$ and $X_2$ must be sufficiently negative to make $B<0$. ($X_1$ and $X_2$ cannot be both negative because of (A5).) In other words, one capital good has to be complementary with labor. Reswitching occurs in this case if the two roots of (A7), $y_1$ and $y_2$, both fall between $y^*$ and 1 where $y^*$ ($<1$) is the solution of

$$g(y^*) = y^{*2} - (m_1 + n_2)y^* - (m_2n_1 - m_1n_2) = 0$$

An inspection shows that this is possible if and only if

(a) $h(1) > 0$

(b) $h(y^*) \geqq 0$

(c) $2 > y_1 + y_2 > 2y^*$

(d) $h(A/2) = -A^2/4 - B < 0$

We have

$$\text{(A9)} \quad [(a_{02}n_1 - a_{01}n_2) + a_{01}]X_1 + [(a_{01}m_2 - a_{02}m_1) + a_{02}]X_2 <$$

[10] If both are zero, the two sectors are independent of each other so that there is no reswitching problem.

[11] If $a_{02}' = a_{02}$, we can easily verify that (5) has at most one root by substituting the equation in the text. Hence, no reswitching occurs.

$$1-(m_1+n_2)-(m_2n_1-m_1n_2)\quad(>0)$$

from (a),

$$\text{(A10)}\quad [(a_{02}n_1-a_{01}n_2)+a_{01}y^*]X_1 + [(a_{01}m_2-a_{02}m_1)+a_{02}y^*]X_2 \leqq 0$$

from (b), and

$$\text{(A11)}\quad 2y^*-m_1-n_2 < a_{01}X_1+a_{02}X_2 < 2-m_1-n_2$$

from (c).

These inequalities can be shown graphically in the $(X_1, X_2)$ plane. As

$$\frac{a_{02}n_1-a_{01}n_2}{a_{01}m_2-a_{02}m_1} \gtreqless \frac{(a_{02}n_1-a_{01}n_2)+a_{01}y^*}{(a_{01}m_2-a_{02}m_1)+a_{02}y^*} \gtreqless \frac{(a_{02}n_1-a_{01}n_2)+a_{01}}{(a_{01}m_2-a_{02}m_1)+a_{02}} \gtreqless \frac{a_{01}}{a_{02}}$$

the bounds of (A9), (A10), and (A11) have slopes such that

$$\left.\frac{dX_2}{dX_1}\right|_{(10)} \lesseqgtr \left.\frac{dX_2}{dX_1}\right|_{(9)} \lesseqgtr \left.\frac{dX_2}{dX_1}\right|_{(11)}$$

Equalities hold only when the capital-intensity condition holds with equality sign. In this case, the three bounds are parallel; the intersection of (A10) and (A11) is apparently empty so that there is absolutely no reswitching. Except for this special case, the three bounds differ in slope in such a way that there is always a nonempty area in the plane that satisfies the three inequalities simultaneously. In Figure 1, the upper bound of (A10) and the lower bound of (A11) intersect at point $A$ where the following equality holds (multiply $(1-y^*)$ to (A11), add (A10), and replace inequality by equality signs):

$$[(a_{02}n_1-a_{01}n_2)+a_{01}]X_1 + [(a_{01}n_2-a_{02}m_1)+a_{02}]X_2 = 1-(m_1+n_2)-(m_2n_1-m_1n_2)-(1-y^*)^2$$

This shows that (A9) is satisfied at $A$. Points sufficiently close to $A$ inside the triangle

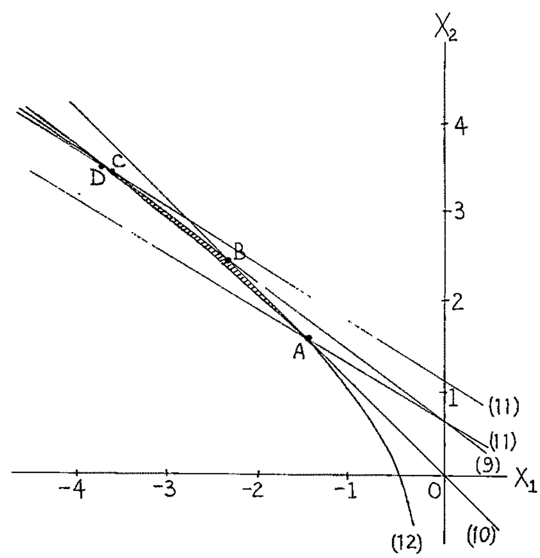

FIGURE 1. TECHNIQUE $I$ OF TABLE 1 RECURS IF TECHNIQUE $II$ IS SUCH THAT $X_1$ AND $X_2$ FALL IN THE AREA $ABCD$
$A(-1.60, 1.60)$, $B(-2.40, 2.40)$, $C(-3.65, 3.50)$, $D(-3.68, 3.52)$.

spanned by the upper bound of (A10) and the lower bound of (A11) satisfy all three inequalities.

For reswitching to occur, however, the roots of (A7) must be real. This is the condition (d) given above, which is

$$\text{(A12)}\quad -\tfrac{1}{4}(a_{01}X_1+a_{02}X_2+m_1+n_2)^2 < (a_{02}n_1-a_{01}n_2)X_1 + (a_{01}m_2-a_{02}m_1)X_2 + (m_2n_1-m_1n_2)$$

As (0, 0) satisfies (A12), the lower bound of (A12) cuts the $X_1$ axis to the left of the origin. We can readily verify that it passes through point $A$ and is tangential to the bound of (A10). As it is convex from above, there is a narrow strip which satisfies (A9), (A10), (A11), and (A12), simultaneously. When $(X_1, X_2)$ falls in this strip, reswitching takes place. Thus, the capital-intensity condition does not eliminate reswitching, even though it narrows down the area in which reswitching is possible.

In the counterexample in the text, we have for technique $I$ the following inequalities which are illustrated in Figure 1:

for (A9): $7X_1 + 8X_2 < 4.8$

for (A10): $X_1 + X_2 \leqq 0$

for (A11): $0.8 < X_1 + 1.5X_2 < 1.6$

for (A12): $-\frac{1}{4}(X_1 + 1.5X_2 + 0.4)^2 < 0.4X_1 + 0.1X_2 + 0.12$

My technique $II$ is obtained for $X_1 = -2.41$, $X_2 = 2.40$, and $a'_{02} - a_{02} = 0.05$. The reader may try other values for himself.

My analysis in this Appendix indicates that reswitching takes place when the two roots of $h(y) = 0$ fall between $y^*$ and 1 where $y^*$ is the largest positive root of $g(y) = 0$. The necessary and sufficient condition for nonreswitching is then the condition that rules it out. One may look for sufficient conditions. What I have accomplished is to show that the capital-intensity condition is not a sufficient condition.

It is easy to demonstrate that substitutability of capital for labor is a sufficient condition for nonreswitching. If there is only one capital good, capital must be a substitute for labor. In this case, either the $m'$ or $n'$ are identically zero. As $B \equiv 0$ in $h(y)$, we have a single positive root for $h(y) = 0$ so that there is no reswitching.

When both goods are used as intermediate inputs, the nonnegativity of $X_1$ and $X_2$ is a sufficient condition. To see this, note that

$$g(1) > 0, \qquad g(m_1) < 0, \qquad g(n_2) < 0,$$
$$1 > y^* > \max(m_1, n_2)$$

We rewrite $h(y)$ as

$$\begin{aligned} h(y) = g(y) &- (a_{01}X_1 + a_{02}X_2)y \\ &- [(a_{02}n_1 - a_{01}n_2)X_1 \\ &+ (a_{01}m_2 - a_{02}m_1)X_2] \end{aligned}$$

so that

$$\begin{aligned} h(m_1) &= g(m_1) - [a_{02}n_1X_1 + a_{01}m_2X_2 \\ &\quad + a_{01}(m_1 - n_2)X_1] \\ h(n_2) &= g(n_2) - [a_{02}n_1X_1 + a_{01}m_2X_2 \\ &\quad + a_{02}(n_2 - m_1)X_2] \end{aligned}$$

Thus, for $(X_1, X_2) \geq (0, 0)$, $h(m_1)$ and/or $h(n_2)$ are negative. Therefore, one root of $h(y) = 0$ is less than $m_1$ and/or $n_2$. This rules out reswitching. In this case, both capital goods appear as substitutes for labor.

When $X_1$ and $X_2$ are opposite in signs, i.e., when one capital good is a substitute for labor and the other is a complement with labor, sufficient conditions for nonreswitching are not readily apparent, but one should be able to derive some of them.[12] For instance, note that

$$\begin{aligned} h(y) = g(y) - y[&\{a_{01} + (a_{02}n_1 - a_{01}n_2)/y\}X_1 \\ &+ \{a_{02} + (a_{01}m_2 - a_{02}m_1)/y\}X_2] \end{aligned}$$

We see that $h(m_1)$ or $h(n_2) < 0$ if the expression in the brackets is nonnegative for $y = m_1$ or $n_2$. A sufficient condition for nonreswitching is that $(X_1, X_2)$ satisfies this inequality.

[12] Joseph Stiglitz, p. 122, introduces one such sufficient condition.

# The Neoclassical Production Function: Reply

*By* LOWELL GALLAWAY AND VISHWA SHUKLA*

The comments of Kazuo Sato and P. Garegnani indicate a technical problem in our original analysis. Its effect is to make it possible for reswitching to occur even though what Sato calls our capital-intensity condition is satisfied, provided that the factor price contours in question are quite similar in nature. Thus, as Sato notes, our condition only "definitely reduces the possibility of reswitching." Unfortunately, all this may be simply a minor exegesis of what is perhaps a trivial question. Let us explain that statement.

Consider the standard case of a full-employment steady-state economy (constant population and labor force) in which alternative two-commodity indecomposable production systems are available. Assume that producers will choose the technique that is "most profitable." Conventionally, this is taken to mean that they will choose the productive technique that will provide the highest profit rate. For example, Luigi Pasinetti states: "Clearly, on grounds of profitability, that technique will be chosen which—for any given wage rate—yields the higher rate of profit" (p. 507). In a micro-economic context one would not quarrel with this proposition. A given investment in capital goods will be more profitable the higher the rate of return on the investment. However, at our highly aggregated (economy wide) level of analysis of the meaning of capital and the nature of the production function, this is not so obvious. At the heart of the Cambridge (England) criticism of neoclassical analysis is the proposition that capital in an aggregate sense can only be measured through the use of some pricing numeraire which itself is functionally related to the level of wage and profit (interest) rates. In this highly interdependent world (illustrated by the two-commodity indecomposable production systems under discussion), it is alleged that the straightforward neoclassical propositions break down because of the interrelationship between the value of capital and the profit (interest) rate. Unfortunately, the analysis upon which this conclusion has been based appears to have ignored the fact that at the aggregate level the phrase "more profitable" has an added dimension that is lacking at the micro-economic level.

This added dimension is the opportunity to employ capital. In the models under analysis the rate of profit and the quantity (in value terms) of capital employed are simultaneously determined. Together, they explain the volume of profits per head associated with a given technique and wage-profit rate combination. Since net output per head for any technique is constant (at the level of the wage rate associated with zero profit rate), profits per head may be calculated by subtracting any wage rate on the factor price contour from the zero profit wage. We have done this for Sato's example (Garegnani's would do just as well) and the results are shown in Table 1. They are fascinating in that they indicate that *at any profit rate the most profitable technique from the standpoint of profits per head is technique I*. But, how important is this? Quite; in a macro-model that assumes 1) full employment and 2) that capital is used solely for the purpose of producing the commodities included in the model.[1] Together, these conditions imply that profits per head are a measure of the total profits associated with the use of any technique. This means that switching from technique *I* to technique *II* in Sato's example as the profit rate falls below .595 involves adopting a production system that yields

* Ohio University.

[1] Actually, in the systems under consideration capital goods are produced simultaneously with consumption goods. In a steady-state equilibrium their current production is just sufficient to permit the replacement of capital goods that have depreciated.

TABLE 1—WAGE RATE-PROFIT RATE COMBINATIONS AND TOTAL PROFITS, TWO ALTERNATIVE TWO-COMMODITY INDECOMPOSABLE PRODUCTION SYSTEMS

| Profit Rate ($r$) | Wage Rate ($w$) | | Total Profits ($rk$) | |
|---|---|---|---|---|

[a] Conventionally defined switchpoint.

less real income to producers, despite the higher profit rates associated with technique *II*. The reason is simple and has been noted previously in the literature:[2] the value of the capital employed with technique *II* is more than enough less than that used in technique *I* to offset the higher profit rates that go with *II*.

What really is involved in moving from technique *I* to technique *II* as $r$ falls below .595? A comparison of the steady-state equilibrium positions associated with the two techniques reveals that the transition amounts to adopting a system of production that produces and employs less capital per head (in value terms) at a higher profit rate with less output per head and a lower level of real income for producers. The puzzling thing is why producers would switch techniques under these conditions. The forces of competition? We think not. At a given wage rate the option is always open to use technique *I* with its lower profit rates but higher level of output per head and producers' real income. No, it would seem that if by the forces of competition we mean the result of maximizing behavior by large numbers of producers, *in the absence of what we prefer to call a "profit rate illusion," technique II would never be adopted and reswitching would not occur in the context of these models.* What we are saying is that the best interests of producers (in terms of economic welfare) are not synonymous with the simple maximization of profit rates when dealing with this level of aggregation. Single-minded dedication to the maximization of the rate of profit can lead producers to adopting courses of behavior that so limit the opportunities for employing capital (with the fixed labor force implicit in the models) that lower real incomes will be their reward.

There is a further implication of this argument, namely, that if the problem is one of choosing among already known alternative two-commodity indecomposable production systems, not only will there be no reswitching, but, in addition, *there will be no switching of techniques.* One technique alone will dominate all others and that technique will be the one that has the greatest output per head. Whatever wage rate exists, profits are maximized by adopting that technique. What does this imply about the aggregate production function in a world of economy wide two-commodity indecomposable production systems? Simply this; it is the system that will yield the highest output per head. As a general rule, that system will generate a non-linear factor price contour which, given our capital-intensity condition, will be well ordered in the sense that higher wage rates and lower profit rates will be associated with

[2] For example, Pasinetti, p. 514, notes this phenomenon and calls it a "remarkable" result because it produces results that conflict with the neoclassical version of things. Of course, he continues to assume that the appropriate object of maximization is the profit rate.

higher capital-labor ratios where capital is measured in value terms.[3]

[3] Another way of putting this is to note that any point on the conventionally defined factor price frontier that is not associated with the technique that yields maximum output per head is non-Pareto optimal in that it is possible to move to another technique and improve the welfare of some members of the society without damaging the welfare of anyone else. For example, profit income may be increased without reducing wage income or, alternatively, workers could hire producers (paying them slightly more than the income they are earning using an inferior technique) to use the dominant technique instead and pocket the gains for themselves.

# A Note on the U Hypothesis Relating Income Inequality and Economic Development

By SHERMAN ROBINSON*

A common empirical finding in the analysis of countries which have undergone economic development is that income distribution first became more unequal, and only in the later phase did it become more equal. This empirical observation has also been seen in modern developing countries—at least the increasing inequality phase—and has acquired the force of economic law. It has a name: the U hypothesis. A number of different economic explanations for the relationship have been presented involving a variety of factors such as productivity changes, differential savings behavior, exploitation of workers, and so forth.[1]

The purpose of this note is to demonstrate that the U hypothesis can be derived from a very simple model with a minimum of economic assumptions. One need only assume that the economy can be divided into two sectors with different sectoral income distributions and that there is a monotonic increase in the relative population of one of the sectors over time. These assumptions seem empirically unexceptional for a country undergoing economic development and are consistent with many models of development such as the Lewis-Fei-Ranis surplus labor models, dual economy models, and the more recent Harris-Todaro migration models.[2] The U hypothesis will be seen to be a necessary implication of the workings of such models.

Assume that the economy is divided into two sectors with different income distributions. The *log* mean and *log* variance of income in the two sectors are given by $Y_1$ and $Y_2$ and $\sigma_1^2$ and $\sigma_2^2$, respectively. Define the population shares of the two sectors as $W_1$ and $W_2$ with:

$$W_1 + W_2 = 1 \tag{1}$$

The overall *log* mean income is given by:

$$Y = W_1Y_1 + W_2Y_2 \tag{2}$$

and the overall *log* variance is given by:

$$\sigma^2 = W_1\sigma_1^2 + W_2\sigma_2^2 + W_1(Y_1 - Y)^2 + W_2(Y_2 - Y)^2 \tag{3}$$

The *log* variance is itself an increasing measure of income inequality. One need not use *log* means and *log* variances, but they are convenient since the *log* variance is a commonly used inequality measure. The arithmetic mean and variance would also do—the algebra is exactly the same.

Assuming that the within-sector distributions remain unchanged over time ($\sigma_1^2$, $\sigma_2^2$, $Y_1$, and $Y_2$ are constant), then from equation (3) inequality is a function only of sectoral population shares and overall *log* mean income. By equation (2), the overall *log* mean is itself a function of sectoral population shares.

Assume that sector 1 is the sector whose relative population share is increasing. Then, substituting (1) and (2) into (3) and doing a bit of algebra, one finally gets:

$$\sigma^2 = AW_1^2 + BW_1 + C \tag{4}$$

where
$$A = -(Y_1 - Y_2)^2$$
$$B = (\sigma_1^2 - \sigma_2^2) + (Y_1 - Y_2)^2$$
$$C = \sigma_2^2$$

If one assumes that the *log* mean incomes are different in the two sectors, then in-

* Assistant professor of economics, Princeton University. I am grateful to Irma Adelman for comments on an earlier draft and to Charles Frank and Richard Webb for useful discussions. They, of course, bear no responsibility for any remaining errors.

[1] See Irma Adelman and Cynthia Morris, p. 188, Simon Kuznets (1955, 1966), and Felix Paukert.

[2] See Kuznets (1966, 1971), W. Arthur Lewis, John Fei and Gustav Ranis, and John Harris and Michael Todaro.

equality is a quadratic function of $W_1$. Since $A<0$, the parabola has a maximum. As $W_1$ increases, inequality first increases, reaches a maximum, then decreases—precisely the U hypothesis.

There is one possible problem. Since by assumption $0 \leq W_1 \leq 1$, it is possible that the maximum value of $\sigma^2$ occurs for a value of $W_1$ outside the zero to one range. Setting the first derivative of (4) equal to zero, the maximum value of $\sigma^2$ occurs when $W_1$ is equal to $\hat{W}_1$:

$$(5) \qquad \hat{W}_1 = \frac{\sigma_1^2 - \sigma_2^2}{2 \cdot (Y_1 - Y_2)^2} + \frac{1}{2}$$

Thus, the more equal are the *log* variances, and the more different are the *log* mean incomes, the closer is $\hat{W}_1$ to 1/2. Empirically, one would expect a much greater difference in *log* mean incomes than in *log* variances and so expect $\hat{W}_1$ to be in the range zero to one.

Some properties of these equations are interesting. The U hypothesis in no way depends on which sector has the higher income. If total income is to rise then $Y_1$ must be greater than $Y_2$, but the U hypothesis depends only on their being different. It also does not matter which sector has the more unequal distribution of within sector income. The difference between $\sigma_1^2$ and $\sigma_2^2$ affects $\hat{W}_1$, but not the existence of the U. If $\sigma_1^2<\sigma_2^2$, then it will take longer for the distribution to start becoming more equal (for a given rate of change of sector population shares), but the turning point exists. It is interesting that even if people are moved from a sector with relatively more equality to one with less, the overall distribution will still become more equal.

A simple example will given an idea of the orders of magnitude involved. Assume the following parameter values:[3]

$$Y_1 = 6.91 \qquad Y_2 = 4.61$$
$$\sigma_1^2 = .40 \qquad \sigma_2^2 = .20$$

[3] The within-group *log* variances are based roughly on data from studies of South Korea and Turkey. The group mean incomes corresponding to the *log* means are rough guesses and the effects of varying them are explored below.

TABLE 1—DISTRIBUTION STATISTICS: VARIOUS GROUP POPULATION SHARES

| $W_1$ | $Y$ | Geometric Means | $\sigma^2$ | Gini Coefficient |
|---|---|---|---|---|
| .10 | 4.84 | 126. | .70 | .44 |
| .20 | 5.07 | 159. | 1.09 | .54 |
| .40 | 5.53 | 252. | 1.55 | .62 |
| .52 | 5.80 | 331. | 1.63 | .63 |
| .60 | 5.99 | 399. | 1.59 | .63 |
| .80 | 6.45 | 633. | 1.21 | .56 |
| .90 | 6.68 | 796. | .86 | .49 |

*Note:* The geometric mean is exp ($Y$). The Gini coefficient is calculated from the *log* variance assuming a lognormal distribution. The overall *log* variance $\sigma^2$ is calculated from equation (4). $(\sigma_1^2-\sigma_2^2)=.20$.

The values of $Y_1$ and $Y_2$ correspond to geometric mean incomes of 1000 and 100, respectively. If one assumes a lognormal distribution, then the arithmetic mean income is a function of the *log* mean and *log* variances and the Gini coefficient is a simple function of *log* variance.[4] The corresponding arithmetic mean incomes are 1221 and 111 and the within-sector Gini coefficients are 0.35 and 0.25 for distributions one and two, respectively. Statistics for the overall distribution given different values of $W_1$ are presented in Table 1. The maximum value of $\sigma^2$ occurs when $\hat{W}_1=.52$. The U relationship between inequality and development appears very distinctly in the example. It is interesting that even when $W_1=.10$ or $W_1=.90$, $\sigma^2$ is significantly different from $\sigma_2^2$ or $\sigma_1^2$.

During the course of economic development, one also might expect the mean income differences of various groups to narrow, perhaps after an initial rise. Table 2 indicates how inequality varies as the ratio of group mean incomes change. If one assumes that group population shares do not change

[4] For a lognormal distribution with *log* variance $\sigma^2$, the Gini coefficient is given by $G=2[\int_{-\infty}^{x} N(0,1)]-1.0$ where $x=\sigma/\sqrt{2}$ and $N(0, 1)$ is the standard normal distribution. The arithmetic mean is equal to exp $(Y+0.5\,\sigma^2)$ where $Y$ is the *log* mean. See J. Aitchison and J. A. C. Brown. Note that the use of this formula for the overall distribution assuming that the within-group distributions are lognormal is only an approximation since the sum of two lognormal distributions is not necessarily lognormal.

TABLE 2—DISTRIBUTION STATISTICS: VARIOUS GROUP INCOME RATIOS

| Income Ratio | $Y_1-Y_2$ | $\hat{W}_1$ | $\sigma^2$ | Gini Coefficient |
|---|---|---|---|---|
| 10 | 2.30 | .52 | 1.63 | .63 |
| 9 | 2.20 | .52 | 1.51 | .62 |
| 8 | 2.08 | .52 | 1.38 | .59 |
| 7 | 1.95 | .53 | 1.25 | .57 |
| 6 | 1.79 | .53 | 1.11 | .54 |
| 5 | 1.61 | .54 | 0.95 | .51 |
| 4 | 1.39 | .55 | 0.79 | .47 |
| 3 | 1.10 | .58 | 0.61 | .42 |
| 2 | 0.69 | .71 | 0.44 | .36 |

*Note:* Income ratio is the ratio of geometric mean incomes, exp $(Y_1)$/exp $(Y_2)$. The variance $\sigma^2$ is calculated from equation (4) for the corresponding turning point value of $W_1$. $(\sigma_1^2-\sigma_2^2)=.20$.

but only that the spread of group mean incomes first widens and then later narrows, one also gets a significant U relationship.

It is possible to compare the relative magnitudes of the effect on inequality of changes in group mean incomes and of changes in group population shares. Define $R=Y_1-Y_2$. The logarithm of the ratio of group mean incomes is $R$. If $Y_1>Y_2$, then $R>0$. Equation (4) can be rewritten as:

$$(6) \quad \sigma^2 = -R^2W_1^2 + [(\sigma_1^2-\sigma_2^2)+R^2]W_1 + \sigma_2^2$$

Take the total derivative of (6) with respect to changes in $R$ and $W_1$:

$$(7) \quad d\sigma^2 = D\,dR + E\,dW_1$$

where $D = 2RW_1W_2$

$$E = R^2(1-2W_1) + (\sigma_1^2-\sigma_2^2)$$

At the turning point $\hat{W}_1$ in equation (5), $E=0$ and only changes in relative mean incomes affect inequality. If $W_1=1/2$, $E=(\sigma_1^2-\sigma_2^2)$ and does not depend on $R$. For a given $R$, $E$ is relatively small when $W_1$ is in the neighborhood of 1/2. Also, given $R$, $D$ is largest when $W_1=W_2=1/2$.

Table 3 gives some values of $D$ and $E$ for various values of $W_1$ and $R$. A change in $R$ of 0.1 corresponds roughly to a decrease of 1.0 in the ratio of mean incomes (say, from

TABLE 3—COEFFICIENTS OF THE TOTAL DERIVATIVE $d\sigma^2=DdR+EdW_1$

| $W_1$ | $R$ | $0.1D$ | $0.01E$ |
|---|---|---|---|
| .10 | 2.30 | .041 | .044 |
| .10 | 1.61 | .029 | .023 |
| .10 | 0.69 | .012 | .006 |
| .20 | 2.30 | .074 | .034 |
| .20 | 1.61 | .052 | .018 |
| .20 | 0.69 | .022 | .005 |
| .40 | 2.30 | .111 | .013 |
| .40 | 1.61 | .077 | .007 |
| .40 | 0.69 | .033 | .003 |

*Note:* $R$ corresponds to income ratios of 10 ($R=2.30$), 5 ($R=1.61$), and 2 ($R=.69$). $(\sigma_1^2-\sigma_2^2)=.20$.

10 to 9). A change in $W_1$ of 0.01 (one percentage point) seems roughly comparable to a change in $R$ of 0.1. "Comparable" means that a country undergoing rapid structural change might achieve such a change in a year or two, although clearly a change in the income ratio from 10 to 9 is far easier than a change from 3 to 2.[5]

It is clear from both Tables 1 and 3 that given $R$, the U relation is very flat around $W_1=1/2$. Changes in $W_1$ from 0.40 to 0.60 have almost no effect on inequality. At the ends where $W_1=0.2$ or 0.1, the effect of changes in $W_1$ are comparable to changes in $R$. In the development process as it has actually occurred, $R$ has typically first increased and then later decreased. The two effects have thus probably reinforced one another in generating the U relationship. If $R$ stays relatively constant during the "middle" period of development, one would find that a country might spend a long time in the trough of the U.

The implication of this exercise is that if the two-sector models that many development economists use are valid, then one should expect that a developing country, in the absence of explicit countervailing policies, will have increasing or unchanged income inequality for a relatively long period. The result is also consistent with the em-

[5] For evidence on the rate of structural change in less developed countries, see Kuznets (1966, 1971) and the author.

pirical findings of Adelman and Morris. Of course, the model is very simple and ignores any systematic changes in the within-group distributions over time. It does, however, trace out the effects of simple structural shifts on income inequality, effects which are significant and should not be neglected in more complicated and more theoretically satisfying models.

# Intermediate Products and the Theory of International Trade: A Generalization of the Pure Intermediate Good Case

*By* JAMES RIEDEL*

Empirical studies of neoclassical, factor-proportions trade theory have long recognized that hypotheses concerning relative factor intensity must be defined in terms of gross factor intensities (accounting for intensities of intermediate products) rather than simply in net factor-intensity terms (i.e., at the last stage of production only).[1] Nevertheless, development of the pure theory of international trade has generally neglected intermediate products. The justification for this convenience has in part been based on a study by Jaroslav Vanek which demonstrated that the introduction of interindustry flows in a two-good model did not affect the traditional theorems (Rybczynski, Stolper-Samuelson, or Heckscher-Ohlin) defined in net factor-intensity terms. However, in a recent study, Raveendra Batra and Francisco Casas demonstrated that the introduction of a "pure" intermediate commodity—one that is produced solely for use in the production of final goods—complicates the issue considerably. They show, in fact, that " . . . most of the traditional trade theorems [defined in net terms] may not hold without additional provisions if such intermediate products are introduced in the model . . . " (p. 297). The basic difference between the Batra-Casas model with pure intermediate products and Vanek's interindustry flow model is the possibility of a conflict between the net and gross factor-intensity ranking of final products.[2]

The conditions which Batra and Casas demonstrate are necessary in order to ensure a uniform ranking of final commodities according to net and gross factor intensity were derived under the explicit assumption that the intermediate good is totally supplied from domestic production. The purpose of the present paper is to generalize the Batra-Casas model to allow the intermediate good to be imported in some proportion.[3] The analytical approach of the present paper is quite different from that taken by Batra and Casas, however. Here the problem is treated as a problem of *ex post* factor-intensity measurement, although the underlying model and necessary conditions to ensure its proper functioning are implicitly the same as described by Batra and Casas. In Section I a measure of gross factor intensity appropriate in an economy importing intermediate inputs is developed. In the following section this measure is applied to the Batra-Casas model, under alternative assumptions regarding the supply source of the intermediate good. It is shown that if some proportion of the intermediate good is imported, then net and gross factor-intensity rankings can be assured to be uniform if and only if—in addition to the

I acknowledge, without implicating in remaining errors, the helpful comments of R. Banerji, F. R. Casas, and L. L. Wegge.

[1] See Wassily Leontief (1953, 1956).

[2] Analyzing a model different from Batra and Casas only with respect to the assumed structure of production, Alok Ray arrived, not surprisingly, at the very same conclusion.

[3] In a recent paper, Albert Schweinberger examines the possibility of a conflict in net and gross factor-intensity ranking in a model containing a traded pure intermediate product. Schweinberger, for reasons not stated, chose to ignore Batra and Casas' proof of absence of the indeterminancy problem (three commodities, two primary inputs), avoiding the problem instead by assuming that trade does not lead to factor price equalization. This assumption allows that although each country produces not more than two of the three goods in equilibrium, the world as a whole will produce all three. The relaxation of the nonspecialization assumption constitutes a quite different model from that analyzed by Batra and Casas, however.

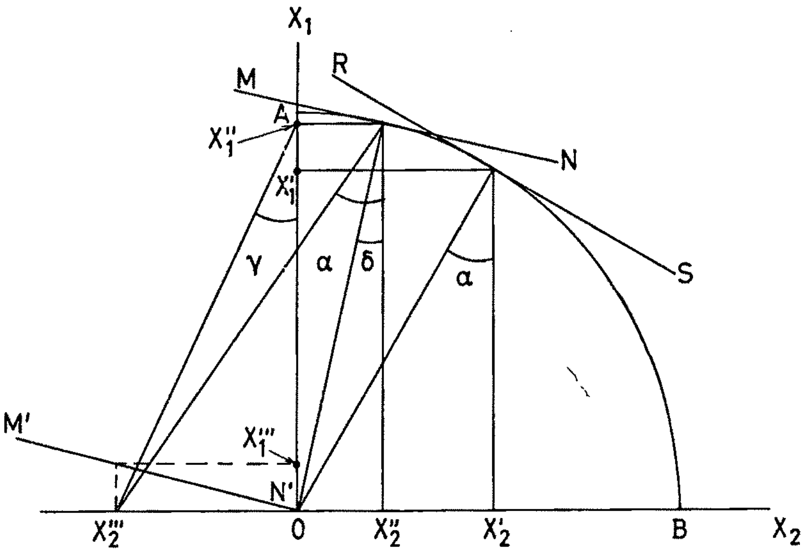

FIGURE 1

Batra-Casas conditions—the proportion of the intermediate good imported for use in producing the two final goods is the same for both goods. In addition, it is shown that if the pure intermediate good is totally imported no complications arise, the Batra-Casas model becomes essentially the same as Vanek's model.

## I. Factor-Intensity Measurement with Imported Intermediate Inputs[4]

Clearly there is no a priori reason to assume any given mix between imported and domestically supplied intermediate goods. The optimal mix will depend on relative prices. Consider the two-good case for simplicity (see Figure 1). Curve $AB$ describes the production possibility frontier between $X_1$ and $X_2$. Assume the production of $OX_1'$ of $X_1$ requires $OX_2'$ of $X_2$ as an intermediate input. The technical coefficient, $a_{21}(X_{21}/X_1)$, is thus equal to the *tan* $\alpha$. For any set of relative prices $(P_2/P_1)$ less than $RS$, such as $MN$ for example, the optimal solution will require some proportion of $X_2$ to be imported.

Given the set of relative prices described by $MN$, the optimal solution will demand that the production of $X_1$ be increased from $X_1'$ to $X_1''$. The production of $OX_1''$, however, requires $X_2'''X_2''$ of $X_2$, of which only $OX_2''$ can be supplied domestically, the remainder $0X_2'''$ necessarily being imported in exchange for $X_1(0X_1'''$ of $X_1)$.[5] Under this set of relative prices, the domestic input coefficient $(d_{ij})$ is expressed by *tan* $\delta$, and the imported input coefficient $(m_{ij})$ by the *tan* $\gamma$.

The importation of intermediate inputs has important implications for the measurement of gross factor intensity.[6] The orthodox measure of gross factor intensity, following Leontief, is computed by taking a weighted average of per unit factor requirements at every stage in production, the weights being the direct and indirect per unit input requirements at each stage of production:

$$k_j^* = \frac{\sum_i C_{Ki} r_{ij}}{\sum_i C_{Li} r_{ij}} \tag{1}$$

[4] The gross factor-intensity measure described in this section was presented in my 1975 paper and applied to the Taiwan economy in an attempt to analyze the rationale of a "footloose" industrial structure.

[5] $M'N'$, parallel to $MN$, defines the terms of trade between $X_1$ and $X_2$.

[6] Note, gross factor intensity is measured in gross output terms (labor and capital per unit output) as is the usual convention.

where $C_{Ki}$ and $C_{Li}$ are the direct capital and labor output ratios, respectively, and where $r_{ij}$ are elements of the inverted Leontief technology matrix $[I-A]^{-1}$. It should be obvious that the standard measure is inappropriate in an economy which imports intermediate inputs, since the $[I-A]^{-1}$ matrix (which weights direct factor intensities at each stage of production) explicitly assumes that all intermediates are domestically produced. If some proportion of the intermediate inputs is imported, however, what is relevant is not the factor requirements of producing the input directly, but rather the factor requirements of producing the goods which are exported in exchange for the imported inputs. Gross factor intensity in an open economy importing intermediate goods should reflect the factor requirements at the last stage of production, in producing the intermediate inputs supplied domestically and in producing the exports which are exchanged for intermediate inputs imported.

If inputs are imported, the domestically produced inputs required directly and indirectly per unit final demand are given by the inverted Leontief matrix of domestic transactions[7]

$$[I - A - M]^{-1} = [I - D]^{-1} = \{s_{ij}\}$$

where $M$ is a matrix of per unit imported inputs $(m_{ij})$.

The labor and capital required per unit output at the last stage of production and in producing the domestic intermediate inputs for the production of commodity $j$ are

$$C^*_{Li} = \sum C_{Li}s_{ij} \tag{2a}$$

$$C^*_{Ki} = \sum_i C_{Ki}s_{ij} \tag{2b}$$

Interindustry transactions in imported inputs are omitted because the demand for imported inputs does not directly affect employment or capital investment in the domestic economy. Nevertheless, imported inputs are not freely available to the economy, much less the domestic producer; they can be acquired (in equilibrium) only through the exchange of domestically produced goods and services, which in turn involve a resource cost. Thus, gross factor intensity in an economy which imports intermediate inputs is accurately measured by the sum of 1) the labor and capital employed in producing domestic inputs and at the final stage of production ($C^*_{Li}$ and $C^*_{Ki}$), and 2) the labor and capital cost implicit in earning the foreign exchange (exporting) with which to purchase imported inputs required directly and indirectly in the production process.

The labor and capital cost of earning one unit of foreign exchange (in equilibrium) is the labor and capital required to produce one unit of exports, which in turn can be defined as the average labor and capital requirements per unit output in each sector of the economy weighted by the distribution of exports from each sector. The labor and capital required at the last stage of production and in the domestic production of inputs which go into exports is thus $C^*_{LF}$ and $C^*_{KF}$, respectively, as defined.

$$C^*_{LF} = \sum_j \left[ \sum_i C_{Li}s_{ij} \right] e_j$$

$$C^*_{KF} = \sum_j \left[ \sum_i C_{Ki}s_{ij} \right] e_j$$

The coefficient $e_j$ is the $j$th sector's share in total exports. Of course the production of exports itself requires imported inputs. If $M^*_j$, defined as[8]

$$M^*_j = \sum_i M_i s_{ij}$$

is the direct and indirect import requirement per unit output of commodity $j$, then

$$M^*_F = \sum_j \left[ \sum_i M_i \cdot s_{ij} \right] e_j = \sum_j M^*_j \cdot e_j$$

is the direct and indirect import requirement per unit export. Thus to produce one unit of exports we need $C^*_{LF}$ units of labor and $C^*_{KF}$

[7] According to standard notation:

$$[D] = \{d_{ij}\}$$
$$d_{ij} = a_{ij} - m_{ij}$$

[8] Note $M_j (= \sum_i m_{ij})$ is the total direct import requirement in the production of the $j$th good.

units of capital at the last stage of production and for domestically produced inputs; and we need $C^*_{LF}M^*_F$ and $C^*_{KF}M^*_F$ of labor and capital, respectively, to produce additional exports to finance the imports which were employed in the original production of one unit of exports. In addition, we recognize that the additional exports (required to finance the imports used in the first round) also require imported inputs. In the first round $M^*_F$ units of imports (foreign exchange = exports) are required; thus in the second round $M^*_F \cdot M^*_F$ units of imported inputs are required, which in turn will entail the employment of $C^*_{LF}(M^{*2}_F)$ labor and $C^*_{KF}(M^{*2}_F)$ capital in the production of exports with which to finance these additional imports. The second round of additional exports, likewise, requires imported inputs $(M^{*2}_F \cdot M^*_F)$ and consequently more exports and hence the employment of still more labor and capital, and so on. The sum of all labor and capital required in the production of one unit of exports (i.e., foreign exchange) is thus

$$\text{(3a)}\quad C^*_{LF} + C^*_{LF}M^*_F + C^*_{LF}(M^{*2}_F) + C^*_{LF}(M^{*3}_F) + \ldots + C^*_{LF}(M^{*n}_F) = \frac{C^*_{LF}}{1 - M^*_F} \qquad n \longrightarrow \infty$$

$$\text{(3b)}\quad C^*_{KF} + C^*_{KF}M^*_F + C^*_{KF}(M^{*2}_F) + C^*_{KF}(M^{*3}_F) + \ldots + C^*_{KF}(M^{*n}_F) = \frac{C^*_{KF}}{1 - M^*_F} \qquad n \longrightarrow \infty$$

since $0 \leq M^*_F \leq 1$.

For any given commodity $j$, therefore, the factor intensity of production as measured by total factor requirement per unit output is given by

$$\text{(4)}\quad k^{**}_j = \frac{\sum_i C_{Ki}s_{ij} + M^*_j\left[\dfrac{C^*_{KF}}{1 - M^*_F}\right]}{\sum_i C_{Li}s_{ij} + M^*_j\left[\dfrac{C^*_{LF}}{1 - M^*_F}\right]}$$

which expresses the two components of total factor cost in an open economy: 1) labor and capital cost at the last stage of production and producing domestic inputs; and 2) labor and capital cost implicit in earning the foreign exchange (fraction of one unit of foreign exchange) with which to purchase imported inputs required directly and indirectly in the production of commodity $j$.

## II. Factor-Intensity Ranking Under Alternative Assumptions Regarding the Supply Source of Intermediate Products

### A. *The Intermediate Product Totally Supplied from Domestic Production*

The assumption that the pure intermediate is totally supplied from domestic production was explicit in the Batra-Casas model, which consisted of three commodities, two final products ($X_1$ and $X_2$), and one intermediate product ($X_3$), and assumed a production structure given by the Leontief matrix as

$$[A] = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ a_{31} & a_{32} & 0 \end{bmatrix}$$

It is clear that if the intermediate inputs are totally supplied domestically the gross factor-intensity measure in equation (4) becomes the same as the orthodox measure in equation (1).[9] Applying this measure to the Batra-Casas model yields

$$k^*_1 = \frac{C_{K1} + C_{K3}a_{31}}{C_{L1} + C_{L3}a_{31}} = \frac{k_1C_{L1} + k_3C_{L3}a_{31}}{C_{L1} + C_{L3}a_{31}}$$

$$k^*_2 = \frac{C_{K2} + C_{K3}a_{32}}{C_{L2} + C_{L3}a_{32}} = \frac{k_2C_{L2} + k_3C_{L3}a_{32}}{C_{L2} + C_{L3}a_{32}}$$

$$k^*_3 = \frac{C_{K3}}{C_{L3}}$$

where $k_i$ is the *net* factor intensity $(K/L)$ of product $i$. The central question upon which the Batra-Casas analysis hinges is,

[9] Note:

$$[I - A]^{-1} = \{r_{ij}\} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ r_{31} & r_{32} & 1 \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ a_{31} & a_{32} & 1 \end{bmatrix}$$

"... if the first commodity is *apparently* capital intensive relative to the second commodity (that is, if $k_1 > k_2$), then will it be *truly* capital intensive (that is, $k_1^* > k_2^*$) ... ?" (p. 304, emphasis added). The condition is that

$$\frac{k_1 C_{L1} + k_3 C_{L3} a_{31}}{C_{L1} + C_{L3} a_{31}} > \frac{k_2 C_{L2} + k_3 C_{L3} a_{32}}{C_{L2} + C_{L3} a_{32}}$$

or

$$C_{L1}C_{L2}(k_1 - k_2) + a_{31}C_{L2}C_{L3}(k_3 - k_2) + a_{32}C_{L1}C_{L3}(k_1 - k_3) > 0$$

which Batra and Casas showed, holds only if

(i) $k_1 > k_3 > k_2$

or

(ii) $k_1 > k_2 > k_3$ and $a_{32}/C_{L2} \geq a_{31}/C_{L1}$

### B. *The Intermediate Product Totally Imported*

The Batra-Casas model is now examined under the assumption that the intermediate is totally imported. As a matter of convenience it is assumed that only $X_1$ is exported, though it makes no difference if both final goods are exported in exchange for the intermediate. Under the assumption that the intermediate is totally imported, the inverted domestic Leontief matrix is

$$[I - D]^{-1} = \{s_{ij}\} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}$$

The per unit direct and indirect imported input requirement in the production of $X_1$ and $X_2$ is

$$M_1^* = \sum M_i s_{i1} = a_{31}$$
$$M_2^* = \sum M_i s_{i2} = a_{32}$$

The gross labor and capital requirement per unit export is

$$\frac{\sum_j \left[ \sum_i C_{Li} s_{ij} \right] e_j}{1 - \sum_j \left[ \sum_i M_i s_{ij} \right] e_j} = \frac{C_{L1}}{1 - a_{31}}$$

$$\frac{\sum_j \left[ \sum_i C_{Ki} s_{ij} \right] e_j}{1 - \sum_j \left[ \sum_i M_i s_{ij} \right] e_j} = \frac{C_{K1}}{1 - a_{31}}$$

since $e_j$ is unity for $X_1$ and zero for $X_2$, by assumption.

Applying the gross factor-intensity measure given in equation (4) yields

$$k_1^{**} = \frac{C_{K1} + a_{31}\dfrac{C_{K1}}{1 - a_{31}}}{C_{L1} + a_{31}\dfrac{C_{L1}}{1 - a_{31}}} = \frac{C_{K1}}{C_{L1}} = k_1$$

$$k_2^{**} = \frac{C_{K2} + a_{32}\dfrac{C_{K1}}{1 - a_{31}}}{C_{L2} + a_{32}\dfrac{C_{L1}}{1 - a_{31}}} = \frac{C_{K2} - C_{K2}a_{31} + C_{K1}a_{32}}{C_{L2} - C_{L2}a_{31} + C_{L1}a_{32}}$$

$$k_3^{**} = \frac{C_{K3}}{C_{L3}} = k_3$$

Algebraic manipulation reveals that if $k_1 > k_2$, $k_1^{**}$ will always be greater than $k_2^{**}$. If the pure intermediate is totally imported, the standard trade theorems defined in net factor intensities remain valid. The intuitive reason for this result is simply that the importation of intermediate goods implicitly involves the substitution of exports (final goods) for the intermediate good in the production process—hence an interindustry flow model à la Vanek.

### C. *The Intermediate Product Partially Imported, Partially Produced Domestically*

The more general case, and certainly the most interesting empirically, is that in which some proportion of the intermediate good is imported and some proportion supplied domestically. Again it makes no difference which of the final goods are exported in exchange for the intermediate. Assume that both $X_1$ and $X_2$ are exported in exchange for $X_3$.

$$(5) \qquad k_1^{**} = \frac{[C_{K1} + C_{K3}d_{31}] + m_{31}\left[\dfrac{[C_{K1} + C_{K3}d_{31}]e_1 + [C_{K2} + C_{K3}d_{32}]e_2}{1 - m_{31}e_1 - m_{32}e_2}\right]}{[C_{L1} + C_{L3}d_{31}] + m_{31}\left[\dfrac{[C_{L1} + C_{L3}d_{31}]e_1 + [C_{L2} + C_{L3}d_{32}]e_2}{1 - m_{31}e_1 - m_{32}e_2}\right]}.$$

$$k_2^{**} = \frac{[C_{K2} + C_{K3}d_{32}] + m_{32}\left[\dfrac{[C_{K1} + C_{K3}d_{31}]e_1 + [C_{K2} + C_{K3}d_{32}]e_2}{1 - m_{31}e_1 - m_{32}e_2}\right]}{[C_{L2} + C_{L3}d_{32}] + m_{32}\left[\dfrac{[C_{L1} + C_{L3}d_{31}]e_1 + [C_{L2} + C_{L3}d_{32}]e_2}{1 - m_{31}e_1 - m_{32}e_2}\right]}$$

$$k_3^{**} = \frac{C_{K3}}{C_{L3}} = k_3$$

Given that some proportion ($\neq 1$) of the intermediate good is imported, the domestic structure of production is reflected in the inverse domestic Leontief matrix

$$[I - D]^{-1} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ d_{31} & d_{32} & 1 \end{bmatrix}$$

The proportion of $X_3$ imported and used in the production of $X_1$ and $X_2$ is denoted $m_{31}$ $(= a_{31} - d_{31})$ and $m_{32}$ $(= a_{32} - d_{32})$, respectively. Applying the gross factor-intensity measure expressed in equation (4) yields expressions for $k_1^{**}$, $k_2^{**}$, and $k_3^{**}$, shown in (5).

Defining the total capital requirement per unit export as $A$, and the total labor requirement per unit export as $B$ (for convenience since they are constants at any one point in time under a given set of prices), the condition under which $k_1^* > k_2^*$, if $k_1 > k_2$, is

$$\frac{C_{K1} + C_{K3}d_{31} + m_{31}A}{C_{L1} + C_{L3}d_{31} + m_{31}B} > \frac{C_{K2} + C_{K3}d_{32} + m_{32}A}{C_{L2} + C_{L3}d_{32} + m_{32}B}$$

or

$$\frac{k_1C_{L1} + k_3C_{L3}d_{31} + m_{31}A}{C_{L1} + C_{L3}d_{31} + m_{31}B} > \frac{k_2C_{L2} + k_3C_{L3}d_{32} + m_{32}A}{C_{L2} + C_{L3}d_{32} + m_{32}B}$$

which, provided $m_{31} = m_{32}$, holds if and only if

(i) $\qquad k_1 > k_3 > k_2$

or

(ii) $\quad k_1 > k_2 > k_3$ and $d_{32}/C_{L2} \geq d_{31}/C_{L1}$

As Batra and Casas previously demonstrated, if the pure intermediate good is produced domestically either condition (i) or (ii) is necessary in order to ensure a uniform ranking of gross and net factor intensities of final products. However, these conditions are insufficient unless the intermediate is *totally* supplied from domestic production. In the more general case in which the intermediate is both imported and supplied domestically, a further necessary condition is required, namely that the proportion imported and used in the production of the final goods is the same for both goods.

### III. Conclusion

The validity of the traditional trade theorems which depend upon the factor-intensity ranking of traded commodities demands that factor intensity be defined in gross terms, rather than in terms of more conventional net factor intensity. Empirical studies of the traditional theorems, in particular "Leontief tests" of the Heckscher-Ohlin theorem, have long recognized the necessity of defining factor intensity in gross terms. Nevertheless, what empirical studies have failed to recognize is that the conventional measure of gross intensity, introduced by Leontief and applied countless times, implicitly assumes that intermediate products are solely pro-

duced and supplied domestically. More appropriately, in an open economy importing intermediate products, gross factor intensity is measured by 1) the factor requirements at the last stage of production and in producing domestic intermediate inputs, and 2) the factor requirements of earning the foreign exchange needed to purchase imported intermediate inputs. It matters not to the relatively labor-abundant economies of Taiwan and Hong Kong, for example, that the steel which goes into transistor radio components is a relatively capital-intensive product, as long as this steel can be obtained in exchange for relatively labor-intensive commodities such as toys, cotton shirts, and the like.[10] In testing whether observed trade patterns conform to theoretical hypotheses dependent upon factor intensity ranking, this factor should be considered. As such, the measure of gross factor intensity developed in Section I is the relevant one for empirical tests of the traditional theorems, as well as for examining in a more general context the theoretical implications of introducing intermediate products into the orthodox factor-proportions trade model.

[10] This argument is developed in my 1975 article.

# Elasticity, Absorption, Keynesian Multiplier, Keynesian Policy, and Monetary Approaches to Devaluation Theory: A Simple Geometric Exposition

*By* HARRY G. JOHNSON*

The history of balance-of-payments theory since the early 1930's has been one of successive "approaches" of increasing degrees of theoretical sophistication. Five stages of analysis (conceptually if not always chronologically) may be distinguished: the simple "elasticity" approach following the classic paper by Joan Robinson, the "absorption" approach, the Keynesian "multiplier" approach, the Keynesian "policy" approach pioneered by James Meade, and most recently the "monetary" approach stemming from the work of Robert Mundell. Differences between these approaches have occasionally been the focus of sharp controversy, most notably in the case of the elasticity and absorption approaches, and recently in the case of the monetary approach as contrasted with other approaches that have in common an emphasis on elasticities or the influence of exchange rate changes on trade flows via relative price changes and international elasticities.

The purpose of the present note is to bring out the key differences between these alternative approaches, as exemplified by a simple case that can be illustrated by a simple diagram. The simple case is that of devaluation by a single country in a world economy so large that macro-economic repercussions of devaluation on real incomes, world money demand relative to supply, and the prices of imported goods can be ignored. A further simplification is the assumption that export supply is perfectly elastic in response to domestic currency price (cost of production is constant) short of "full employment," interpreted as a specific level of total output, after which point supply is perfectly inelastic. For simplicity, also, where the analysis involves full-employment conditions the initial equilibrium point is assumed to coincide with exact full employment. Finally, international security transactions are assumed absent, all capital movements taking the form of money flows; and all money is assumed to be international money, to avoid problems (important in reality) of substitution between international reserve assets and "domestic credit." The last assumption raises the problem that a devaluation alters the amount of domestic money valued in foreign currency, and vice versa; this problem is ignored until the end of the exposition.

Figure 1 graphs income earned from export sales $X$ plus domestic purchase of home-produced goods $cE$ against domestic expenditure $E$, both measured in domestic unit values of domestic product (at some point below it will be convenient to assume measurement in terms of foreign currency unit

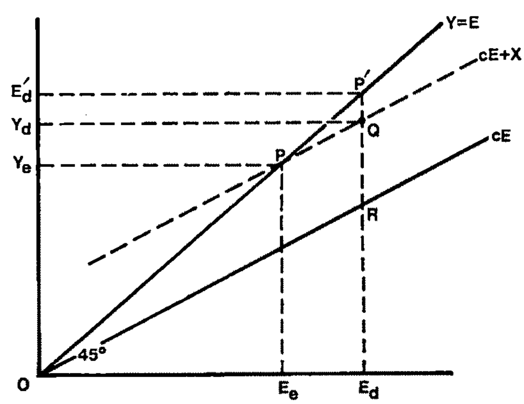

FIGURE 1

* Professor of economics, University of Chicago.

values). Export sales are an increasing function of the foreign exchange rate $r$. The division of total domestic expenditure between the vector $cE$ and the 45° line $Y=E$ is assumed to be a constant ratio relationship, and to depend on the exchange rate $r$; if the elasticity of demand for imports (with constant total expenditure) is greater than unity, $cE$ rises as $r$ rises (the exchange rate depreciates, domestic cost of exports remaining constant) and vice versa. The vector $cE+X=D$, total (foreign and domestic) expenditure on domestic output, increases or decreases with $r$ according as the well-known elasticity criterion is satisfied. This criterion can be written for the case of initial equality of exports and imports or of domestic expenditure and income as $\eta_h+\eta_f>1$, where $\eta_h$ and $\eta_f$ are the (constant-expenditures) elasticities of home and foreign demands for imports; it is worth noting that since, with expenditure constant, an excess supply of one good means an excess demand for the other, the criterion can equally well be written as $\eta_h+\epsilon_f>0$, where $\epsilon_f$ is the elasticity of foreign supply of imports, which is merely the condition that a fall in the price of a good leads to an excess demand for it.

In Figure 1, $Y_e=E_e$ at $P$ represents a situation of balance-of-payments equilibrium, with exports equal to imports and domestic expenditure equal to income; $Q$, on the other hand, is a situation of balance-of-payments disequilibrium, with imports in excess of exports and expenditure in excess of income by $P'R-QR=P'Q=E_d'Y_d$. The excess in each case is financed by a reduction of cash balances (loss of reserves) $P'Q$.

The fundamental difference between the monetary approach and the other four approaches listed consists in the fact that, according to the monetary approach, the loss of reserves and cash $P'Q$ must reduce the stock of money available next period and in subsequent periods (unless this is made good by a policy of continuous money creation by the country's monetary authorities, via substitution of domestic credit for international reserves in the portfolio of the central bank, a possibility here excluded by assumption); this will reduce the level of domestic expen-

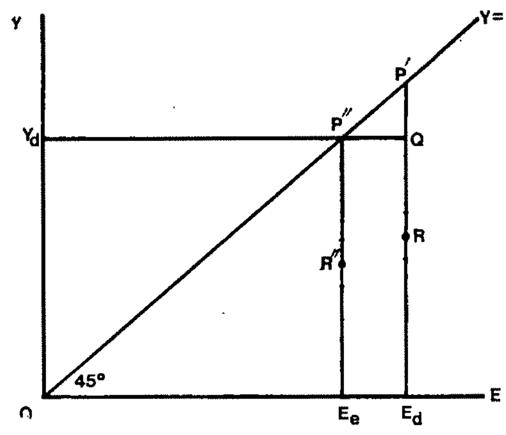

FIGURE 2

diture (to less than $E_d'$) next period; and the process will continue until equality is restored between exports and imports, and between expenditure and income, at the equilibrium point $P$ (with $Y_e=E_e$). On the other approaches, by contrast, the disequilibrium will repeat itself period after period until policy changes are introduced (in the form of devaluation, deflation, or both) that will be effective in establishing an equilibrium between exports and imports, expenditure and income, at the point $P$ or some similar point along the 45° line $Y=E$ through the origin $O$.

The difference between the other four approaches may now be examined and simply described. The "elasticity" approach, at least in one very common version of it, holds output constant (at $Y_d$ in Figure 2) and considers the conditions under which devaluation will correct the excess of imports over exports. Implicitly, this also means by assumption that devaluation corrects the excess of expenditure over income; and this involves the implicit assumption, not by any means natural to demand theory, that changes in expenditure are neutralized by changes in saving. Specifically, in diagrammatic terms the movement from disequilibrium to equilibrium (from $P'$ and $E_d$ to $P''$ and $E_e$) involves an increase in exports and reduction in imports amounting to $P'Q$ accompanied by a corresponding reduction of domestic expenditure by $E_dE_e$. The most nat-

ural assumption, though one that underlines the unreality of the necessary assumptions of the analysis, is that the proceeds of any increase in exports and the savings from any decrease in imports expenditure (noting that a smaller quantity of imports might be outweighed by a higher domestic currency price) are simply added to domestic savings or more accurately reduce domestic dissaving. Incidentally, the point $R''$ below $P''$ in the diagram, which represents the division of equilibrium income and consumption between domestic goods consumption and consumption of imports, may be above or below the level of the vector $OR$, though normally assumed to be above, according to whether the elasticity of demand for imports is assumed to be greater or less than unity; $R''$ may even be above $R$, if the elasticity is sufficiently greater than unity to offset the effect on domestic goods consumption of the reduction in total expenditure that is assumed to accompany devaluation.

The contrasting "absorption" approach, in the major variant that does not allow for the existence of unemployment and make use of the "propensity to absorb" and the multiplier, can be illustrated by assuming that the variables in Figure 2 are measured in foreign currency values, that $Y_d$ is the full-employment level of output, and that at full employment domestic currency prices of both exports and imports adjust immediately to world levels. A devaluation hence has no effect through relative price changes and elasticities, and can be effective in improving the balance of payments (in foreign currency terms) only to the extent that the inflation of domestic currency prices incidentally reduces the excess of absorption (real expenditure) over (real) income. The approach contemplates two alternative routes for such incidental absorption-reducing effects: a "Keynesian" route involving redistribution of income from workers to capitalists or taxpayers to government that may (but not necessarily will) reduce total demand as a function of aggregate real income; and a "monetary" route, involving the "real balance effect" of inflation in reducing the purchasing power of domestic money. The treatment of the real balance effect in this approach is obviously defective in recognizing the effect of inflation in reducing the real value of the nominal quantity of money through price increase while ignoring the effect of the initial deficit itself in reducing real balances by reducing nominal money stocks through payment of the deficit.

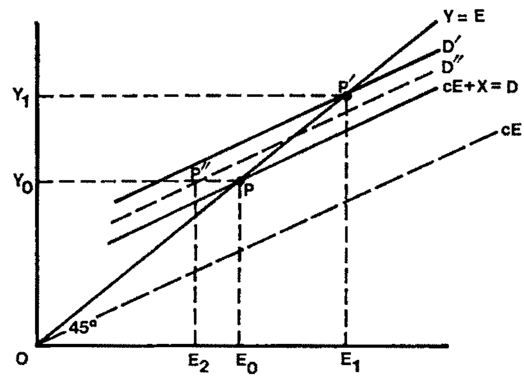

FIGURE 3

The Keynesian "multiplier" approach makes good the deficiency of the simple "elasticity" approach by recognizing and allowing for the implications of changes in expenditure on output, income, expenditure, and again output for balance-of-payments equilibrium. For simplicity, consider in Figure 3 a country initially in equilibrium with exports equal to imports and expenditure equal to income ($E_0 = Y_0$) at $P$, which proceeds to devalue in order to create a balance-of-payments surplus. The devaluation will, if the elasticity condition is fulfilled, shift the $D$ curve upward to $D'$, and, through the multiplier, increase domestic output to $Y_1$. But this fact indicates nothing about what happens to the balance of payments, even though Keynesian analysis has frequently been interpreted as showing merely that the balance of payments will improve by something less than the "primary" effect of devaluation on export and import demand. The balance of payments will improve only if the multiplier effect of higher output on total domestic expenditure (domestic goods plus imports) is less than the increase in income itself, that is, if the new $E$ lies to the

left of $E_1$ (and of course, by the usual assumption that increased income leads to increased expenditure, right of $E_0$); otherwise, the devaluation, by increasing imports more than exports, will worsen the balance of payments. The crucial requirement, given the fulfillment of the elasticity condition, is that expenditures rise less than output: in other words, that the country have a positive marginal propensity to save, or a marginal propensity to "absorb" less than unity.

Actually, it should be noted, the use of the term "marginal propensity to save" in this context is a potentially seriously misleading misnomer. For the "saving" in question is really "hoarding," the devotion of an excess of total income over total expenditure, or saving plus consumption over investment plus consumption, or of domestic saving over domestic investment, to the acquisition of additional (international) money balances. And while the term hoarding has occasionally been used in the literature, it is typically not recognized that while a positive rate of saving (acquisition of capital assets) or even (to abandon the assumption excluding international securities transactions for the moment) of net acquisition of foreign securities, may be reasonably assumed, a positive rate of acquisition of international reserves (money) related to income and persisting as a flow over all succeeding periods is not a reasonable assumption.

The "monetary" approach, by contrast, maintains that any such international monetary flow is a transient element in a stock-flow adjustment process, which must eventually come to an end. This in turn implies that the level of expenditure, whether it lies initially to the left or the right of $E_1$ (representing respectively a balance-of-payments surplus and deficit) must converge on the point $E_1$, with domestic expenditure equal to income (which has risen due to devaluation to $Y_1$, the ultimate equilibrium being depicted by $P_1$).

The Keynesian "multiplier" approach assumes unemployed resources whose rate of utilization can vary without ulterior consequences as a result of devaluation. The more sophisticated Keynesian "policy" analysis originated by Meade assumes, in contrast to previous "positive" analysis of the effects of an arbitrarily introduced devaluation, that the country under analysis has a policy authority which utilizes "financial" (fiscal and monetary) and "exchange rate" (or, in a fuller analysis, trade and exchange control) policy in order to implement objectives with respect to full employment ("internal balance") and the balance of payments ("external balance"). The analysis can be illustrated by reference again to Figure 3, where $Y_0$ now represents full-employment output (and price stability) and the balance of payments is initially in balance consistently with full employment at the point $P$ and the exchange rate and financial policy being appropriately selected to make the sums of both exports and domestic consumption, and imports and domestic consumption, equal to full-employment output $Y_0$ and expenditure $E_0$. The country now seeks to develop a balance-of-payment's surplus while maintaining full employment. If it were to deflate domestic expenditure, assuming a positive marginal propensity to spend, it would improve its balance of payments at the expense of unwanted domestic unemployment; if it devalued, assuming satisfaction of the elasticity condition, it would shift the $D$ curve upwards, requiring output above the full-employment target level (whether the increased demand would actually be satisfied, or simply produce inflationary pressure, is a question not necessary to pursue here). The solution is to combine a devaluation with a deflation in exactly the right proportions to maintain full-employment total (foreign plus domestic) demand for output while reducing total domestic demand for foreign and domestic goods below the level of total domestic output by fiscal on monetary restraint. Diagrammatically, the demand curve for domestic output can be thought of as being shifted upward by devaluation from $D$ to $D'$, and then partially shifted back downward by domestic deflation to a location $D''$, such that domestic output remains at $Y_0$, domestic expenditure is at $E_2$, and the balance-of-payments surplus and excess of domestic income over domestic expenditure is $E_2E_0$.

The Keynesian policy approach, like the other three approaches, is as mentioned subject to the criticism that it ignores the stock-flow adjustment consequences of the reserve flow associated with a balance-of-payments deficit or surplus. This adjustment process means that the combined policies of devaluation and deflation cannot produce a flow equilibrium balance-of-payments surplus of $P''D=E_2E_0$. Instead, the period-by-period expansion of cash balances consequent on the balance-of-payments surplus will gradually raise the level of expenditure; but any point on $D''$ above the level of $Y_0$ necessarily involves an inflationary excess of demand above the full-employment level, which (on a strict interpretation of "full employment") requires a domestic price level increase sufficient to reduce exports and increase imports sufficiently to make room for the additional domestic demand. Such an increase is equivalent to an appreciation of the foreign exchange rate, which partially offsets the initial devaluation; and in the long run the economy must return to the equilibrium position $P$ with no "effective" devaluation of the exchange rate (that is, the nominal devaluation is exactly offset by an inflation of domestic prices).

In conclusion, something must be said about the abstraction of the analysis from the change in the conversion ratio between domestic and foreign currencies inherent in a devaluation. This is not a problem with the "absorption" approach, since the devaluation is assumed to be offset by a corresponding domestic price inflation; and it can be ignored with the simple elasticity approach, given the prior unacceptability of the assumption that the effects of changes in export earnings and import expenditures on expenditure or domestic output are somehow neutralized. Problems arise with the Keynesian "multiplier" and "policy" models, however, inasmuch as these models assume either a varying or constant (policy maintained) level of domestic output at given domestic currency prices, and therefore a change in the foreign currency value of domestic output as a result of devaluation. In the policy case certainly, with constant value of output in domestic currency, and in the multiplier case with sufficiently low values of the relevant demand elasticities and high value of the marginal propensity to hoard, the effect of devaluation is to reduce the foreign currency value of domestic income and therefore, presumably, the country's demand for money expressed in international units. It will thereby induce a balance-of-payments *deficit* and *reserve outflow* rather than, as usually assumed, a surplus and reserve inflow, to the extent that the domestic monetary circulation consists of or is backed by international money and is therefore increased in domestic currency value by devaluation. This theoretical complication, which might have some practical implications for actual devaluation experience, can be removed by assuming that international reserves are held by an exchange equalization authority that finances its holdings by the issue of domestic-denominated liabilities and sterilizes any capital gain (or possibly loss) on existing stocks for international reserves due to devaluation (or revaluation).

# IN MEMORIAM

## GEORGE W. STOCKING

## 1892–1975

George Ward Stocking was born in Clarendon, Texas, on September 24, 1892, and died in Portola Valley, California, on June 7, 1975.

Clarendon was and is a small, isolated town on the dusty plain of the Texas Panhandle, where the Stocking family produced a numerous and remarkable group of brothers and sisters who had distinguished careers in government, medicine, and academic life. George graduated from Clarendon College in 1910. After following several trades, he served on the Bureau of Education of the Philippine Islands in 1915–16 and as superintendent of the Clarendon public schools in 1918–19, meanwhile finding time to get a baccalaureate degree at the University of Texas and to serve in the Air Service in World War I.

After returning to the University of Texas for an M.A. in 1921, Stocking went to Columbia for the Ph.D. in economics (1925), writing his dissertation on "The Oil Industry and the Competitive System," which remained one of his leading interests all his life. After service at the University of Vermont, the National Industrial Conference Board, and Dartmouth College, he again returned to the University of Texas at Austin in 1925. Thereafter he alternated periods of teaching with leaves of absence in New York and Washington until 1947, when he began the final phase of his academic career at Vanderbilt University in Nashville, Tennessee.

Stocking's government work included service as member and chairman of the Petroleum Labor Policy Board of the National Recovery Administration, director of the Fuels Division of OPA, and member of the War Labor Board for the 8th Region. He was a director of the Federal Reserve Branch of Dallas, San Antonio Branch, during 1943–46. For many years he served on various occasions as an arbitrator in labor disputes.

While at the University of Texas, Stocking published books on the oil industry (1925) and the potash industry (1931), and several articles on the oil industry and public policy toward it. In 1944 he began his fruitful association with the Twentieth Century Fund, in collaboration with Myron Watkins, which resulted in publication of the definitive trilogy, *Cartels in Action* (1946), *Cartels or Competition?* (1948), and *Monopoly and Free Enterprise* (1951).

As his early life might have led one to predict, George Stocking had some elements of the prairie populist in his makeup. In the unorthodox atmosphere of the University of Texas, dominated by institutional economics, Stocking was generally regarded as a conservative, even a traditionalist; in the then-ironbound conservatism of Vanderbilt he appeared as one of the first "liberals" of the postwar development. All his life he distrusted bigness and power. His major writings analyzed the origins and effects of size and power, of manipulation and conspiracy; at the same time they affirmed his hopes for the American competitive system and his belief that what had gone wrong with free competitive enterprise could be set right. At times he expressed frustration that businessmen and fellow economists did not all share his views; one of his major professional addresses was entitled "Saving Free Enterprise from its Friends." In his own work he had little taste for theoretical abstractions and legal subtleties, and showed marked antipathy toward such concepts as "workable competition" and the Rule of Reason, which he regarded as subterfuges and evasions: *genuine* competition was the goal, and any economist or lawyer should be able to recognize what it was. His published views on the matter were collected in *Workable Competition and Antitrust Policy* (Vanderbilt University Press, 1961).

The creation of the department of economics at Vanderbilt was one of his proudest achievements. He brought together a number of economists, established or promising, who took a considerable risk in going to an unproven institution in the South; it was primarily trust in George Stocking that led them to do so. He was able to attract financial support for his faculty's research, again primarily on the strength of his reputation. His deep personal concern for members of his faculty was one of his most noteworthy qualities. "The old labor arbitrator and one-time Bible salesman," one of his former associates said recently, "had a remarkable ability to get people to work together." He was a stimulating teacher who loved to play Devil's advocate to provoke debate in the classroom. He took great pains with his students and spent his time liberally with them, among other things in improving their ability to express their ideas clearly and briefly. Several of his students at Vanderbilt are now among the leading figures in industrial organization and antitrust policy.

While at Vanderbilt, George Stocking became President of the Southern Economic Association (1952) and the American Economic Association (1958). For the American Economic Association he edited, with Richard B. Heflebower, the volume of *Readings in Industrial Organization and Public Policy* (1958). Toward the end of his active career he turned his attention to the international oil industry. While spending 1960–61 in the Middle East as visiting professor at the American University at Beirut, and during other visits to the Middle East, he did extensive field research for his last book, *Middle East Oil: A Study in Political and Economic Controversy*, a timely and prophetic study published in 1970. He maintained an active interest in world oil developments to the day of his death.

# NOTES

## EIGHTY-NINTH ANNUAL MEETING OF THE AMERICAN ECONOMIC ASSOCIATION

Atlantic City, New Jersey, September 15–18, 1976

*Preliminary Announcement of the Program*

**Wednesday, September 15, 1976**

10:00 A.M. EXECUTIVE COMMITTEE MEETING

**Thursday, September 16, 1976**

8:30 A.M. EQUILIBRIUM IN MARKETS WHERE PRICE EXCEEDS COST
*Chair:* ROBERT E. HALL, Massachusetts Institute of Technology
*Papers:* DENNIS CARLTON, University of Chicago
Uncertainty, Production Lags, and Pricing
RICHARD GILBERT, University of California, Berkeley
Resource Extraction with Differential Information
A. MICHAEL SPENCE, Harvard University
Product Differentiation and Barriers to Entry
*Discussants:* PAUL JOSKOW, Massachusetts Institute of Technology
F. M. SCHERER, Northwestern University

8:30 A.M. ENVIRONMENTAL PRIORITIES: HEALTH VS. AMENITY (Joint Session with the American Association of Environmental Economists)
*Chair:* WILLIAM BAUMOL, New York University and Princeton University
*Papers:* LESTER LAVE, Carnegie-Mellon University
Evaluation of Benefits—Safety vs. Amenity
ROBERT DORFMAN AND NANCY DORFMAN, Harvard University
Socioeconomic Groups and Environmental Priorities
ALLEN KNEESE, University of New Mexico
(To be announced)
*Discussants:* (To be announced)

8:30 A.M. MICRO-ECONOMICS (Contributed Paper Session)
*Chair:* CAROLYN SHAW BELL, Wellesley College
*Papers:* JAMES B. HERENDEEN, Pennsylvania State University, AND RAYMOND LOMBRA, Board of Governors of the Federal Reserve System
A Financial Model of the Banking Firm
CAROL C. MCDONOUGH, University of Lowell
The Demand for Manuscript Review
GORDON C. WINSTON, Williams College
Capacity at the Level of the Firm, the Sector, and the Economy
S. Y. WU, University of Iowa
Monopoly Power and Stable Price Policy
*Discussant:* OLIVER WILLIAMSON, University of Pennsylvania

8:30 A.M. INCOME MAINTENANCE (Contributed Paper Session)
*Chair:* ROBERT J. LAMPMAN, University of Wisconsin, Madison
*Papers:* BENNETT HARRISON AND MARTIN REIN, Massachusetts Institute of Technology
Some Microeconomic Relationships Between Work and Welfare
KENNETH C. KEHRER et al., Mathematica Policy Research
The Initial Labor Supply Findings from the Gary Income Maintenance Experiment
ROBERT I. LERMAN, University of Wisconsin
A Reappraisal of Negative Tax and Employment Subsidy Approaches to Reforming Welfare
REBECCA A. MAYNARD, Mathematica Policy Research
The Effects of an Income Maintenance Program on School Performance of Children

Elizabeth A. Roistacher, Queens College
Short-Run Housing Responses to Income Changes
*Discussant:* Harold Watts, Columbia University

8:30 A.M. Non-Pecuniary Economics I (Contributed Paper Session)
*Chair:* Joseph L. Seneca, Rutgers University
*Papers:* Brian Forst and Kathleen B. Brosi, Institute for Law and Social Research
A Theoretical and Empirical Analysis of the Prosecutor
Itzhak Goldberg, Hoover Institution
Enforcement of Work Discipline—Detection, Rewards and Fines
Thomas J. Kniesner and Solomon W. Polachek, University of North Carolina, Chapel Hill
Scholastic Achievement: The Student as a Multi-Product Firm
Charlotte D. Phelps, Temple University
A Comparison of Adam Smith's Comments on Non-Pecuniary Rewards for Work with Contemporary Concepts and Measures of Non-Pecuniary Rewards for Work
*Discussant:* Lester Thurow, Massachusetts Institute of Technology

10:30 A.M. Endogenous Theories of Racial Discrimination (Joint Session with the National Economic Association)
*Chair:* Alfred L. Edwards, University of Michigan
*Papers:* David H. Swinton, State University of New York, Stony Brook
Labor Force Conflict Model
Gerald Jaynes, University of Pennsylvania
Information and Screening Model
Gerry Oster, City University of New York
A Marxist Model of Discrimination
*Discussants:* A. Michael Spence, Harvard University
Kenneth J. Arrow, Harvard University
Julian Ellison, Black Economic Research Center

10:30 A.M. New Directions in the Economics of Information Transfer
*Chair:* Fritz Machlup, New York University and Princeton University
*Papers:* William Baumol, New York University and Princeton University, and Yale Braunstein, New York University
An Empirical Analysis of the Production and Distribution of Information
Jack Hirshleifer and John Riley, University of California, Los Angeles
Review of New Information Theory Applications
Fritz Machlup, New York University and Princeton University
Summary
*Discussants:* Donald W. King, Market Facts, Inc.
Stephen Kagann, The John and Mary Markle Foundation

10:30 A.M. Discrimination (Contributed Paper Session)
*Chair:* Marcus Alexis, Northwestern University
*Papers:* O. L. E. Mbatia, University of California, Irvine
The Economic Effect of Fair Employment Laws on Occupations—Progress of Black Americans 1954–1972
Ralph E. Smith, The Urban Institute
Has the Recession Been an Equal Opportunity Dis-Employer?
David L. Vinje, Pacific Lutheran University
Alternative Economic Development Strategies on U.S. Indian Reservations
Michelle J. White, University of Pennsylvania
Job Suburbanization and the Welfare of Central City Minority Groups
*Discussant:* Donald W. Katzner, University of Massachusetts

10:30 A.M. Risk and Regulation in Commercial Banking (Joint Session with the American Finance Association)
*Chair:* John R. Bunting, First Pennsylvania Corporation
*Papers:* Samuel B. Chase, Jr., Samuel B. Chase, Jr., Inc., Washington, D.C.
The Regulation of Risk: Role of the Market
Andrew F. Brimmer, Harvard University
The Management of Bank Failure: Franklin National vs. Bankhaus Herstatt
Hyman P. Minsky, Washington University
Banking in a Fragile Financial Environment

*Discussants:* JACK GUTTENTAG, University of Pennsylvania
ROBERT C. HOLLAND, Board of Governors of the Federal Reserve System
CHARLES J. ZWICK, Southeast Banking Corporation
THOMAS MAYER, University of California, Davis

10:30 A.M. ANALYSIS OF DOMESTIC INFLATION
*Chair:* GARY FROMM, National Bureau of Economic Research
*Papers:* ROBERT J. GORDON, Northwestern University
Analysis of Domestic Inflation: Theory
JACK E. TRIPLETT, U.S. Bureau of Labor Statistics
Analysis of Domestic Inflation: Measurement
JOEL POPKIN, National Bureau of Economic Research
Analysis of Domestic Inflation: Transmission
*Discussants:* CHARLES L. SCHULTZE, The Brookings Institution and University of Maryland
WILLIAM NORDHAUS, Yale University
NANCY S. BARRETT, U.S. Congressional Budget Office

12:30 P.M. JOINT LUNCHEON (With the American Finance Association)
*Chair:* ALEXANDER A. ROBICHEK, Stanford University
*Speaker:* PAUL C. VOLCKER, Federal Reserve Bank of New York

2:00 P.M. ENERGY AND RESOURCES (Contributed Paper Session)
*Chair:* ROBERT S. PINDYCK, Massachusetts Institute of Technology
*Papers:* ROBERT C. ANDERSON, Environmental Law Institute
Public Policies Toward the Use of Scrap Materials
A. BRADLEY ASKIN, RICHARD L. FARMAN, GERARD L. LAGACE, AND ARTHUR J. MALLOY, Federal Energy Administration
Energy Policy and the Economy: An Empirical Analysis
DONALD A. HANSON, Ohio State University
The Value of an Exhaustible Natural Resource: Some Simple Cases
EDWARD JOHN RAY, Ohio State University
OPEC: Monopoly Control or Countervailing Power
JULIAN L. SIMON AND JOSEPH BEN-UR, University of Illinois at Urbana-Champaign
Demand, Cost, and Prices in Oligopoly: Theory, Simulation, and Oil as an Example
*Discussant:* DALE JORGENSON, Harvard University

2:00 P.M. INTERNATIONAL ASPECTS OF INFLATION
*Chair:* BERT G. HICKMAN, Stanford University
*Papers:* KARL BRUNNER, University of Rochester, AND ALAN H. MELTZER, Carnegie-Mellon University
An International Comparison of Inflation Patterns
IRVING B. KRAVIS, University of Pennsylvania and National Bureau of Economic Research, AND ROBERT E. LIPSEY, Queens College and National Bureau of Economic Research
The Adjustment of Domestic Prices to Foreign Price Changes
J. M. PARKIN, University of Western Ontario
A "Monetarist" Analysis of the Generation and Transmission of World Inflation in the 1960's and 1970's
*Discussants:* KEITH JOHNSON, Columbia University
RONALD MCKINNON, Stanford University
ROBERT J. GORDON, Northwestern University

2:00–
4:30 P.M. WELFARE ECONOMICS (Joint Session with the Econometric Society)
*Chair:* LEONID HURWICZ, University of Minnesota
*Papers:* ABBA P. LERNER, Queens College
Marginalism, Socialist and Anti-Socialist
KENNETH J. ARROW, Harvard University
Extended Sympathy in Social Choice
STANLEY REITER, Northwestern University
Information, Incentive, and Performance in the $(\text{New})^2$ Welfare Economics
*Discussants:* ABRAM BERGSON, Harvard University
THOMAS MARSCHAK, University of California, Berkeley
JERRY KELLY, Syracuse University

2:00 P.M. DISTRIBUTION OF INCOME AND WEALTH
*Chair:* IRMA ADELMAN, University of Maryland
*Papers:* GRAHAM PYATT, IBRD and University of Warwick
International Comparisons of Inequality
E. WAYNE NAFZIGER, Kansas State University
Entrepreneurship, Social Mobility, and Income Redistribution: The South Indian Case in Comparative Perspective
CHRISTOPHER CLAGUE, University of Maryland
The Supply of Skills and the Earnings Distribution
*Discussants:* DONALD HARRIS, Stanford University
CARMEL ULLMAN CHISWICK, IBRD
SHERMAN ROBINSON, Princeton University

2:00 P.M. ECONOMIC PROBLEMS CONFRONTING HIGHER EDUCATION
*Chair:* ROBERT H. STROTZ, Northwestern University
*Papers:* WALTER ADAMS, Michigan State University
(To be announced)
EARL CHEIT, University of California, Berkeley
(To be announced)
WILLIAM BOWEN, Princeton University
(To be announced)
*Discussants:* (To be announced)

4:00 P.M. SPECIAL SESSION: ECONOMIC ISSUES OF THE CAMPAIGN '76
*Chair:* (To be announced)
*Papers:* (To be announced)

8:00 P.M. RICHARD T. ELY LECTURE
*Chair:* RICHARD A. EASTERLIN, University of Pennsylvania
*Speaker:* SIMON KUZNETS, Harvard University
Two Centuries of Economic Growth—Reflections on the U.S. Experience

## Friday, September 17, 1976

8:30 A.M. AMERICAN ECONOMIC GROWTH: IMPORTED OR INDIGENOUS? (Companion Session to Richard T. Ely Lecture)
*Chair:* RICHARD A. EASTERLIN, University of Pennsylvania
*Papers:* ROBERT E. GALLMAN, University of North Carolina, Chapel Hill
Human Capital in the First Eighty Years of the Republic: How Much Did America Owe the Rest of the World?
J. R. T. HUGHES, Northwestern University
What Difference Did the Beginning Make?
NATHAN ROSENBERG, Stanford University
American Technology: Imported or Indigenous?
*Discussants:* MOSES ABRAMOVITZ, Stanford University
STANLEY LEBERGOTT, Wesleyan University
HENRY ROSOVSKY, Harvard University

8:30 A.M. RECENT CONTROVERSIES IN MONETARY THEORY
*Chair:* LEONALL ANDERSEN, Federal Reserve Bank of St. Louis
*Papers:* ROBERT CLOWER, University of California, Los Angeles
Microfoundations of Monetary Theory
EDWIN BURMEISTER, University of Pennsylvania, AND STEPHEN J. TURNOVSKY, Australian National University
Price Expectations and Stability in a Short-Run Macroeconomic Model with Money and Other Assets
JOHN RUTLEDGE, Claremont Men's College
Irving Fisher and Autoregressive Expectations
*Discussants:* KARL BRUNNER, University of Rochester
(To be announced)

8:30 A.M. THE ECONOMICS OF THE TWO-EARNER FAMILY (Joint Session with the Committee on the Status of Women in the Economics Profession)
*Chair:* ISABEL SAWHILL, The Urban Institute

*Papers:* JUNE O'NEILL, Council of Economic Advisors
The Equity of Social Security Benefits
MYRA STROBER, Stanford University
Wives' Labor Force Behavior and Family Consumption Patterns
JANE H. LEUTHOLD, University of Illinois
The Impact of Taxes on the Work Decision of the Two-Earner Family
*Discussants:* SHIRLEY JOHNSON, Vassar College
CAROLYN SHAW BELL, Wellesley College
BENJAMIN OKNER, U.S. Congressional Budget Office

8:30 A.M. APPLICATIONS OF THE DEMAND-REVEALING PROCESS (Joint Session with the Public Choice Society)
*Chair:* GORDON TULLOCK, Virginia Polytechnic Institute and State University
*Papers:* THEODORE GROVES, Northwestern University
On the Possibility of Efficient Social Choice with Compensation
WILLIAM A. VICKREY, Columbia University
Demand Revelation: Subsidies and Lump-Sum Payments
PAUL B. BROWNING AND T. NICOLAUS TIDEMAN, Virginia Polytechnic Institute and State University
Dynamically Efficient Institutions for Pollution Control
*Discussants:* KENNETH J. ARROW, Harvard University
EDWARD H. CLARKE, Office of Management and Budget
ROBERT DORFMAN, Harvard University

8:30 A.M. INCOME DISTRIBUTION (Contributed Paper Session)
*Chair:* MANORANJAN DUTTA, Rutgers University
*Papers:* BARRY CHISWICK, Council of Economic Advisers
The Effect of Americanization on Earnings
RICHARD T. CURTIN, University of Michigan
Perceptions of Distributional Equity: Their Economic Bases and Consequences
STEPHEN FRANKLIN, The Urban Institute
Microsimulation of Income and Wealth Distributions
TIMOTHY SMEEDING, University of Utah
Annual Comprehensive Income Inequality in the United States: 1968 and 1972
EDWARD STEINBERG, U.S. Department of Commerce
Earnings Increases, 1969–74
*Discussant:* MARTIN BRONFENBRENNER, Duke University

10:30 A.M. RADICAL ECONOMICS (Contributed Paper Session)
*Chair:* BERNARD SAFFRAN, Swarthmore College
*Papers:* DAVID LAIBMAN, Brooklyn College, City University of New York
Toward a Marxian Theory of Economic Growth
DALE J. POIRIER, University of Toronto
Econometric Methodology and the Radical Political Economics Literature
BRETT A. SMITH, Knox College
Worker Participation and Productivity: Another Look at the Evidence
*Discussant:* GEORGE R. FEIWEL, University of Tennessee

10:30 A.M. TAXES AND GOVERNMENT EXPENDITURE DECISIONS AFFECTING REAL ESTATE (Joint Session with the American Real Estate and Urban Economics Association)
*Chair:* JOHN KAIN, Harvard University
*Papers:* (To be announced)

10:30 A.M. APPLICATIONS OF MICROSIMULATION METHODOLOGY
*Chair:* JODIE T. ALLEN, Mathematica, Inc.
*Papers:* RICHARD R. NELSON, Yale University, AND SIDNEY G. WINTER, University of Michigan
Simulation Modeling of Schumpeterian Competition
BARBARA R. BERGMANN, ROBERT L. BENNETT, AND HARRY H. KELEJIAN, University of Maryland
Macroeconomics through Microsimulation: How Much Does Money Matter?
GUY H. ORCUTT, Yale University, AND JAMES D. SMITH, Yale University and The Urban Institute
Contextual Causes of Death Explored with Microanalytic Simulations
GUNNAR ELIASSON, Federation of Swedish Industries
Competition and Market Processes in a Simulation Model of Swedish Industry
*Discussants:* SHERMAN ROBINSON, Princeton University
JAMES L. PIERCE, University of California, Berkeley
CHARLES C. HOLT, The Urban Institute

10:30 A.M. INVITED STUDENT PAPERS (Joint Session with Omicron Delta Epsilon)
*Chair:* LOUISE NELSON, Davidson College
*Papers:* PETER MURRELL, University of Pennsylvania
Representation of Choice in Long-Term Planning
BETTY DANIEL, University of North Carolina, Chapel Hill
The Effectiveness of Stabilization Policies in Open Economies under Conditions of Inflation and Inflationary Expectations
RUSSELL P. BOISJOLY, Indiana University
Default Risk and the Theory of the Firm
*Discussants:* (To be announced)

10:30 A.M. CAPITAL FORMATION: WHERE, WHY, AND HOW MUCH?
*Chair:* ANDREW F. BRIMMER, Harvard University
*Papers:* ROBERT EISNER, Northwestern University
Capital Shortage: Myth and Reality
MARTIN S. FELDSTEIN, Harvard University
Does the United States Save Too Little?
BEATRICE N. VACCARRA, U.S. Bureau of Economic Analysis
Some Reflections on Capital Requirements for 1980
*Discussants:* BARRY BOSWORTH, The Brookings Institution
ROBERT LINDSAY, New York University
MURRAY L. WEIDENBAUM, Washington University
BURTON G. MALKIEL, Council of Economic Advisers

10:30 A.M. MARKET AND PLAN; PLAN AND MARKET (Joint Session with the Association for Comparative Economic Systems)
*Chair:* ABRAM BERGSON, Harvard University
*Papers:* RICHARD MUSGRAVE, Harvard University
The U.S. Case
ARON KATSENELINBOIGEN, University of Pennsylvania, AND HERBERT S. LEVINE, University of Pennsylvania and Stanford Research Institute
The Soviet Case
DEBORAH D. MILENKOVITCH, Barnard College
The Yugoslav Case
*Discussants:* GORDON TULLOCK, Virginia Polytechnic Institute and State University
PAUL SWEEZY, *Monthly Review*
GARY FROMM, National Bureau of Economic Research

12:30 P.M. LUNCHEON HONORING THE 1975 NOBEL LAUREATES IN ECONOMICS (Joint with the Econometric Society)
*Chair:* LAWRENCE R. KLEIN, University of Pennsylvania
*Speaker:* KENNETH J. ARROW, Harvard University

2:00 P.M. IMPACT OF RECENT DEVELOPMENTS IN PUBLIC FINANCE THEORY ON PUBLIC POLICY DECISIONS
*Chair:* JULIUS MARGOLIS, University of Pennsylvania
*Papers:* HUBERT LEVY-LAMBERT, Société Générale, Paris, France
Pricing and Investment Decisions in the French Public Sector; Recent Theoretical Developments and Practical Application
JOSEPH STIGLITZ, Stanford University
Efficiency and Equity Considerations in the Reform of the Tax System
*Discussants:* DAVID BRADFORD, Princeton University and U.S. Treasury
MARTIN FELDSTEIN, Harvard University

2:00 P.M. MONETARY THEORY FOR OPEN ECONOMIES: THE STATE OF THE ART
*Chair:* RALPH C. BRYANT, Board of Governors of the Federal Reserve System and The Brookings Institution
*Papers:* CHARLES FREEDMAN, Bank of Canada
Microeconomic Theory for Financial Intermediaries in an Open Economy
MICHAEL ADLER AND BERNARD DUMAS, Columbia University
Microeconomic Theory for Firms in an Open Economy
DALE W. HENDERSON, Board of Governors of the Federal Reserve System
Macroeconomic Theory: Modelling the Interdependence of National Money and Capital Markets
*Discussants:* RONALD L. MCKINNON, Stanford University
DWIGHT JAFFEE, Princeton University
JÜRG NIEHANS, The Johns Hopkins University

*Discussant:* PETER B. KENEN, Princeton University

# ANNOUNCEMENTS

The eighty-ninth annual meeting of the American Economic Association will be held in Atlantic City, New Jersey, September 16–18, 1976. The Employment Registry and Center will be open from September 15 to 18.

As the annual meeting is being held at an early point in the academic year, it may not be possible to complete all job placement activity through the offices of the Employment Registry and Center. Accordingly, the American Economic Association will hold a special job placement meeting for two days, at a Midwestern location, during January 1977.

## *Resolutions for Consideration at the Annual Business Meeting*

The Executive Committee at its meeting on March 8, 1974, voted to require that, to be considered at the annual business meeting, proposed resolutions must be submitted to the Secretary at least one month in advance in writing with signatures of the proposer and the second, both of whom must be members in good standing. The Secretary will reproduce the proposed resolutions and make copies available in advance of the meeting. The next business meeting will begin at 9:30 P.M. on September 17, 1976. The deadline for proposed resolutions is, accordingly, August 17. They should be sent to the Secretary, American Economic Association, 1313 21st Avenue South, Nashville, Tennessee 37212.

Nicolaus and Associates have been appointed the official travel coordinator for the Atlantic City meetings of Allied Social Science Associations. Group air fares may be arranged from your city and for groups as small as fifteen. These fares usually run about 25 percent below regular coach fare. Some examples using current fares subject to change are:

| Round Trip: | Coach | Group |
|---|---|---|
| Boston-Atlantic City | $ 91.46 | $ 61.46 |
| Detroit-Atlantic City | $161.46 | $ 87.46 |
| San Francisco-Atlantic City | $389.46 | $310.46 |

Flights will be arranged for other cities if enough individuals show interest. Air reservation forms and general information on flights and costs are available by telephoning Nicolaus and Associates collect (800+433-2897) or by writing to 1201 N. Watson Road, Suite 118, Arlington, Texas 76011.

## *Nominations for AEA Officers*

The Electoral College on March 19 chose Jacob Marschak as nominee for President-Elect of the American Economic Association in the balloting to be held in the autumn of 1976. Other nominees (chosen by the nominating committee) are: for Vice-President (two to be elected), Robert Eisner, Albert O. Hirschman, Anne Krueger, Roy Radner; for member of the Executive Committee (two to be elected), Marcus Alexis, Samuel Bowles, Robert Lampman, Marc Nerlove.

Under a change in the bylaws as described in the *Papers and Proceedings* of this *Review*, May 1971, page 472, additional candidates may be nominated by petition, delivered to the Secretary by August 1, including signatures and addresses of not less than 6 percent of the membership of the Association for the office of President-Elect, and not less than 4 percent for each of the other offices. For the purpose of circulating petitions, address labels will be made available by the Secretary at cost.

## *1977 Nominating Committee of the AEA*

In accordance with Section IV, paragraph 2, of the bylaws of the American Economic Association as amended in 1972, President-Elect Lawrence Klein has appointed a Nominating Committee for 1977 consisting of Walter W. Heller, Chairman; Nancy S. Barrett, Huey J. Battle, David M. Gordon, Bert G. Hickman, Irving B. Kravis, and Ralph W. Pfouts. Attention of members is called to the part of the bylaw reading, "In addition to appointees chosen by the President-elect, the Committee shall include any other member of the Association nominated by petition including signature and addresses of not less than 2 percent of the members of the Association, delivered to the Secretary before December 1. No member of the Association may validly petition for more than one nominee for the Committee. The names of the committee shall be announced to the membership immediately following its appointment and the membership invited to suggest nominees for the various offices to the Committee."

The Executive Committee of the American Economic Association, at its March 1976 meeting, voted to establish an ad hoc committee to explore the problems and issues involved in the federal funding of economic research, and to advise the Executive Committee whether the Association should take a more active role in seeking research support. The ad hoc committee is to report to the next meeting of the Executive Committee, September 15, 1976, in Atlantic City.

The ad hoc committee is chaired by Stanley Lebergott, Wesleyan University, and includes the following members: Milton Friedman, University of Chicago; Gary Fromm, National Bureau of Economic Research; Zvi Griliches, Harvard University; and Robert Solow, Massachusetts Institute of Technology.

Any member of the Association who is interested in the issues and wishes his or her views to be considered by the ad hoc committee is invited to communicate promptly with the chairman or any of its members.

The U.S. Census Bureau is now working on plans for the 1980 census and decisions have to be made in the relatively near future. For example, the full content of

the basic census questionnaire must be determined by the spring of 1977 so that further preparatory steps can be accomplished successfully. Although there are many constraints on the census in terms of what and how much information can be collected and tabulated, the Bureau believes that it is very important to obtain and review the recommendations of as wide a range of users and potential users of decennial census data as possible. The Census Bureau is therefore anxious to have the ideas of members of the American Economic Association. If you have any suggestions, questions, or comments on the 1980 census, please send them to the Director, U.S. Bureau of the Census, Washington, D.C. 20233.

---

The annual meeting of the International Studies Association/South will be held at the University of Virginia, Charlottesville, late October 1976. The theme of the conference is "The New International Economic Order." Persons interested in presenting papers or taking part in the program should contact the program chairman, Professor William Tyler, department of economics, University of Florida, Gainesville, FL 32611.

---

The University of Missouri-Rolla, in cooperation with the Missouri Energy Council is sponsoring the third annual UMR/MEC Energy Conference, to be held October 12–14, 1976. The theme is "Energy Crises: An Evaluation of Our Resource Potential." Papers, which may be of an applied, theoretical, or interdisciplinary nature, should be submitted for review as soon as possible. Economists from government and industry as well as academic economists are encouraged to participate. The program chairpersons are Christopher Garbacz, Vaman Rao, and William Desvousges, Economics, University of Missouri-Rolla, Rolla, Missouri 65401.

---

The Regional Science Association announces the second Victoria Lapham Dissertation Award for research on the problem of measurement, valuation, and analysis of neighborhood effects. The award will consist of a stipend of $5,000 plus tuition and fees to enable a Ph.D. candidate to devote full time to his(her) dissertation during 1976–77. For additional information, write David E. Boyce, Secretary, Regional Science Association, 3718 Locust Walk, Philadelphia, PA 19174.

---

Old Dominion University and Norfolk State College invite participation in the third annual Conference on The Urban South, to be held February 17 and 18, 1977, on the campus of Old Dominion University. The conference is designed to bring together urban specialists from all the social sciences and from public life in a series of multidisciplinary meetings and panels. Persons interested in participating in the conference should contact Professor Carl Abbott, Department of History, Old Dominion University, Norfolk, VA 23508, or Professor Robert Wolensky, Department of Sociology Norfolk, State College, Norfolk, VA 23504, by September 15, 1976.

---

A file of back issues of the *American Economic Review* (1967–75) will be donated to a library or educational institution. Anyone interested in receiving such a donation should apply to Dexter M. Keezer, Truro, Massachusetts 02666.

---

*Notice of cancellation* of the Amos Tuck School Seminar on Problems of Regulation and Public Utilities. The announcement printed in the March issue of this *Review*, page 247, should be disregarded.

---

Economists who are *strongly* oriented toward the humanities, who use humanistic methods in their research, and who will be participating in meetings abroad that are concerned with the humanistic aspects of their discipline are eligible to apply for travel grants of the American Council of Learned Societies. Specifically, economists may be eligible if (a) they deal with the history of economic thought or economic history, and (b) if their approach is qualitative and descriptive rather than quantitative and statistical. Conferences dealing with the establishment of social policy or legislation are generally ineligible. The deadlines for applications to be received in the office of the American Economic Association are: for meetings scheduled between June and September, February 15; for meetings scheduled between October and January, June 15; for meetings scheduled between February and May, October 15. Application forms may be obtained from C. Elton Hinshaw, Secretary, American Economic Association, 1313 21st Avenue South, Nashville, Tennessee 37212.

---

## *Deaths*

James J. Breen, department of economics, Clark University, Jan. 13, 1976.

William B. Gates, Jr., professor of economics, Williams College, Dec. 22, 1975.

James A. Maxwell, department of economics, Clark University, Dec. 31, 1975.

Clara Eliot Raup, Palo Alto, California, Jan. 17, 1976.

Abraham C. Burstein, director of economic research, New York City Human Resources Administration, Apr. 1975.

## *Visiting Foreign Scholars*

Pekka Ahtiala, University of Tampere, Finland: visiting professor of economics, Northwestern University, Jan. 1, 1976.

## *Promotions*

Michael S. Anselmi: assistant professor, department of economics, geography, and management, U.S. Air Force Academy, July 1, 1975.

Ashok Bhargava: assistant professor, department of

economics, University of Wisconsin-Whitewater, fall 1975.

Howard A. Clark: assistant professor, department of economics, geography, and management, U.S. Air Force Academy, July 1, 1975.

Kenneth H. Fleming: assistant professor, department of economics, geography, and management, U.S. Air Force Academy, Jan. 1, 1976.

John C. Fletcher: assistant professor, department of economics, geography, and management, U.S. Air Force Academy, July 1, 1975.

Karl D. Gregory: professor, School of Economics and Management, Oakland University.

Robert L. Gustavson: assistant professor, department of economics, geography, and management, U.S. Air Force Academy, Jan. 1, 1976.

Kenneth M. Hammer: professor of economics, University of Wisconsin-Whitewater, fall 1975.

Robert O. Heavner: assistant professor, department of economics, geography, and management, U.S. Air Force Academy, Jan. 1, 1976.

Gregory C. Hildebrandt: assistant professor, department of economics, geography, and management, U.S. Air Force Academy, Jan. 1, 1976.

Kirk Y. K. Kim: associate professor, department of economics, University of Wisconsin-Whitewater, fall 1975.

Stuart C. Kirk: assistant professor, department of economics, geography, and management, U.S. Air Force Academy, July 1, 1975.

Leon Korobow: assistant vice president, Bank Supervision and Relations Function, Federal Reserve Bank of New York, Jan. 1, 1976.

Bruce D. Mills: assistant professor, department of economics, geography, and management, U.S. Air Force Academy, Jan. 1, 1976.

Russell R. Raney: professor of economics, University of Dayton, Sept. 1976.

William E. Straw: assistant professor, department of economics, geography, and management, U.S. Air Force Academy, Jan. 1, 1976.

Robert L. Taylor: associate professor, department of economics, geography, and management, U.S. Air Force Academy, July 1, 1975.

F. Ray Webb: assistant professor, department of economics, geography, and management, U.S. Air Force Academy, July 1, 1975.

William J. Weida: assistant professor, department of economics, geography, and management, U.S. Air Force Academy, Jan. 1, 1976.

Allen E. Wolf: associate professor, department of economics, geography, and management, U.S. Air Force Academy, July 1, 1975.

Lloyd Woodman, Jr.: associate professor, department of economics, geography, and management, U.S. Air Force Academy, Jan. 1, 1976.

Charles J. Yoos II: assistant professor, department of economics, geography, and management, U.S. Air Force Academy, July 1, 1975.

Roger J. Zoeller: assistant professor, department of economics, geography, and management, U.S. Air Force Academy, Jan. 1, 1975.

### *Administrative Appointments*

Kirk Y. K. Kim: chairman, department of economics, University of Wisconsin-Whitewater, fall 1975.

David J. Cantor: associate dean, Golden Gate University, Feb. 1, 1976.

### *Appointments*

John Achterhof: research associate, department of economics, Iowa State University, Sept. 1, 1975.

Lizardo de las Casas: research associate, department of economics, Iowa State University, Oct. 1, 1975.

J. Markham Collins: assistant professor of economics, University of Dayton, Sept. 1, 1975.

Leslie C. Denend: instructor, department of economics, geography, and management, U.S. Air Force Academy, July 1, 1975.

Robert C. Drury: University of Wisconsin-Milwaukee: instructor, department of economics, University of Wisconsin-Whitewater, fall 1975.

Linda Edwards: research associate, National Bureau of Economic Research, Dec. 1, 1975

Dana R. Katnik: instructor, department of economics, geography, and management, U.S. Air Force Academy, July 1, 1975.

Abba P. Lerner: visiting professor, department of economics, Florida State University, Jan. 1976.

Hosseine Morewedge, University of Southern California: visiting professor of petroleum economics, University of Washington, Dec. 23, 1975.

Ronald H. Rasch: instructor, department of economics, geography, and management, U.S. Air Force Academy, July 1, 1975.

Dorothy P. Rice: director, National Center for Health Statistics, U.S. Department of Health, Education, and Welfare.

Thomas P. Rothrock, University of Missouri: instructor, department of economics, University of Wisconsin-Whitewater, fall 1975.

Henry H. Stick: associate professor of finance, University of Dayton, Sept. 1, 1975.

John Strauss: assistant professor, department of economics, Iowa State University, Sept. 10, 1975.

James B. Streets: instructor, department of economics, geography, and management, U.S. Air Force Academy, Jan. 1, 1976.

### *Leaves for Special Appointments*

Pekka Ahtiala, University of Tampere, Finland: Minister of Economic Affairs of Finland, 1975.

Istvan B'Racz, Quinnipiac College: National Science Foundation Faculty Fellow, department of economics, Columbia University, Jan.-Dec. 1976.

Paul F. Rizza, Slippery Rock State College: Fulbright lecturer, Helsinki School of Economics, Jan. 1976.

Ron D. White, Wichita State University: Evaluation and Systems Studies Branch, Federal Energy Administration, Feb. 2, 1976.

### *Resignations*

Richard A. Levins, Iowa State University, Sept. 16, 1975.

## NOTE TO DEPARTMENTAL SECRETARIES AND EXECUTIVE OFFICERS

When sending information to the *Review* for inclusion in the Notes Section, please use the following style:

A. Please use the following categories:

1—Deaths
2—Retirements
3—Foreign Scholars (visiting the USA or Canada)
4—Promotions
5—Administrative Appointments
6—New Appointments
7—Leaves for Special Appointments (NOT Sabbaticals)
8—Resignations
9—Miscellaneous

B. Please give the name of the individual (SMITH, John W.), his present place of employment or enrollment: his new title (if any), and the date at which the change will occur.

C. Type each item on a separate 3x5 card and please do not send public relations releases.

D. The closing dates for each issue are as follows: *March*, November 1; *June*, February 1; *September*, May 1; *December*, August 1.

This announcement supersedes and replaces a letter which was sent annually from the managing editor's office. All items and information should be sent to the Assistant Editor, *American Economic Review*, Box Q, Brown University, Providence, Rhode Island 02912.

*Please mention* THE AMERICAN ECONOMIC REVIEW *When Writing to Advertisers*

# The American Economic Review

## ARTICLES

SEPTEMBER 1976

# THE AMERICAN ECONOMIC ASSOCIATION

Founded in 1885

• Published at George Banta Co., Inc., Menasha, Wisconsin.

• THE AMERICAN ECONOMIC REVIEW, including four quarterly numbers, the *Proceedings* of the annual meetings, the *Directory*, and Supplements, is published by the American Economic Association and is sent to all members five times a year, in March, May, June, September, and December.

Association membership dues for 1976, which include a subscription to both The *American Economic Review* and the *Journal of Economic Literature*, are as follows:

$25.00 for regular members with rank of assistant professor or lower, or with annual income of $12,000 or less;

$30.00 for regular members with rank of associate professor, or with annual income of $12,000 to $20,000;

$35.00 for regular members with rank of full professor, or with annual income above $20,000;

$12.50 for junior members (registered students). Certification must be submitted yearly.

Subscriptions (libraries, institutions, or firms) are $37.50 a year. Only subscriptions to both publications will be accepted. Single copies of either journal may be purchased from the Secretary's office, Nashville, Tennessee.

For foreign postage, add: PUAS countries, $3.20; all other countries and Canada, $3.75.

• Correspondence relating to the *Papers and Proceedings*, the *Directory*, advertising, permission to quote, business matters, subscriptions, membership and changes of address should be sent to the Secretary, C. Elton Hinshaw, 1313 21st Avenue South, Nashville, Tennessee 37212. Change of address must reach the Secretary at least six (6) weeks prior to the month of publication. The Association's publications are mailed second class.

• Second-class postage paid at Nashville, Tennessee and at additional mailing offices. Printed in U.S.A.

# THE AMERICAN ECONOMIC REVIEW

September 1976

VOLUME 66, NUMBER 4

• Manuscripts and editorial correspondence relating to the regular quarterly issue of this REVIEW should be addressed to George H. Borts, Managing Editor of THE AMERICAN ECONOMIC REVIEW, Brown University, Providence, R.I. 02912. Manuscripts should be submitted in duplicate and in acceptable form and should be no longer than 50 pages of double-spaced typescript. A submission fee must accompany each manuscript: $15 for members; $30 for nonmembers. *Style Instructions* for guidance in preparing manuscripts will be provided upon request to the editor.

# The Inflationary Mechanism in the U.K. Economy

*By* R. J. Ball and T. Burns*

Perhaps one might be forgiven for supposing that, after thirty years of continuing inflation in the United Kingdom, a clear consensus would have emerged among economists, politicians, and men of business as to the causes of that inflation and the steps necessary for its cure. Unfortunately, this is not the case, although the disagreements are often exaggerated for political purposes and the arguments polarized in the sharpness of academic debate. The latest trend in the United Kingdom is to divide the participants into "Keynesians" and "monetarists," to do battle like mediaeval knights jousting at the tournament.

The explanation of prevailing disagreements is in itself complex. It is partly ascribable to the usual difficulties of adequately testing alternative hypotheses against limited sets of time-series data when it is not always possible to reject particular hypotheses against the statistical facts. It must also be said that differences arise that are not so much closely allied to analytical arguments, but which reflect the taste or persuasion of individuals with regard to prescriptions for policy. It is not unknown for positions to be rationalized by subsequent analysis rather than the logical development proceeding in the opposite direction.[1]

In this paper, we argue that the inflationary process in the *U.K.* economy cannot be simply fitted into either a so-called monetary or a Keynesian framework. The process is a more complicated one that cannot be described simply in terms of the behavior of the money supply on the one hand or the behavior of organized labor on the other. In agreement with the monetarists, it is important to differentiate between the inflationary process under fixed and floating exchange rate regimes, while in opposition to them, we assign a more important role to price and wage inflexibilities in the analysis of imported inflation and the process of adjustment to monetary change.

The discussion is divided into two main sections. In Section I, we attempt to clear the ground by reviewing the analytical arguments that frame the conclusions drawn from empirical data, and in Section II, apply the analysis to an examination of inflation in the *U.K.* economy over the last twenty years. Finally, we make some observations with regard to inflation policy.

## I

### A. *Do Trades Unions Cause Inflation?*

To this question, the monetarist gives a clear negative answer. In his world of flexible and adjustable labor markets, a stable (not necessarily zero) rate of inflation is associated in a closed economy with a unique or "natural" rate of unemployment.[2] The story in an open economy,

* Professor of economics, and senior lecturer in economics, respectively, London Business School.

[1] It is interesting to observe the situation in the United States in the late 1950's when industrial leaders ascribed inflation to trades unions, and trades unions were ascribing it to market forces. In the United Kingdom at the time, the reverse was true. Differences in preferred policies largely account for this intercountry difference at the time.

[2] As set out by Milton Friedman (1968).

which is discussed below, is not as simple, but the conclusion about the role of trades unions remains essentially the same. Given the natural rate of unemployment and equilibrium in the overall labor market, the stable rate of inflation will then depend on the rate of increase of the money stock per unit of output. Trades unions in this story cannot affect the rate of inflation, but they can affect the rate of unemployment that is consistent with a stable rate of inflation, by helping to determine the position of the aggregate supply curve for labor. The conclusion that emerges is that the actions of trades unions cannot affect the long-term rate of inflation, but can affect the level of employment. Or, putting the matter more dramatically, trades unions do not cause inflation, they cause unemployment. This argument manifestly depends on certain assumptions about the role of supply and demand in determining the level of aggregate real wages and certain further assumptions about the flexibility of both nominal wages and prices in the adjustment process.

The critics of this position have tended to be characterized as Keynesians with no belief in the working of market forces and who espouse a particularly crude theory of the way in which the monopoly power of trades unions affects the rate of increase in costs and subsequently prices.[3] Using this model, the Keynesians in Britain have been taken to assume that the money wage level is essentially exogenous and that no attention is paid by anyone other than the hardline monetarists to the behavior of the money supply in the inflationary process. It is possible that there are those who would adopt such a view, although an examination of the literature suggests that this is a straw man largely invented rather than reflecting any major body of thought. Notable exceptions perhaps can be found in the contribution of Albert G. Hines and in a recent article by Lord Kahn. It is, however, not shared by a large number of economists who would probably describe themselves as of a Keynesian persuasion.

A more sophisticated version of the argument and one which gained some credibility in the 1960's goes as follows. In the short run, the power of trades unions does permit them to force up the level of money wages and prices at a given level of employment. In addition, it may be agreed that no inflation is likely to be sustained for any significant period without an increase in the quantity of money, ruling out for the sake of argument any escape due to a rise in the velocity of circulation. If the authorities wish to sustain the level of employment then, following this union pressure on wages and prices, the money supply must be allowed to rise to accommodate it. If the increase in the money supply does not take place then, in the longer run, persistent inflationary pressure from trades unions must result in rising unemployment until, if the traditional Phillips curve is in operation, rising unemployment will choke off the rate of inflation. Thus, while in the monetarist world the trades unions can affect the rate of unemployment, in this world they can affect both the rate of inflation and the rate of unemployment. If monetary policy is accommodating, the conclusion is that the economy is operating on a labor standard in the sense defined by John Hicks (1955) whereas, if the authorities stand firm in the face of trade union pressure, unions can choose their rate of inflation or their unemployment rate, but not both. Under this argument, the Phillips curve does not vanish in the long run as expected, but approaches actual inflation in the sense of Friedman and Edmund Phelps. There is a long-run tradeoff between the rate of unemployment and the rate of wage change. The critical issue in this scenario turns not on a simple question about the monopoly power of unions, but on the specification and nature of the Phillips curve itself. The proponents of this

[3] The argument is put with particular force by A. A. Walters.

view might, therefore, agree with the monetarists that a tight control of the money supply is an essential part of any policy to contain inflation.

The practical consequences of such a model are, however, complicated by the view held by many that the volume of unemployment required to restrain the power of the unions is neither socially nor politically acceptable, so that other means must be found through some version of incomes policy to restrain the unions from requiring the authorities to enforce the unemployment/inflation tradeoff. In principle, this is in itself an empirically testable proposition, although in practice there have been some technical difficulties in establishing an acceptable statistical estimate of versions of the Phillips curve since the mid-1960's. Moreover, there is disagreement as to whether even the more stable unemployment/wage relationships estimated before that period can be interpreted as reflecting labor market behavior or the effects of changes in profitability rather than unemployment itself. (For example, see Ball, 1973, Hicks, 1975, and Kahn.)

In addition, there is a further aspect of the role of trades unions discussed by Ball (1973) which focuses on the wage transmission mechanism that operates to diffuse wage increases through the economy as a whole. This mechanism is discussed in Section Ic below. The upshot of this argument is that the existence and raison d'être of trades unions introduces inflexibilities into the labor market in the short run in such a way that inflationary pressure is created by the adjustments of relative prices to relative costs between different sectors, which is exacerbated in an open economy operating with a fixed exchange rate.[4]

Our own view as will be clearly demonstrated in Section II of this paper is that inflation in the United Kingdom since the war cannot be related in any simple way to the monopoly power exercised by trades unions. This is not to say that the power and strength of trades unions is irrelevant to understanding the inflationary process. It is to say that the power of trades unions and the pattern of collective bargaining introduces inflexibilities into the way in which the money wage level responds to changes in the pressure of demand and forces the authorities into difficult decisions with regard to the tradeoff between unemployment and the inflation rate.

### B. *The Role of Demand*

The role of demand and its effect on output and prices cannot be discussed independently of what assumptions are made about the exchange rate regime that is in operation. We begin with a fixed rate system operating in the context of an economy such as the United Kingdom that is substantially open.

In such an economy, demand pressure will not necessarily exert a great deal of direct pressure on prices, but will manifest itself in a material deterioration in the balance of payments. As long as the exchange rate is maintained then, in the open economy, the scope for manufacturers to pass on cost increases is limited by the behavior of world prices. In this case, the major impact of wage increases that results from excessive demand would be expected to be upon nonmanufactured prices, company profits, and ultimately unemployment, although clearly there is a limit to the extent that the balance of payments can deteriorate without putting pressure upon the exchange rate. Demand pressure and the consequent power of

[4] The argument is set out by Ball (1973), pp. 254–55. A mythology as to our views on this matter since has arisen from the fact that, for short period forecasting in the early 1970's, the money wage rate was treated as exogenous. The reasons for this are set out in Ball (1971). We have never suggested that the money wage is an institutional datum determined by trade union monopoly power as some critics seem to believe. A careful reading of Ball (1973) and its first edition in 1964 should make that clear.

trades unions also have an important role in determining the views of the authorities with regard to the exchange rate, and it has been widely assumed that, if the government's "target" rate of unemployment cannot be met in association with a satisfactory balance of payments, then the exchange rate is in disequilibrium. Hence, throughout the postwar period, there has been a presumption that the exchange rate may be used as an instrument to solve the dilemma.

However, along with others,[5] it has been argued at length by Ball, Burns, and J. S. E. Laury, that under free collective bargaining the effects of devaluation on the balance of payments are only temporary and that devaluation will be followed by an adjustment of both wages and prices to the higher sterling prices of both exports and imports. Thus, under a fixed exchange rate system, the ultimate effects of excessive demand pressure will operate on the price level at one remove, by causing the exchange rate to be depreciated, so diverting the demand pressure from the balance of payments to the domestic price level, leaving the authorities faced with the inevitable choice of devaluing the currency or sitting out the required rate of unemployment.

By common consent, the role of the money supply in this fixed exchange rate system is limited. Under this system, even the monetarists must concede that the stock of money is essentially demand rather than supply determined. Normally, the required money balances will be supplied by the authorities. The monetary approach tells us that a shortage or an excess of money balances will be provided or eliminated through the medium of a balance-of-payments surplus or deficit. Given this analysis under a fixed rate system, which has largely characterized the United Kingdom since 1945, it is surprising that correlations between money and prices for the economy established by those of a monetary persuasion have been interpreted as showing the causality flowing from money to prices, rather than the other way around for most of the period. Until mid-1972, Britain operated an essentially fixed rate system which, as discussed in the next section, hardly makes it plausible to account at one stroke for the rate of inflation in simple money supply terms. As has often been emphasized (for example, by Johnson), with a fixed exchange rate system, the key monetary variable becomes the rate of domestic credit expansion and its major role is the determination of the balance of payments and the split of the increase in the money supply between domestic and overseas money.

Under a floating exchange rate system, however, the picture changes to an extent that does not seem to have been grasped in the United Kingdom where the inflation debate has followed a rather rigid cost versus demand format for over twenty years. In principle, a floating exchange rate returns to each country the power to determine its own rate of inflation rather than being dictated to by the outside world. Under a floating regime, the rules change. Interest rates have a major impact on domestic monetary conditions; demand changes and particularly monetary expansions now make themselves felt on the declining exchange rate and the subsequent inflation, rather than on the balance of payments. Large balance-of-payments deficits may occur without the predictable currency crisis that would have accompanied even smaller deficits under a fixed rate system. As argued in the next section, this means that an empirical account of the history of the inflation in the postwar years must distinguish clearly between the prefloating and postfloating eras.

[5] Particularly proponents of the monetary theory of the balance of payments, e.g., Rudiger Dornbusch, Harry Johnson, Robert Mundell. Their ideas have been used to specify models, which in principle can be estimated, e.g., David Laidler, Peter Jonson.

### C. *Productivity Inflation*

Neither the monetarists nor the proponents of the simple Phillips curve analysis have adequately integrated into their accounts of the inflationary process the stresses introduced by differential rates of productivity growth throughout the economy, both between the fast and slow growing sectors of the economy and between traded and nontraded goods.

The general thesis is that money wages and prices exhibit strong downward rigidities for a variety of reasons, including the basic role of trades unions in negotiating money wages. Given a high degree of money wage inflexibility in a downward direction, changes in relative prices in line with changes in relative costs are associated with a rise in the general price level at any given rate of unemployment. Put another way, with downward price rigidity, inflation becomes a method of distributing the gains of increased efficiency throughout the economy.[6]

The significance of this mechanism is denied by the monetarists at the outset on the general ground that such price and wage rigidity cannot be demonstrated to exist. To quote Michal Parkin, "There is no reason to suppose why wages in the fast growing sectors should not rise less quickly than productivity with prices of the output of that sector falling. Indeed, that has been quite common across a wide range of manufactures" (p. 37). We would argue that this is untrue other than in electronics and certain high technology industries. It is indeed the case that there have been major shifts in the United Kingdom in *relative* prices since the war, but one would be hard put to substantiate that there have been widespread falls in *absolute* prices; indeed the overall rate of inflation of the prices of manufactured goods discussed in the next section makes it clear that this cannot have been the case. The resolution of the issue must largely depend on circumstances as yet not experienced, rather than from historical data analysis. Parkin goes on to argue that, "Finally, the hypothesis is quite incapable of explaining the wage explosion of the late 1960's." That is indeed true, but the argument developed later in this paper does not require this to be the case. The problem raised under this heading is only part of the total story, providing a mechanism whereby inflation is transmitted throughout the economy.

[6] See Ball (1973), pp. 289–301.

### D. *Can Rising Import Prices Cause Inflation?*

Since the deterioration of the *U.K.* balance of payments in 1973, and the inflation rate in 1973 and 1974, there has been a major debate as to how far the behavior of the balance of payments and the rate of inflation can be ascribed to external influences resulting in rising levels of import prices.

The monetarist answer is simple. Rising import prices cannot cause inflation provided that the government stabilizes the supply of money, since the rise in the price of imported goods will be offset by falls in the prices of other goods, keeping the average the same. The case is simply put by Walters who argues that for import prices to affect the rate of inflation is to deny the laws of supply and demand. Furthermore, they argue that the existence of a balance-of-payments deficit implies that the country concerned is exporting inflation, because the growth of money supply will be less than the rate of domestic credit expansion and the level of demand is higher than in the world as a whole.

To this, there are three answers. The first is that, even accepting the argument at face value, there is no mention of the time span over which this behavior of the average price level is to be distributed, particularly as the *U.K.* monetarists have gone out of their way to emphasize the

long lags in adjustment in the economic system. Thus, whatever the long-run outcome of the policy prescribed, it could still be true that, over a significant period (say, eighteen months), the rise in the price level could be directly attributed to the rise in import prices.

The second answer takes us back to the whole question of price inflexibility which, as we have seen, is rejected by the monetarists in connection with the discussion of productivity inflation. A priori appeals to price flexibility do not settle the issue as to whether rising import prices can or cannot permanently raise the price level. If money prices in general are sufficiently inflexible downwards then, other things being equal, rising import prices can raise both the levels of unemployment and the price level at the same time.

Thirdly, the monetarist argument assumes a degree of substitutability between externally and domestically produced goods that does not exist. As emphasized by J. Bispham, the extreme example of this arises in the case of the oil price. No one believes (except perhaps an extreme monetarist) that for the world as a whole to have attempted to offset the inflationary effects of the rise in the world oil price by policies of severe demand restrain would not have produced a most disastrous deepening of the depression on top of what actually took place. Once again, we are back to the question of the flexibility of wages and prices and the costs of adjustment which probably as a substantive issue divide some of us more from the general position of the monetarists than any other.[7] It may well be the case that this degree of flexibility varies from country to country and where there are strong trades unions and a dominant oligopolistic industry the problem is worse. For the United Kingdom, we believe that is a problem within the range of unemployment and growth experienced since the war.

In a discussion of the impact of import prices, it is useful to distinguish between increases in the prices of world manufactures (in which market the United Kingdom can compete) and increases in the prices of commodities (in which the United Kingdom cannot compete). In the case of an increase in the world manufactured price level, it is fair to argue that this should be accompanied by a balance-of-payments surplus and it is open to the United Kingdom to resist this by stabilizing the supply of money and allowing the exchange rate to appreciate. This policy was successfully pursued by Germany during this period. The difficulty with this strategy is that, because of time lags and short-run imperfections in the market, this will normally involve a short-run loss of competitiveness as exchange rates adjust ahead of prices. Thus, during the 1972-75 period, the German dollar export price level rose faster than the *U.K.* dollar export price level.[8] This may appear to be a reasonable price to pay, but the emphasis throughout this period in Britain has been upon the need to remain "competitive" in order to protect employment and manufacturing industry. To this extent, the monetarists are right, although it is important to recognize the short-term effect of the lags involved. However, when com-

[7] In this respect, we are inclined to side in part with Friedman (1970) as against James Tobin. Price and wage inflexibility plays an important role in our analysis. Our differences with the monetarists do not primarily stem from the specification of the liquidity preference function which we believe to have been improperly specified by Keynes. However, we would not accept Friedman's view that wage inflexibility is a deus ex machina introduced out of thin air. We take it as an observed and important fact about how the *U.K.* economy has operated.

[8] Between 1972 and the first quarter of 1975, the dollar value of world manufacturing export prices rose by 66 percent. West German manufacturing prices rose over the same period by 74 percent and the United Kingdom's by 53 percent. See *NIESR Review* published by the National Institute of Economic and Social Research, November 1975, Table 19.

modity prices rise faster than manufactured prices, the nature of the problem changes. It is not possible to revalue against an adverse movement of the terms of trade against manufactures without seriously affecting manufacturing exports. The problem is to adjust to the terms of trade movement. Given the degree of price inflexibility, it is inevitable that this will lead to an increase in the average price level even if domestic costs do not change. Moreover, there is a second set of problems involved in the reaction of wages to the terms of trade movement. In the face of powerful bargaining groups, the share of labor incomes in the economy is likely to rise substantially at the expense of profits as wages rise in reaction to the price increases. This presents the government with the kind of dilemma outlined above, with the further problem that a substantial proportion of its own expenditure is upon wages and salaries. One strategy is to allow company liquidity to decline, to insist on raising state industry prices and to raise taxes to cover any increase in its costs with the inevitable effects upon unemployment. The second is to attempt to subsidize prices, to allow the budgetary position to deteriorate, to borrow from abroad, and attempt to obtain some social control of incomes. Both strategies involve severe political risks.

## II

### A. *The Inflationary Process—Pre-1967*

Following our discussion of Section I, we now apply the conclusions to an examination of inflation in the British economy over the last twenty years. Initially, it is useful to divide the period under consideration into three. The first lasts from the end of the Korean War to 1967 and the sterling devaluation. This was a period of fixed exchange rates and a time when the world price level showed only a modest average increase. Between 1954 and 1967, the average British inflation rate, measured by the retail price index, was 3.2 percent per annum while the consumer spending deflator during the same period rose on average by 3 percent per annum. This was a faster increase than in the United States and Germany during this period (1.7 and 2.3 percent per annum, respectively), but slower than in Japan (3.7 percent per annum) and France (4.25 percent per annum).[9]

TABLE 1—AVERAGE PRICE INCREASE: 1954–67

Britain traded substantially in the market for manufactured goods in which competition increased steadily through the years and the increase in Britain's manufactured prices was substantially set by the world price level. The average inflation rates for this period are shown in Table 1. Over these years, the world export price for manufactured goods rose by only 1.1 percent per annum, while the *U.K.* export price of manufactures rose by 2.2 percent per annum. British wholesale prices of manufactures rose by the same amount as export prices, suggesting that export prices are representative of manufacturing prices as a whole. The purchasing power parity doctrine[10] suggests that these price levels should move together because of the high substitution rates between countries brought

[9] It is worth underlining these figures. It seems nowadays to be taken for granted that the United Kingdom has always headed the inflation league since the war. This is simply not so. With the notable exceptions of the United States and Germany as quoted, the British inflation rate was less than many, until the events of the 1970's that are discussed subsequently. The source of the figures is the *NIESR Review*, November 1975, Table 18, and previous issues.
[10] See Gustav Cassell.

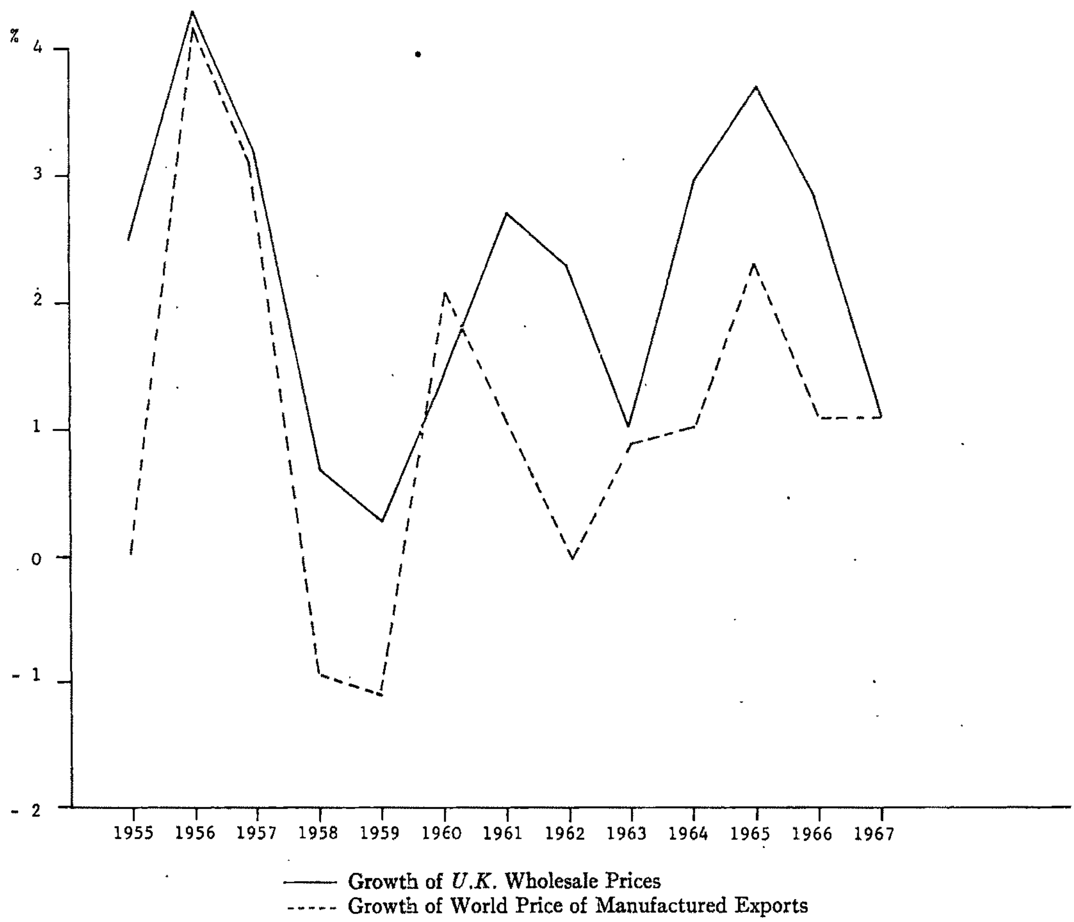

FIGURE 1. *U.K.* WHOLESALE PRICES AND WORLD MANUFACTURED EXPORT PRICES

about by the high degree of competition in the market for manufactures. Figure 1 shows that over the period[11] the cyclical movement in the growth of *U.K.* wholesale prices was substantially the same as for world export prices of manufactured goods, although throughout, British prices rose faster. Two alternative, but not incompatible, reasons can be advanced for this discrepancy. The first is that competition in the market for manufactured goods is imperfect and export prices are affected by the behavior of domestic costs which, in the United Kingdom, were rising at a faster rate than unit costs in the world as a whole. The second is that, while the equilibrium prices for manufactured goods will move together, it is possible for a country to be over- or undervalued as a result of large exchange rate changes and this discrepancy is only gradually removed. Thus, during the period of adjustment, the price level in the country that is initially undervalued will rise at a faster rate than prices in the world as a whole. Similarly, the price level in an initially overvalued currency would rise less rapidly than for the world as a whole. In principle, this process of adjustment will take place in a competitive market for demand reasons or in an

[11] See data source, Table 1.

FIGURE 2. *U.K.* AND *U.S.* REAL EXCHANGE RATE (1958 PRICES)

*Sources:* London and Cambridge Economic Service; *Economic Trends; Historical Statistics of the United States; Statistical Abstract of the United States, 1975.*

imperfectly competitive market because undervaluation of the currency reduces real income and puts upward pressure upon wages. The higher wage levels in turn lead to price increases until equilibrium is reached relative to the world price level. It seems to us quite plausible to assume that in 1954 sterling was still undervalued following the excessive devaluation of 1949 and a substantial part of the faster rise in export prices experienced in Britain represents an adjustment to the world price level as described above.

Some evidence for this view is shown in Figure 2. This shows the behavior during the century of the "real" exchange rate between Britain and the United States; i.e., the nominal exchange rate multiplied by the relative price levels in the United Kingdom and the United States. The price indices are based upon 1958 and therefore the real exchange rate is in 1958 prices. During most of this century, this real exchange rate has been relatively stable other than during wars or following substantial nominal currency appreciations and depreciations. Following these disturbances, the tendency has been for the relative price levels to adjust, so that the real average rate returns to "par," which over the period has averaged around three dollars to the pound in 1958 prices. As has been emphasized by Bela Balassa, there is no necessity for this real exchange rate to be constant; the exchange rate can only be expected in the long run to equalize traded goods prices, whereas the consumer price indices used here include nontraded prices. The movement of the consumer price index relative to export prices assuming money wage equalization within an economy will depend upon the relative growth of productivity in the traded and nontraded sectors. The faster that productivity rises in the traded sector relative to the nontraded sector, then the faster nontraded prices will rise relative to traded prices and the faster the retail price index will rise relative to export prices. A similar effect will result the higher is the share of

TABLE 2—BEHAVIOR OF WHOLESALE AND RETAIL PRICES: 1970=100

| | Prices | | Earnings | | Output per person employed | |
|---|---|---|---|---|---|---|
| | Wholesale Manufactures | Retail | Manufacturing | Whole Economy | Manufacturing | Whole Economy |
| 1963 | 78.0 | 73.9 | 64.2 | 64.9 | 77.9 | 82.1 |
| 1964 | 80.3 | 76.3 | 69.1 | 69.6 | 84.0 | 85.0 |
| 1965 | 83.3 | 80.0 | 73.8 | 74.7 | 85.4 | 87.5 |
| 1966 | 85.6 | 83.1 | 78.4 | 79.6 | 86.9 | 88.8 |

[a] Shown in percent.

nontraded goods in the economy. Hence, if the "productivity gap" between the sectors in the United States was higher than in Britain, or the share of nontraded goods higher, the real exchange as measured here would fall over time. However, even if we assume the real exchange rate has been falling over the period,[12] the chart still suggests substantial undervaluation in 1950, and it is the mid-1960's before equilibrium is again reached.

Thus, to summarize the 1954–67 period, *U.K.* export prices rose in total by 15 percent more than world prices, although the cyclical movement was similar. We consider that a substantial part of this excess follows from the undervaluation of sterling at the beginning of the period although wage pressures caused in part by demand pressures may also have had a part to play.

While *U.K.* wholesale prices rose by the same amount as export prices (20 percent), retail prices on the other hand rose by an average of 3.2 percent per annum. The underlying mechanism has been outlined above. Wages in the manufacturing sector are determined by the growth of productivity in manufacturing and the increase in manufacturing prices. Demand pressures and the principle of comparability then results in wages in the nonmanufacturing sector rising by the similar magnitude. It then follows that if prices in the nonmanufacturing sector are determined by unit costs, then prices overall will rise by the growth in manufacturing prices plus a proportion (equal to the share of nonmanufacturing in the economy) of the gap between productivity growth in manufacturing and nonmanufacturing.

This process can be illustrated by the figures in Table 2 where we show the relative behavior of manufactured and retail prices. (On a consistent basis, data are only available since 1963.) Earnings in manufacturing and the whole economy rise by an almost identical 6 percent per annum, but productivity in the economy as a whole only rises by 2.8 percent per annum compared with 3.7 percent per annum for manufacturing alone.

As expected, retail prices (at 3.6 percent per annum) rise faster than manufactured prices (at 2.6 percent per annum) by an amount equal to the growth in manufacturing productivity compared to produc-

[12] The apparent downward trend is strongly influenced by the pre-1914 figures. These are particularly suspect as there are various figures for the *U.S.* consumer prices prior to 1914. For this example, the *U.S.* figures prepared by Albert Rees were used.

TABLE 3—GROWTH OF PRICES IN INDUSTRIAL COUNTRIES[a]

| Average Annual Growth 1958–1967 | Export Prices of manufactures | Consumer Prices | Consumer Prices relative to export prices |
|---|---|---|---|
| United States | 1.6 | 1.6 | 0 |
| Japan | −0.6 | 5.0 | 5.6 |
| France | 2.4 | 3.7 | 1.2 |
| Germany | 1.0 | 2.4 | 1.4 |
| United Kingdom | 1.75 | 2.75 | 0.9 |

*Sources:* Tables 18 and 19, *NIESR Review*, November 1975, and previous issues.
[a] Shown in percent.

tivity growth in the whole economy. The same principle can be seen if we compare the relative growth of total consumer prices and manufactured export prices in the large industrial countries. These figures are shown in Table 3. The results are much as the theory outlined above would suggest. Being the most rapidly growing country, Japan is well ahead of the other countries and has the largest growth of consumer prices relative to export prices; Germany comes second with France third, while Britain and the United States have the smallest gap between the growth of consumer and export prices.

Although seasonally adjusted unemployment remained below 600,000 for the entire period, the trend was unmistakably upward. Measured as a percentage of the labor force, unemployment was less than $1\frac{1}{2}$ percent at the beginning of the period and reached new heights in each recession as the undervaluation of the currency disappeared and the *U.K.* manufactured prices rose faster than world prices, while at the same time as we have already stressed, the share of profits in the economy was steadily reduced.[13] One of the features of the undervaluation of sterling in the early 1950's was the low unemployment rate that followed. The major problem was that this brought with it exaggerated views of the target level of unemployment, leading to the expectation that balance-of-payments equilibrium would be consistent in the longer run with such low rates.

As during each recession unemployment increased to yet higher levels, the authorities met this with even greater reflation in an attempt to arrest its upward movement. The combination of the reflation and the deteriorating relative price position meant that the current account deficit also increased in each cycle: from 0.9 percent of the gross domestic product (*GDP*) at the peak of the 1955 cycle to 1.1 percent in 1960 to 1.2 percent in 1964.[14] Although unemployment was high by postwar standards, the current account was in deficit at almost 1 percent of the *GDP* in 1967 making three years of deficit out of the last four. Sterling was devalued in November of that year in the mistaken belief that the inability to combine the target unemployment rate with an adequate current account performance was due entirely to an incorrect exchange rate rather than a mistaken unemployment target.[15]

## B. *The Inflationary Process: 1967–72*

The second distinct period is from 1967 to 1972. This has many of the characteristics of pre-1967, although it was now set against the background of a sharp acceleration in the world price level, the ad-

[13] Between 1955 and 1967, the share of profits, excluding stock appreciation as a proportion of total domestic incomes, fell from 16.4 to 12.9 percent.

[14] See *National Income and Expenditures*, 1964–74.

[15] This should be qualified by saying that the belief might not necessarily have been mistaken if the subsequent incomes policy pursued by the Labor government had been sustained. In the event, the "real income frustration" described by Ball (1971) persuaded the government to abandon the policy, finally allowing the real income adjustment in the face of the exchange rate change to be blown away. It was a mistaken belief to the extent that the devaluation was undertaken without a realization of the subsequent need to make the community accept the reduction in the rate of growth of real incomes.

TABLE 4—WORLD PRICES AND *U.K.* PRICES: 1967=100

| | World price manufactures | *U.K.* price of manufactures exports | | *U.K.* wholesale prices | *U.K.* retail prices | Earnings in *U.K.* | Unit labor costs |
|---|---|---|---|---|---|---|---|
| | $ | $ | £ | | | | |
| 1967 | 100.0 | 100.0 | 100.0 | 100.0 | 100.0 | 100.0 | 100.0 |
| 1968 | 100.0 | 94.7 | 109.4 | 103.9 | 104.7 | 108.2 | 102.6 |
| 1969 | 101.1 | 97.9 | 113.0 | 108.0 | 110.3 | 116.6 | 107.4 |
| 1970 | 109.9 | 105.3 | 121.5 | 115.6 | 117.4 | 130.6 | 117.6 |
| 1971 | 115.4 | 112.6 | 131.6 | 126.0 | 128.4 | 145.4 | 128.9 |
| 1972 | 124.2 | 122.1 | 135.4 | 132.7 | 137.5 | 164.2 | 140.2 |

*Sources:* Tables 19 and 25, *NIESR Review,* November 1975, and Tables 90 and 93, *Economic Trends.*

justment of prices following the further 15 percent devaluation, and the impact of the wage and price policy in affecting the timing of these adjustments. During most of the period, the economy was subject to substantial deflation via government spending cuts and tax increases so that by 1970 the budget was in surplus to the extent of 1.7 percent of the gross domestic product compared to a deficit of 4.7 percent in 1967.[16] At the same time, this deflation combined with the exchange rate depreciation led to a substantial overseas payments surplus by 1970 and 1971, although by the end of 1971 unemployment had approached the million mark for the first time in the postwar period.

The data are set out in Table 4. After being stable in 1967–69, the world price of manufactured exports (expressed in dollars) rose by 23 percent in the following three years to a figure 24 percent above its 1967 level. The *U.K.* price of manufactured exports (measured similarly) rose by 22 percent over the same period. Naturally, following the devaluation, the British export price level fell (expressed in dollars), but by 1970 it was above its 1967 level and by 1972 it had virtually caught up with the world price and the pre-devaluation situation had been restored. Hence, expressed in sterling over the same period, export prices rose by 35 percent. Once again, the wholesale price index follows the export price level, although with an adjustment lag, but by 1972, it had risen by almost 33 percent over the 1967 level. Retail prices rose by a little under 1 percent per annum faster than wholesale prices again reflecting the productivity gap discussed above. During 1967 to 1969, when the incomes policy was in operation, unit labor costs rose by 2.6 percent less than the retail price index, but by 1970, following the collapse of the incomes policy, that gap had been closed. Wages, costs, and prices kept in step in 1971, but in 1972 wage costs moved almost 2 percent ahead of prices.

In Figure 3, we have plotted the behavior of the *U.K.* share of the world money supply on a dollar basis.[17] This falls steadily from 7 to 6.2 percent from 1963 to 1967, while the *U.K.* share of world industrial output falls from 7.5 to 6.8 percent.[18] Following the 1967 devaluation, the dollar value of the *U.K.* share of the world

[16] See *National Income and Expenditures,* 1964–74.

[17] World money supply is defined here simply as the unweighted sum of the dollar value of the money stock in the United States, Canada, Japan, France, Germany, Italy and the United Kingdom. See *International Financial Statistics.*

[18] The *U.K.*'s share of world industrial output is the ratio of the United Kingdom and O.E.C.D. Industrial Production (1970=100) multiplied by the 1970 weight of 6.2 percent. See *NIESR Review,* November 1975, Table 24.

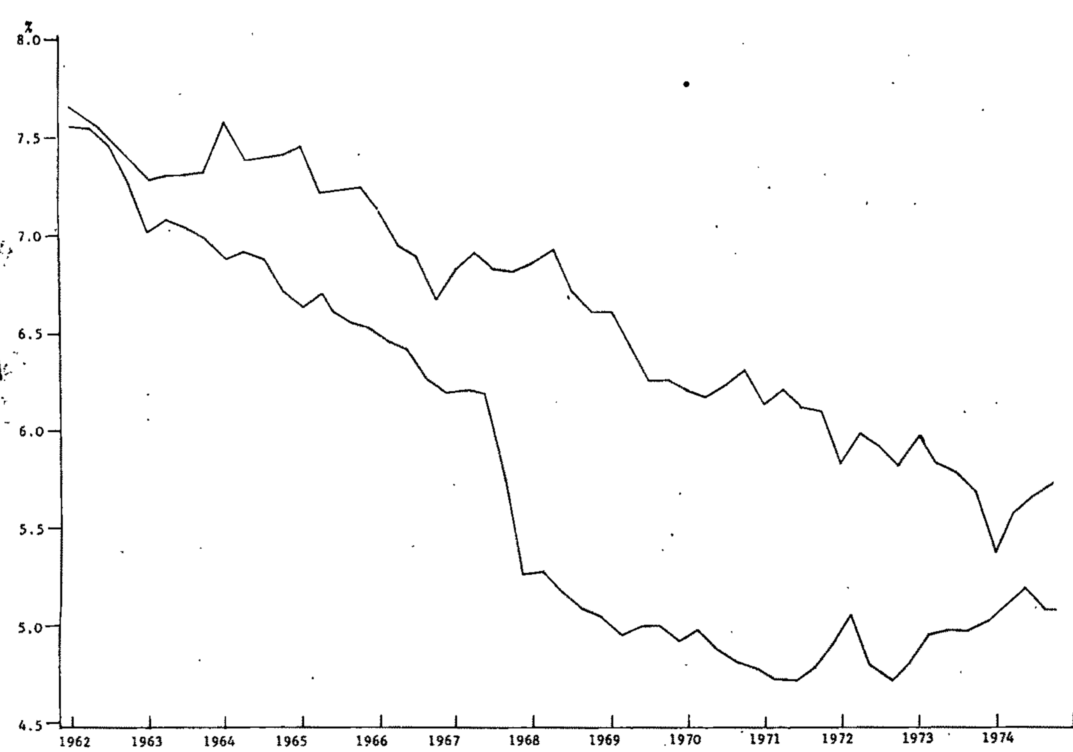

FIGURE 3. *U.K.* SHARE OF WORLD MONEY SUPPLY (BOTH IN DOLLARS) AND SHARE OF INDUSTRIAL OUTPUT

money stock fell sharply, but in the period that followed, the economy acquired the necessary money balances so that by 1972, the share was back on trend and the predevaluation situation was restored along with the price level.

We can, therefore, interpret the increased rate of inflation during the period as partly due to the higher world inflation rate and partly to the adjustment following the 1967 devaluation which in turn followed the expansionary measures of the mid-1960's. Thus, while we have argued that the demand pressures of the mid-1960's had only limited impact upon the inflation rate at the time, the inflation was merely postponed until the exchange rate was adjusted and price paid in the final years of the decade.[19]

### C. *The Inflationary Process: 1972–75*

The third distinct period lasts from 1972 to the time of writing. During this period, the world inflation rate increased still further so that the problems of domestic policy were conducted against an even more unhelpful world background. World commodity prices doubled, oil prices quintupled, and world manufactured prices (expressed in world currency)[20] rose by 35 percent between 1973 and 1975.

Since mid-1972, sterling has been allowed to fluctuate although there has still been substantial official intervention in the market. The dwindling balance-of-payments surplus that accompanied the domestic expansion triggered the crisis in July of that year. This substantially changed the situation as it effectively

[19] The postponement was also due in part to the incomes policies followed by the government from 1966–69. This further delayed the inflation that might have been expected to show itself more rapidly after the devaluation.

[20] To calculate the world price level in "world currency" we have taken the world price in dollars, transformed into sterling and multiplied by the "effective" *U.K.* exchange rate.

TABLE 5—WORLD PRICES AND *U.K.* PRICES: 1972=100

| | World price manufactures | | | Effective exchange rate | *U.K.* price of manufacturing exports | *U.K.* wholesale prices | *U.K.* retail prices | *U.K.* labor costs |
|---|---|---|---|---|---|---|---|---|
| | $ | £ | World Currency | | | | | |
| 1972 | 100.0 | 100.0 | 100.0 | 100.0 | 100.0 | 100.0 | 100.0 | 100.0 |
| 1973 | 111.7 | 120.1 | 108.0 | 89.9 | 111.7 | 107.3 | 109.2 | 109.2 |
| 1974 | 143.4 | 153.4 | 132.7 | 86.5 | 141.1 | 132.4 | 126.7 | 130.0 |

*Sources: NIESR Review*, November 1975, and *Economic Trends.*

marked the end of the fixed rate system as far as Britain was concerned. It affects our analysis as it is no longer possible to take as exogenous the sterling value of the world export price level; this, in principle, could be anything, depending upon the behavior of the exchange rate. With an endogenous exchange rate, the link with the world price level is lost and the price level within this analysis is indeterminate. Some other form is necessary to constrain its movements.

The basic information is laid out in Table 5. Between 1972 and 1975 the world price of manufactured exports, expressed this time in world currency terms, rose by 45 percent with half of the increase coming in 1974. In part, this can be attributed to the demand pressures resulting from the 1972-73 expansion, but in part it is also the result of the higher oil prices and the increased demand for manufactured exports by the oil-producing nations. In addition to this increase in world prices, the *U.K.* exchange rate relative to the world depreciated by over 20 percent, thus leading to an increase in world prices, expressed in sterling of 85 percent. British manufactured export prices and wholesale prices did not adjust fully to this rise, but by 1975 were between 65 and 75 percent higher than in 1972. Furthermore, the growth in retail prices during the past two years has been less than the growth in wholesale prices, in contrast to early years when they grew around 1 percent per annum faster. This was to be expected as the increase in oil prices changed the relative prices of manufactured goods and nonmanufactured goods in favor of manufactured goods. However, as we can see in the table, unit labor costs rose faster than wholesale prices and, therefore, the entire burden of this shift and much of the fall in output in 1975 has been felt by profits and other nonwage incomes. Between 1967 and 1972, consumer prices rose by 1 to $1\frac{1}{2}$ percent per annum faster than manufactured prices, whereas, between 1972 and 1975, the increase in consumer prices has been less than for export manufactured prices. In Germany and France, the behavior was similar with consumer prices rising less than export prices over the period and in Japan, the two prices grew by a similar amount, whereas normally consumer prices grew much faster. In the United States, the gap was much greater, probably reflecting the greater impact of reduced demand pressures.[21]

Thus, most of the difference in the behavior of inflation rates in the United Kingdom relative to the rest of the world can be seen in the behavior of the exchange rate. This raises the issue of cause and effect. Did the exchange rate adjust because of price behavior sparked off by wage demands, or did the exchange rate fall take

[21] Between 1972 and 1975 (second quarter), German export prices in local currency rose by 30 percent and consumer prices by 21 percent; in France, the figures were 46 and 35 percent; in Japan, 52 and 53 percent; in the United States, 53 and 27 percent.

FIGURE 4A. EFFECTIVE EXCHANGE RATE AND MONEY SUPPLY

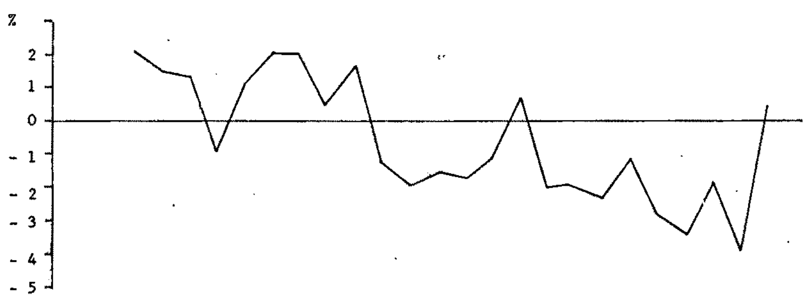

FIGURE 4B. RESERVE CHANGE AS PROPORTION OF MONEY SUPPLY

place initially because of the monetary expansion and the domestic wage and price level adjustment afterwards. In terms of timing, the evidence seems to support the latter hypothesis. The bulk of the exchange rate fall (13 percent) had taken place by September 1973 and, at that time, compared with 1972, *U.K.* prices had risen by little more than world prices.[22] The miners were making threatening noises, but the scale of the confrontation was not then evident.

In our view, there is a strong presumption that the declining exchange rate was in part related to the conduct of monetary policy. In turn this caused goods prices and factor prices to change, but in response to disequilibrium between internal and external price levels, rather than to direct demand pressures upon goods prices. Some evidence for this view is given in Figure 4. Here we have computed the ratio of the money stock to the trend of output in the United Kingdom and its main trading partners, and compared the movement of the ratio of these corrected money stock figures with the *U.K.* effective exchange rate.[23] It is clear that the money supply

[22] By the third quarter of 1973, *U.K.* consumer prices were 9.1 percent above the average for 1972. For the United States, the percentage rise was 7.3; for Germany, 7.4; for France, 8.4; for Japan, 13.5 and Italy, 11.5.

[23] Between 1967 and 1974, the ratio of United Kingdom to world industrial production fell by 2.4 percent

relative to trend industrial production in Britain started to rise much faster than for the world as a whole from the beginning of 1972. This continued until the beginning of 1974, since when the rate of increase has been slower. This is a very simple formulation of the relative excess supply of money as it assumes a unitary income elasticity in all countries. Yet the "effective" exchange rate follows the movement of the relative money variable very closely. The difference between the two lines suggests that the exchange rate was undervalued in 1971, overvalued in 1974, and back on course by the middle of 1975. This pattern is consistent with the inflow and outflow of "reserves" as measured by the difference between the increase in the money supply and the rate of domestic credit expansion as a proportion of the money supply.

The implication of this is that the United Kingdom was directly responsible for having a higher rate of inflation than the rest of the world due to inadequate control of the money supply and that, during 1974 and 1975, the internal price level was adjusting to the movement of the exchange rate in 1972 and 1973. This leaves open the question of the extent to which even the world inflation rate could have been avoided by a strict monetary policy and exchange rate appreciation.[24] As we argued above, this analysis suggests that this would indeed have been possible if the United Kingdom had been prepared to suffer the consequences of the temporary overvaluation in the same way as Germany. This issue cannot be removed from the problem of the underlying weakness of the United Kingdom growth rate. A country with an expanding share of world exports is in a much stronger position than one in which the long-run trend of unemployment has been rising and is considered politically to be "excessive."

## III

We conclude that the history of inflation in the United Kingdom since World War II reflects three forces at work of differing significance at different periods of time. The first has been the tendency to wish to run the economy from time to time at rates of growth of total demand that have not been consistent with the underlying position of the balance of payments, resulting in pressure on, and ultimately changes in, the exchange rate. The second has been the impact on the economy of external price changes, such as during the Korean War, and during the commodity boom of the 1970's culminating in the rise in the world price of oil. The third reflects the mechanism of adjustment through which efficiency increases are distributed within the economy in an institutional framework that leads to substantial downward money wage and price inflexibility.

Some unpalatable conclusions stem from this paper and from the arguments put forward in Ball, Burns, and Laury. The first is that, under a fixed exchange rate system and with free collective bargaining, it is impossible for the *U.K.* authorities to control either the rate of inflation independently from that of the rest of the world or the rate of unemployment. For any given rate of growth of world activity, there exists a rate of growth of domestic demand that is consistent with balance of payments current account equilibrium, and

per annum. This trend was used as the relative output series to deflate the ratio of the money stocks in the United Kingdom and the world in order to capture the long-run movement of output. Each series was indexed on 1970=100. The world money supply is the weighted sum of local currency money supply in the countries described above, where the weights are the 1970 exchange rate of dollars per local currency.

[24] In fact, it could be argued that it was quite unreasonable to have expected the United Kingdom to have done any better than the world average by pursuing such policies. The example of Germany hardly makes the point, since the bulk of the adjustment fell on immigrant workers who were simply shipped home. In retrospect, the criticism of the United Kingdom is that, in a sense, it chose to do worse than the world average and failed to get away with it. In the end, at least some of the unemployment came anyway. It would, however, have been very much greater, if thoroughgoing monetary prescriptions had been applied during this period.

hence, at a given moment with given technology, a certain behavior of unemployment. A rate of growth of demand above this rate can only be sustained by repeated devaluation of the currency accompanied by periodic bouts of inflation. A floating rate enables the country to regain control over the domestic price level, but does nothing to avoid the necessity of adjusting fiscal and monetary policy primarily toward the balance of payments and the exchange rate rather than the level of employment except at a major inflationary cost.

In this context, the role of an incomes policy is primarily to avoid the basic confrontation between inflation, the balance of payments, and the rate of unemployment. It is not a substitute for proper demand policies aimed at achieving an appropriate balance in government spending and taxing activities that must take the foreign balance into account. It can help in preventing the community from attempting to price itself at a level that is inconsistent with the country's overall efficiency levels in relation to world markets and to prevent erosion of the necessary rate of profitability without the necessity of creating massive unemployment in order to achieve the same objective.

Finally, it should be said that the need to restrain the demands for increases in real incomes will vary in relation to longer term issues concerning increased efficiency and industrial change in the economy that are outside the scope of this paper. The balance of payments and the rate of inflation will continue to act as constraints on increasing real incomes to the extent that fundamental problems of structure are not resolved and to the extent that explicit choices about the use of scarce resources, between private consumption and investment, and between the public and private sectors are avoided. A persistent demand for resources in excess of what can be enjoyed will only lead to further depreciation of the exchange rate, an erosion of profitability and, ultimately, to higher levels of unemployment than would otherwise have to be the case.

# Inflation in Britain: A Monetarist Perspective

*By* David Laidler*

"... the ideas which civil servants and politicians and even agitators apply to current events are not likely to be the newest. But, soon or late, it is ideas, not vested interests, which are dangerous for good or evil." *J. M. Keynes*

## I

From 1953 to 1969 the British inflation rate never exceeded 5 percent, and the unemployment rate rose above 3 percent of the labor force in only one quarter (1:1963). In 1975 the inflation rate reached a peak of over 30 percent in the second quarter, unemployment reached 5 percent of the labor force, and at the end of the year, was still rising rapidly. The contention of this paper is that Britain's difficulties in the 1970's arise from ill-designed policies based upon long and widely held misconceptions about how the economy works. The basic error committed has been to neglect to control the money supply while pursuing an unrealistically low unemployment target, primarily by fiscal means.[1] Monetary expansion, largely a by-product of "full employment" fiscal policies, has been responsible for the high British inflation rate of the early 1970's.

Figure 1 portrays the time-series behavior of inflation, unemployment, and two measures of the rate of monetary expansion over the period 1953–75.[2] To argue

* University of Western Ontario. This paper draws heavily on the work of the University of Manchester SSRC Inflation Workshop of which I, with Michael Parkin, was joint director. An earlier version of this paper was given at the University of Western Ontario Money Workshop and the University of Chicago Money Workshop. Extremely valuable criticism was received on these occasions. I am particularly grateful to Parkin, Douglas Purvis, Milton Friedman, and Robert Lucas for their comments, but nevertheless exonerate them of all responsibility for the contents of this version.

[1] The view that the quantity of money is unimportant is an article of faith in British Keynesian economics, receiving its most famous statement in the Radcliffe *Report*. It is still influential. See, for example, the evidence of Wyn Godley and Lord Kahn to the House of Commons Public Expenditure Committee in 1974. See House of Commons (1974, paras. 25–26, p. 18 and paras. 269–70, pp. 90–91, respectively).

There has, however, always existed a minority of economists in Britain who have taken the opposite position on this matter. See, for example, the evidence of Lionel (now Lord) Robbins and Frank Paish to the Radcliffe Committee, Alan Walters, and Harry Johnson. So-called "monetarist" views however have never, as far as one can tell, had any influence on policy. The reader who wishes to assess the extent to which the author of this paper is being wise after the event is referred to the author (1975, chs. 4 and 10), written in late 1970 and early 1972, respectively.

[2] Two measures of monetary expansion are presented here because it is often asserted that the two series in question tell markedly different stories. However, such differences are much more apparent on a quarter by quarter basis than they are over a longer time period. The long-term qualitative behavior of the series is very much the same. My own preference has always been to pay rather more attention to the broader money supply series, but nothing crucial hinges on this.

Note that with the introduction of the "Competition and Credit Control" reforms in late 1971 the banking system became much freer to produce near monies bearing interest at competitive rates. Such liabilities are included in $M_3$ but excluded from $M_1$. Thus the sharp downturn in the rate of expansion of $M_1$ at the beginning of 1972 reflects not a turnaround in monetary policy, but a substitution out of demand deposits into various types of time deposits suddenly available on more favorable terms. By the same token, the continued acceleration of $M_3$ growth through 1972 certainly owes something to this same effect and overstates the expansiveness of monetary policy. At the end of 1973, changes in the reserve requirements against interest bearing liabilities made it much less attractive for the banks to emit these. The rather rapid expansion of $M_1$ in 1974 at least partly reflects a shift towards non-interest bearing deposits rather than renewed monetary expansion, while the data on $M_3$ overstate the tightness of policy for similar reasons. Nevertheless, with greater flexibility of interest rates on near monies, one would expect the turning point in the $M_1$ series to come a little

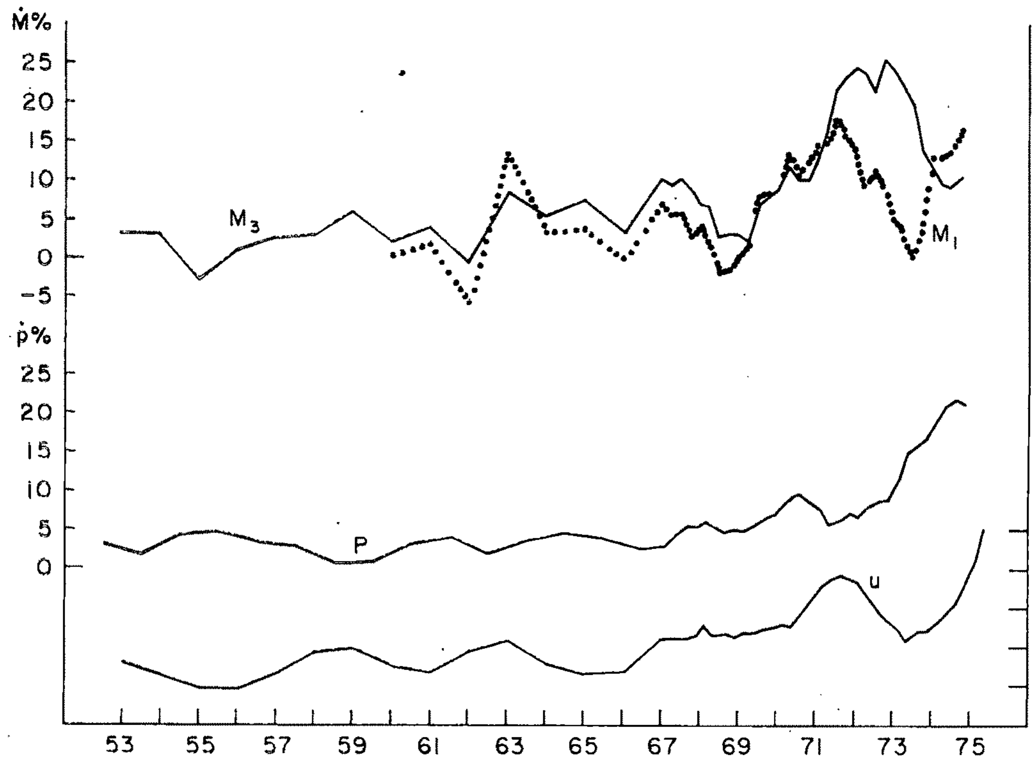

FIGURE 1

$M_1$= Annual first differences of the natural logarithm of Narrow Money; 1960–67 observations are annual, thereafter quarterly. Basic data are for end-period stocks. *Source: IFS*, various issues.

$M_3$= As $M_1$ but basic data are for money plus quasi money. *Sources:* 1960–75 *IFS*, various issues; 1953–60 *Bank of England Statistical Abstract*. Note that the Bank of England data include government deposits with Commercial Banks and the *IFS* data exclude them. This minor inconsistency between the series is probably of little importance when estimating percentage rates of change.

$P$= Annual first difference of the natural logarithm of the retail price index; 1953–67 basic data are annual averages centered in midyear; 1967–75 data are quarterly averages centered in mid quarter. *Source: NIESR Review*, various issues.

$U$= Period averages of the percentage of the labor force unemployed, Great Britain; 1953–67 annual averages; 1968–75 quarterly averages, seasonally adjusted. *Source: NIESR Review*, various issues.

that variations in the rate of monetary expansion are the main cause of variations in the inflation rate by no means implies that there should be any simple correlation between the two series, as I have shown elsewhere (1975, ch. 7). Nevertheless, results presented there for the *U.S.* economy do suggest that marked changes in the monetary expansion rate have a discernible impact on the inflation rate with about a two-year time lag, and the

before that in $M_3$ when monetary policy is changed. For example, as policy tightens up, short-term interest rates rise, and a substitution out of demand deposits into interest bearing bank liabilities involves the growth rate of $M_1$ turning down while that of $M_3$ is temporarily sustained.

Finally note that for the period over which quarterly data are plotted the monetary expansion rates are annual logarithmic first differences of end quarter data; these changes are centered on the end of the second quarter of the one-year period over which they are measured, and, as is well known, such measures tend to shift turning points backwards in time when these are sharp. These considerations are important in assessing just when, in 1973, monetary policy began to tighten up. My own inclination is to argue that the process began gently early in the year, being associated with the authorities beginning to meet a much larger fraction of government borrowing by securities sales to the nonbank public and became severe in the final quarter.

data charted in Figure 1 are consistent with the claim that a roughly similar relationship governs the behavior of British data. The pattern is particularly marked from 1968 onwards, but some might claim to discern a similar, though much less clear-cut, relationship for earlier years as well.[3] The transmission mechanism between monetary expansion and the inflation rate that underlies this interpretation of the evidence involves the initial impact of monetary changes falling on real aggregate demand—for which the unemployment rate may be regarded as a proxy—and thence influencing the inflation rate. Inspection of Figure 1 shows that such a "Phillips curve" relationship is clearly present in the pre-1967 data, vanishes between 1967 and 1971, and then begins to reestablish itself, although at much higher levels of inflation and unemployment, thereafter.

Two interrelated questions are prompted by the data charted in Figure 1. First, the pursuit of high employment with fiscal policy was just as much a characteristic of British policy before 1967 as after: why did a policy that apparently succeeded for nearly two decades fail so badly in the 1970's? Second, why did the Phillips curve disappear between 1967 and 1971? The answers offered to these questions in the next few pages may be summarized as follows. A fixed exchange rate and a low inflation rate in the world economy lay at the root of the apparent success of Keynesian policies in Britain before 1967. These policies led to the devaluation of 1967, which coincided with the beginning of the Vietnam War inflation that ultimately destroyed the Bretton Woods system. The way in which these changes impinged upon Britain accounts for the temporary disappearance of the Phillips curve after 1967. However this phenomenon was interpreted by those in control of British policy, as confirming a belief, widely held in the 1950's but temporarily unfashionable in the 1960's, that inflation was to be explained in terms of "wage push" factors, many of them noneconomic. As a direct result of this misreading of the evidence, in 1972 fiscal policy accommodated by monetary expansion and a flexible exchange rate was combined with wage and price controls in an attempt simultaneously to reduce unemployment, increase real growth, and reduce the inflation rate. The current condition of the British economy is the direct consequence of this policy, but because this diagnosis is not widely accepted in Britain, there is now a grave danger that the errors of 1972–73 might be repeated.

## II

A version of the "natural unemployment rate" hypothesis is an important implicit component of this paper's basic thesis. My first task is to show how this hypothesis can be reconciled with the behavior of the economy over the 1953–67 period. The expectations augmented Phillips curve in terms of which this hypothesis is usually formulated may be written:

[3] Nevertheless the case for attributing a role to monetary policy in generating inflation during the pre-1967 period does not rest on Figure 1. Rather it rests on the studies of Michael Artis and Bob Nobay and Bank of England (1970a, b) which use data from this earlier period. They do find evidence consistent with the view that changes in the quantity of money influenced certain variables, including money income and hence the inflation rate with a "long and variable" time lag. However, the results these studies generated were certainly much less clear-cut than those produced by similar studies done for the *U.S.* economy. Charles Goodhart of the Bank of England, the author of one of the Bank's studies, expressed a similar view of the results generated by these studies in 1974. See House of Commons (1974, para. 346, pp. 111–12). The extent to which these results reflect the fact that the British economy in the 1950's and 1960's was so stable that there was little systematic variation in income and prices to explain, and the extent to which they reflect the fact that the interaction of money and prices in a rather open fixed exchange rate economy where an interest rate stabilization policy is being pursued is more complicated than in a relatively closed economy, is too complex a question to enter into here. For a simple formal analysis of the interaction of money and inflation in a fixed exchange rate open economy model, see the author (1975, ch. 9).

$$(1) \qquad p = g(u) + X \qquad g' < 0$$

where $u$ is the deviation of unemployment from its "natural rate," $p$ is the inflation rate, and $X$ the expected inflation rate. It is common to postulate that expectations of inflation are formed according to a first-order error learning scheme applied to the actual inflation rate, but this hypothesis ignores the fact that data on the past time path of inflation are not usually the only information readily available and relevant to forecasting its future time path; where such extra information is available, economic agents are likely to make use of it. In a fixed exchange rate open economy, the time path of the price level in the rest of the world is of vital importance. It does not take much sophistication to know that if a fixed exchange rate is to be maintained, domestic inflation cannot forever deviate from that ruling in the world economy. If agents expect the exchange rate to be maintained, then they will also expect the domestic inflation rate to converge on that ruling abroad. There must be many specific hypotheses about the formation of inflationary expectations in an open economy compatible with this rather general set of propositions, but one, admittedly *ad hoc*, model that I have experimented with elsewhere with considerable success, has expectations about domestic inflation being revised according to a weighted average of the deviations of domestic and world inflation from the previously expected rate of inflation.[4] Thus, with $\Pi$ as the world rate of inflation, the change in the expected inflation rate is written as

$$(2) \quad X - X_{-1} = d[v(p_{-1} - X_{-1}) + (1-v)(\Pi_{-1} - X_{-1})] \quad 0 < d, v < 1$$

Combining this expression with equation (1) and solving for a situation in which $p = p_{-1}$ and $u = u_{-1}$ yields

$$(3) \qquad p = \frac{g}{1-v} u + \Pi_{-1}$$

Equation (3) *appears* to show that a "long-run" tradeoff between inflation and unemployment is implicit in this approach to modeling the Phillips curve for an open economy, that a lower unemployment rate may be maintained forever at the cost of a higher but not accelerating inflation rate.[5] However, this result is an illusion. It can hold only for so long as the exchange rate is held constant and is expected to remain constant. The true implication of equation (3) is that if an open economy maintains a lower than natural unemployment rate, this will result in a higher inflation rate than that ruling in the rest of the world and hence in a secularly worsening balance of payments situation. What appears at first sight to be a steady state will be one for just so long as foreign exchange reserves permit it to be sustained.

In Britain, over the period 1953–67, too low an unemployment target was set, the country experienced an inflation rate higher on average than that ruling in the rest of the world, and that higher inflation rate was associated with a secular deterioration in the balance of payments.[6] Apparently successful "Keynesian" full-employment policies thus culminated in the devaluation of November 1967. Data illustrating this argument are charted in Figure 2. Devaluation was bound to produce a

[4] See Rodney Cross and the author, and the author, forthcoming.

[5] It is worth noting that for some countries Cross and I found that $v$ was not different from zero, implying that there is no difference in slope between the long- and short-run inflation unemployment tradeoffs in those countries; Britain, however, was not one of them, $v$ taking a value of about one-half for that country.

[6] But the unemployment target was perhaps not set very far above the natural rate. Malcolm Gray, Parkin, and Michael Sumner estimate the natural rate to have been 1.8 percent over the 1953–67 period, while the actual rate averaged 1.54 percent. Their estimate is subject to a wide margin of error and certainly looks low, but is not obviously inconsistent with Phillips' estimate that a 2.5 percent unemployment rate was compatible with price stability in postwar Britain, since the expected inflation rate was surely slightly positive over the relevant period.

short-term step up in the inflation rate as British prices adjusted to the new exchange rate, and the lower level of real income implicit in it, even if the inflation rate ruling in the rest of the world had remained constant. But, as Figure 2 also shows, in 1967 the world inflation rate was already accelerating. This acceleration is usually explained as being the result of *U.S.* policies toward financing the Vietnam War.[7] Devaluation and the simultaneous step up in the world inflation rate largely account for the acceleration of British in-

[7] British economists do not always attribute the worldwide inflation of the late 1960's and 1970's to this cause. Thus Sir Henry Phelps-Brown, while admitting that monetary expansion might have been a permissive factor, puts the acceleration of inflation on a worldwide scale down to wage push factors based upon rising real income expectations. Such expectations are transmitted across national boundaries by the motor car and television, these playing the same role as the bicycle, the popular press, and the cinema in the period 1899–1914. He views the Paris students' revolt of 1968 as a crucial event that "sparked a prairie fire of strike action that spread across Europe" (pp. 5–6). Lord Kahn, on the other hand, believes that the breakdown of wage and price controls in Holland in the early 1960's was the source of accelerating worldwide inflation. As he told the House of Commons Expenditure Committee, "In fact it was really from the Netherlands in the second half of the 60s that the infection of wage inflation started and spread to most of the main industrial countries" (p. 82 in House of Commons, 1974, para. 233).

flation after 1967.

Figure 2 shows that the balance of payments did not respond immediately to the 1967 devaluation. Whether this was due to slowness of quantities of imports and exports to respond to relative price changes or to the fact that British monetary policy continued to be expansionary after devaluation is not of central importance.[8] The problem did lead in 1968 to the International Monetary Fund requiring a policy of monetary stringency as a condition of aid, a policy which was adopted and which, it has already been argued, had its effect in 1970–72, at first solely on unemployment and only subsequently on the rate of inflation.

## III

The experience of 1967–71 was widely misinterpreted in Britain, by professional economists and "informed opinion" alike. In the 1960's the Phillips curve in its original form unaugmented by inflationary expectations had gained acceptance among both groups as a valid hypothesis about the relationship between wage inflation and unemployment. For example, at least two of the three operational large-scale forecasting models in terms of which so much discussion of policy took place had, until the late 1960's, treated price inflation as largely depending upon a wage inflation rate determined by some form of Phillips curve. By 1971 the Phillips curve had been dropped from these models leaving money wage inflation as an exogenous variable in all three of them.[9] This change was proximately caused by the failure of the nonexpectations augmented version of the curve to deal with post-1967 data, but also reflected renewed and increasing acceptance of the position, popular in the 1950's, that wage and hence price inflation was the result of wage-push factors of mainly domestic origin.[10] The alternative view that the accelerating inflation of 1967–71 was largely imported with an overlay attributable to the 1967 devaluation found few supporters in 1971.

Crucial to reinforcing the belief that inflation was a matter of domestically originating wage-push was the so-called "wage explosion" of 1969–71. Between 1966 and 1969 the rate of increase of hourly wage rates averaged 5.2 percent per annum; between 1969 and 1971 it averaged 11.1 percent per annum, and that at a time when unemployment averaged about 2.7 percent of the labor force, an unusually high figure by past standards. In retrospect this episode is not difficult to explain. As Table 1a shows, the rate of growth of real wage rates over the 1966–67 to 1970–71 period was similar to rates achieved in the late 1950's and early 1960's. The growth of real wage rates was unusually slow in the mid-1960's. Moreover, as Table 1b shows, price inflation began to accelerate immediately after 1967 and money-wage inflation did not immediately accelerate so rapidly. Some of this wage lag was due to the effect of wage and price controls which had strong short-term effects on wages in 1966–67, and also in 1968 according to some studies (see Parkin and Sumner, 1972, chs. 1, 4, 10). Some of it was perhaps due to lags in the adaptation of expectations to an accelerating and largely imported price

[8] For a detailed analysis of this question, see Peter Jonson and Henryk Kierzkowski.

[9] The three models to which I refer here are those of the Treasury, the National Institute of Economic and Social Research, and the London Business School, respectively. All three treated the wage inflation rate as an exogenous variable, forecast on a judgemental basis, in 1970. (See House of Commons, 1974, para. 456, p. 134; Johnson and Nobay, chs. 1 and 2 with respect to these three models.) It is not clear from the above sources that money wages were ever treated as anything but an exogenous variable in the Treasury model in the 1960's, but Phillips curves definitely were incorporated in the other two.

[10] A typical and comprehensive statement of this point of view in the literature of the 1950's is to be found in Lord (then professor) Kahn's evidence to the Radcliffe Committee. See *Memoranda of Evidence*, Vol. 3, pp. 141–44.

TABLE 1a—AVERAGE ANNUAL PERCENTAGE CHANGE OF PRICES, HOURLY WAGES, REAL HOURLY WAGES, FIVE-YEAR PERIODS, 1956–71

| Period | Prices | Wages | Real Wages |
|---|---|---|---|
| 1956–61 | 2.29 | 4.38 | 2.09 |
| 1957–62 | 2.40 | 4.25 | 1.85 |

Prices: logarithmic first difference at annual rates of retail price index.

Real Wages: col. 2 –col. 1.

inflation. On this interpretation the "wage explosion" simply represents a "catch up" whose underlying causes were strong enough, for a while, to offset the effects of monetary stringency and rising unemployment.[11]

However, this interpretation was very much a minority view at the time. The proceedings of the conference on "The Current Inflation" held at the London School of Economics on February 22, 1971 (reprinted in Johnson and Nobay, 1971) give considerable insight into the state of contemporary opinion. As Harry Johnson put it in his Introduction to the proceedings, "the prevailing mood of the conference seemed to be to dismiss a change in external influences in favor of a change in internal influences, as a primal causal factor in the current inflation" (pp. x–xi). The internal influences in question all centered on the idea of exogenous wage push.[12] By the end of 1971, those in a position to influence British policy were united in the view that the inflation rate was not susceptible to any policy-relevant extent,

[11] Note that an article in the *National Institute Economic Review* (*NIESR Review*) for February 1971, reprinted in Johnson and Nobay (1971) under the name of its author Michael Artis, contained evidence to show that inflationary expectations were systematically influencing wage behavior, though not with a unit coefficient; moreover the relevance of the "Nordic" model of imported inflation (see G. Edgren, K. O. Faxen, and G. E. Ohdner) to the contemporary British situation was considered and recognized. Artis did not, however, develop these ingredients into an analysis of the type offered here.

[12] The following quotations are typical: Jim Ball of the London Business School: "My own favorite candidate is . . . the frustration hypothesis . . . wage earners seek to realize some real wage objectives the frustration of which eventually causes the Phillips curve to shift" (pp. 47–48), though he did note that this hypothesis needed to be squared with the existence of inflation in a number of countries. Leslie Dicks-Mireaux of the Bank of England: "I would not argue that there is an overriding external factor common to the recent inflation; indeed we must probably look to factors closer to home not all of which perhaps are economic" (p. 184). Ralph Turvey, former Deputy Chairman of the Prices and Incomes Board: "it is a question of relative deprivation and the perception of social justice which is the key to understanding what has happened" (p. 200). Sir Fred Catherwood, Director General of the National Economic Development Office: "we are in a position where a key factor of production, which is labour, can be withdrawn and it pays to pay a premium all the time to keep [labor] in full supply. This to me is the major cause of wage inflation" (p. 189). For other recent British statements of hypotheses linking causes of inflation to the institutional structure of the labor market, and other noneconomic factors, see, for example, Aubrey Jones, Sir John Hicks (1974, ch. 3), and Peter Wiles. It is one of the oddities of British debates at the turn of the decade that although the inflationary problems of the time were proclaimed as being something new, requiring equally novel explanations, the explanations that were then actually advanced bore so much resemblance to those which Lord Kahn had put to the Radcliffe Committee more than a decade earlier as explanations of the mild inflation of the 1950's. Moreover, these explanations owe a great deal to the analysis of labor market institutions developed by Hicks in the *Theory of Wages* (1932) and further developed by him in the 1950's. Compare Hicks (1955).

to influence by variations in the level of aggregate demand.[13] Thus, when in that winter, and with a little journalistic license (see Britain, 1975, pp. 70–72), unemployment reached the magic number of 1 million, the scene was set for the implementation of an economic policy which, though coherent enough in terms of this new prevailing orthodoxy, was from a "monetarist" viewpoint inherently contradictory. The strategy, crystallized in Mr. Barber's 1972 budget, involved using fiscal policy to stimulate aggregate demand, and letting monetary expansion take up the resulting public sector deficit lest high interest rates interfere with real expansion or discomfort owner occupiers.[14] Initially an attempt was made to get voluntary controls on wages and prices accepted, but by November 1972 statutory controls were introduced to deal with inflation.[15] Exchange rate flexibility was adopted, explicitly to ensure that balance-of-payments problems did not, as they were judged to have done in the past, jeopardize the pursuit of full employment and growth.

The government were showered with praise for their policy. The National Institute of Economic and Social Research did criticize the budget, it is true, but for not being expansionary enough (see the *NIESR Review*, May 1972). *The Economist*, though noting that the public sector borrowing requirement might lead to monetary expansion, and putting little faith in informal and voluntary wage and price controls, nevertheless concluded that "Within the context of a budget that ignored [getting to grips with wage inflation] Mr. Barber produced something very close to the best economic strategy that a now very professional Chancellor could" (Mar. 25, 1972, p. 13). By November, when statutory controls were introduced, *The Economist* welcomed them with the comment that "It has been obvious for at least the past two years that Britain can avoid South American style inflation only by enforcing a statutory incomes policy" (Nov. 11, 1972, p. 13). No possibility of conflict between rapid expansion of aggregate demand and a policy of wage and

[13] The sharp fall in the inflation rate that was associated with the high unemployment rate ruling in 1971, as the Phillips curve began to reestablish itself, did not have any effect on those who held this view. Indeed it was still the view of the Treasury as late as 1974 that no policy-relevant tradeoff between inflation and unemployment existed. See House of Commons (1974, paras. 465–66, p. 136). In 1974, Patricia Brown of the Treasury explained the fall-off in the inflation rate in 1971–72 in the following terms. "Looking at the rate of growth of the Retail Price Index for the second quarter 1970 to the second quarter 1971, and then the second quarter 1971 to the second quarter 1972, there is a very sharp difference in the rate of growth of food prices . . . the prices of services provided by nationalized industries . . . direct to consumers . . . went up at 17½ percent over the first twelve-month period and only 7½ percent in the second twelve-month period. I think that these two factors probably largely account for the slowing down in the Retail Price Index as a whole" (p. 137 in House of Commons, 1974, para. 69). Perhaps the reader will agree that there is more than a little confusion here between describing what happened to the components of the index on the one hand, and explaining the behavior of its overall value on the other.

[14] 1971 did of course see the advent of new regulations for the Banking System that at least paid lip service to enabling the authorities to exert greater control over monetary aggregates. Whatever the purpose of "Competition and Credit Control," from the very outset the authorities made it clear that steps would always be taken to protect the level of mortgage interest rates under the new regime. See Bank of England *Quarterly Bulletin*, June 1971, para. 15, p. 192. The advocates of variable interest mortgages in the United States should learn from British experience, where such debts are typical, that their existence ensures that all mortgaged homeowners, and not just new borrowers, acquire a vested interest in the maintenance of low interest rates thus creating an immensely powerful pro-inflationary political pressure group. I believe that the desire of all parties to placate owner-occupiers (over 50 percent of all households) played an important role in the political processes that underlay Britain's failure to get to grips with her inflationary problems in the early 1970's.

[15] Note that by 1972 there existed a large body of evidence that suggested that with the exception of the 1948–49 episode, wage and price controls had had no systematic influence on inflation. See Parkin and Sumner, ch. 1, for a survey of this evidence, and note particularly that by then, the initial finding of Richard Lipsey and Parkin (ch. 4 of Parkin and Sumner) that controls did reduce the rate of inflation in conditions of high demand had been discredited.

price controls was noted, not just because inflation was regarded as independent of the level of aggregate demand in the economy, but because expansion of real output and consumption were actually regarded as necessary prerequisites for the success of controls.

An increase in output could be relied on to reduce unit labor costs and hence lead to a short-term slackening off of price inflation; in the longer term an expansion of real consumption would enable the living standards of the labor force to be raised, hence fulfilling the very expectations of rising real incomes the frustration of which, in conditions of slow growth, was supposed to be the main cause of inflation. As the *NIESR Review* for August 1972 put it, "The present situation in the British economy permits a rapid expansion of output for the next two or three years and requires, in the short period at any rate, a sharp increase in consumption. It is the most favorable possible situation for the introduction of [incomes] policies . . ." (p. 6). In November, it returned to the same theme: "The prospects for success of Phase II [of the newly introduced policy] are themselves dependent on the growth of the economy and *on our forecast* some additional stimulus is likely to be needed if the Chancellor's target [of 5 percent real growth] is to be achieved. There certainly seems little need for actually *cutting* public expenditure plans for 1973" (p. 6).[16]

Mr. Barber's "go for growth" policy of 1972–73 was qualitatively similar to Mr. Maudling's 1963–64 "dash for growth," and based on similar intellectual foundations. The Maudling policy quickly foundered on balance-of-payments problems. In 1972, the adoption of exchange rate flexibility against the background of the crumbling Bretton Woods system ensured that the consequence of Mr. Barber's policy would instead be a falling exchange rate and accelerating domestic inflation. However, the adoption of exchange rate flexibility was, in particular, singled out for praise, a typical reaction being that of *The Economist*, which referred to "an extraordinary conversion [of the Government] to the sensible doctrine that the right way to meet any balance of payments deficit will be to set sterling floating" (Mar. 25, 1972, p. 11).

Given only the existence of a stable aggregate demand for money function in the United Kingdom, and there was abundant evidence of this by 1972, there was no conceivable way in which the Conservative Government's policy could have succeeded in achieving the goals of price stability and rapid growth at a high level of employment.[17] In 1972 the money supply was al-

[16] The recipe of high employment and rapid growth as a cure for inflation has, of course, been a long-standing theme in postwar British economics. Thomas (now Lord) Balogh's evidence to the Radcliffe Committee dealt with it in some detail. See *Memoranda*, Vol. 3, pp. 40–41. In fairness to Balogh, however, it should be noted that in 1958 his call was for an expansion of *investment* to stimulate long-term *growth* as a prerequisite for a *voluntary* incomes policy. The 1972 budget concentrated almost entirely upon generating an expansion of *consumption* while the incomes policy that eventually went with it was *statutory*. There was more than a little confusion between long-term growth of productive capacity on the one hand, and short-term expansion up to a level of output that fully utilized existing capacity on the other, underlying economic policy in 1972–73. More than a vestige of the views under discussion here is to be found in a recent paper by Lord Kahn who argues that low unemployment reduces inflationary pressures by making the Trade Unions more willing to cooperate with wage and price controls.

[17] Quite apart from the early studies of Arthur Brown and A. M. Khusro, and Paish's evidence to the Radcliffe Committee, ignored by them in their *Report* (*Memoranda*, Vol. 3, pp. 182–88, *Minutes of Evidence*, pp. 693–700), by early 1972 there were in print studies by Noel Kavanagh and Walters, Douglas Fisher, the Bank of England (1970a), and the author and Parkin, all of which confirmed the existence of a stable demand for money function. There also existed at least three studies that seemed to show that monetary policy variations were associated (albeit weakly) with fluctuations in nominal income with a long and variable time lag (Artis and Nobay, Bank of England, 1970a, b). None of these studies had any influence on policy apparently because the relationships which they produced were not sufficiently well determined to be useful in short-term forecasting exercises. For the Treasury's view on this, see House of Commons (1974, paras. 477–84, pp. 138–39). Recent work by Artis and Mervyn Lewis suggests

ready expanding rapidly, largely as a result of a favorable balance of payments, but also as a result of the implementation of the Competition and Credit Control reforms which had left the banking system with substantial excess reserves. The large public sector borrowing requirement (about 4 percent of *GDP*) implicit in the 1972 budget, coupled with a commitment to hold down interest rates, implied a strong, domestically originating, stimulus to monetary expansion. Under a fixed exchange rate this would have been bound to wipe out the existing surplus and run the balance of payments into deficit, exactly as had happened in 1964, but in 1972 the commitment was to let the exchange rate go in such circumstances.

The possible outcome of the Conservative Government's policy lay between two-not-very-distant extremes. On the one hand, wage and price controls would be ineffective from the outset, domestically originating monetary expansion would lead first to an intensification of an already incipient expansion of real output, and thence to inflation and a falling exchange rate. On the other hand, controls might have some initial success. In this case monetary expansion, not being directly absorbed by rising domestic prices, would spill over into the foreign sector driving the exchange rate even further down than it would fall if controls were ineffective. The result in this case would be an increasingly distorted relative price structure in the economy which eventually would force the abandonment of controls. In either case the inflation rate was bound to accelerate and sterling bound to depreciate. The inevitable duly began to happen in 1972. The monetary expansion rate continued to rise; unemployment started to fall rapidly; inflation to accelerate, slowly at first; the balance of payments went into deficit; and the exchange rate began to fall, reaching a level 10 percent below its trade weighted average Smithsonian parity with other currencies by the end of 1972 and 18 percent below by the end of 1973.

## IV

The conventional and widely accepted interpretation of the 1972–73 boom in Britain is that a correctly conceived policy, reasonably well implemented, foundered as a result of imported inflationary pressures beyond the control of the British authorities. As *The Economist* explained the matter at the time: "Rising import prices and devaluation robbed Mr. Heath of success in stages 1 and 2 [of his incomes policy] and threaten his growth strategy through the impact of high interest rates and monetary restraint to defend sterling" (Oct. 6, 1973, p. 87). *The Economist* did not consider the possibility that "devaluation" might have been the consequence of the government's "strategy" and nor do any of the other proponents of the foregoing interpretation of the events of 1972–73.

Cost accounting exercises do indeed show that over this period rising import prices "contributed" more to domestic inflation than did changes in money wages, profits, or indirect taxes. Such exercises, interesting though they are for the evidence they generate about the behavior of relative prices, are in Britain often interpreted as saying something about the proximate causes of inflation. A clear statement of the approach to the analysis of inflation that leads to such an interpretation was given by G. D. N. Worswick, the director of the National Institute, to the House of Commons Public Expenditure subcommittee: "The principal [factors determining the movement of prices] are the level of wages and costs. The secondary one is profit margins. . . . Thirdly there is the intervention by government by taxes or subsidies to raise or lower the market price from the factor cost price. Fourthly

that competition and credit control did not render the demand for money function unstable after 1971.

there is the import cost. In the last two or three years there has been a world wide increase in the rate of inflation. . . . But who is causing it and how we interact with each other is complicated. We suffer from the world wide rise in commodity prices. . . . The position we started with with the freeing of the exchange rate allowed it to fall rather in comparison with our competitors, which adds to the import prices. To blame that on the incomes policy introduced in 1972 would be, in a certain sense perverse" (House of Commons, 1974, para. 115, p. 38). The Treasury's evidence to the same committee (paras. 462–69, pp. 135–37) shows that their approach to the analysis of inflation is the same as that of Mr. Worswick and *The Economist*, though they did not apply the analysis specifically to the 1972–73 period.[18]

It is above all the behavior of the unemployment rate during the 1972–73 boom that has led so many to believe that inflation since 1972 could not have its source in domestic monetary and fiscal policies and hence must be "imported." As Figure 1 shows, inflation began to accelerate when the level of unemployment was high by historical standards, and even at the peak of the boom it stood above 2 percent, a rate higher than the *average* for the 1953–67 period. This is treated as prima facie evidence that there existed considerable spare capacity in the economy throughout 1972–73.[19] Nevertheless, it is not difficult to reconcile the existence of a "high" unemployment rate with a demand induced explanation of accelerating inflation.

First, and least important, the mechanics of an expectations-augmented Phillips curve, when expectations are based on some kind of error learning mechanism, predict that when unemployment is falling, inflation will accelerate before the natural unemployment rate is reached. There is evidence that such an expectations scheme fits British data rather well.[20] Second, if as many believe, wages and prices respond more rapidly to excess demand than to excess supply, then an expansion of demand that is accompanied by an increase in the dispersion of demand pressure across micro markets will lead to inflation rising above its expected rate *before* the natural unemployment rate is

[18] In its November 17, 1973 issue *The Economist* produced data purporting to show that domestically generated inflation in Britain over the previous year had been lower than in any other OECD country, attributed this to the success of wage and price controls, and headlined the article "The miracle that Ted [Heath] pulled off, and nobody saw him do it." On July 27, 1974, *The Economist* again argued that "Mr. Heath's success in holding [wages] back with his counter-inflation policy begun in the autumn of 1972 is striking. But as wage increases slowed down, import prices took off" (p. 85). For an example of a similar cost accounting exercise masquerading as an explanation of inflation in a learned journal, see R. G. D. Allen. Hicks takes a position somewhat similar to Worswick. He argues that Britain's problem in the 1970's is imported inflation, that the rises in commodity prices that took place in world markets in the 1970's were largely independent of the inflationary policies pursued in industrialized countries, hence were an exogenous source of inflation in those countries, and were not to be counteracted with monetary policy. Even so, his own calculations show that the British import price index which showed an increase from 100 to 1970 to 226 by the end of 1974, would, if recalculated in terms of Deutschmarks, have reached a value of 148 over the same period. In short, 78 percentage points of the change in the index may be attributed to the behavior of exchange rates. See Hicks (1975, p. 10).

[19] The National Institute of Economic and Social Research devoted pages 24–33 of its November 1973 *Review* to the question of whether or not the economy was "overheated," and concluded that there was no reason to suppose that it was. Though not stated in such terms the conclusion was that the natural unemployment rate had not shifted since the 1960's and that the economy was operating well above that natural rate in mid-1973. There is no space here to enter into a critique of the means whereby the *NIESR* reached this conclusion; suffice it to say that I did not then, nor do now, find the relevant arguments convincing, but certainly recognize that this matter is crucial to the interpretation of the 1972–73 boom that I am advancing here. Note that Gray, Parkin, and Sumner estimate that the natural unemployment rate had risen from under 2 percent in the 1950's and 1960's to over 3 percent of the labor force by 1973, but also note that this estimate is subject to a wide margin of error.

[20] See equations (1)–(3) above, although that formulation of the curve is more relevant to a fixed exchange rate regime. Note also that John Carlson and Parkin show that a species of adaptive expectations explains survey data on British inflationary expectations rather well.

reached. There is evidence that the 1972–73 boom was accompanied by just such an increase in dispersion of demand both between industries and regions.[21] Finally, the natural unemployment rate of the British economy was by 1972 well above the level that had prevailed in the 1950's and 1960's. As Figure 1 shows, unemployment rose secularly throughout the period 1953–75, but this tendency was particularly marked after about 1966.

This increase in the natural unemployment rate was widely discussed in Britain in the late 1960's and early 1970's, the phenomenon usually being referred to as a shift in the vacancy-unemployment relationship. It seems to have had a number of sources. The low birth rate of the interwar years coupled with the high postwar birth rate meant that by the late 1960's, older workers reaching retirement age and young relatively inexperienced workers made up an unusually high proportion of the labor force. Moreover, there is some evidence to suggest that until the late 1960's labor hoarding by firms involved the existence of a certain amount of hidden unemployment. This unemployment became visible not only as a result of a "shake out" of labor during the rather deep 1970–71 recession but also as a result of a considerable improvement in the economic status of the unemployed that was brought about in the mid-1960's. Further, there is evidence to suggest that the latter factor contributed to an increase in search unemployment.[22]

Nevertheless the behavior of unemployment over the 1972–73 period simply confirmed those who held it in their belief that inflation was not the result of domestic policies. The *NIESR* went so far as to interpret the behavior of the balance of payments, which had gone from a current account surplus of £0.07 billion in 1972 to a deficit of £1.47 billion, or over 2 percent of *GDP*, in 1973 despite an 18 percent fall in the exchange rate over the two previous years, as providing evidence *against* the presence of general excess demand in the economy.[23] However, even if the deterioration of the balance of payments and the decline in the exchange rate were not attributed to the conduct of domestic policy by the authorities and their advisors, these factors certainly began to influence the conduct of policy at some time in 1973. Although the miners' strike, the three-day week, and the February election marked the final collapse of the Conservative Government's policy in early 1974, that policy had been changing for a few months previously. Although expansionary policies were not blamed for the behavior of the balance of payments and the exchange rate, contractionary policies were nevertheless implemented in order to deal with these problems.

## V

We have seen that monetary policy became sharply contractionary in 1973, and continued in that vein throughout 1974. This change roughly coincides with a large increase in the share of public sector borrowing financed by sales of debt to the nonbank public. This ratio averaged 35 percent over the last three quarters of 1972 and 55 percent in 1973. Whether the reversal of the monetary aspect of economic policy was deliberate or accidental is hard to say, for it has been and remains the constant claim of all political parties that they

[21] See the *NIESR Review*, Nov. 1973, pp. 28–29, for a discussion of the dispersion of aggregate demand in 1973.

[22] On demographic factors, see Foster; on labor hoarding see Taylor; and on the role of the level of unemployment benefits see Dennis Maki and Z. A. Spindler. Samuel Brittan provides a useful summary of the evidence on these matters.

[23] See the *NIESR Review*, Nov. 1973, p. 30. The case put there rests on the volume of imports and exports having grown at the same pace during the boom, whereas it is argued that had there existed domestic excess demand, the volume of imports should have increased more than that of exports. The *NIESR* did not consider the behavior of the exchange rate relevant to interpretation of this evidence, and did not explain why.

would not resort to a tight money policy in order to combat inflation, but this turnaround was shortly followed by an attempt to reverse fiscal policy as well. The borrowing requirement of the public sector for 1973–74 generated by the March 1973 budget was just under £4½ billion or about 7 percent of *GDP*. A supplementary budget introduced in December 1973 sought substantially to reduce the borrowing requirement for 1974–75, and at the beginning of March 1974 it was forecast to be £3.4 billion. Although some observers were worried that the reversal was being implemented a bit too rapidly for comfort, particularly as far as the rate of monetary expansion was concerned, it nevertheless appeared that in the winter of 1973–74, some kind of rough and ready sanity was being restored to the conduct of macroeconomic policy in Britain despite prevailing economic orthodoxy. In fact, the very opposite was happening.

Budgets are usually an annual affair in Britain, but the December 1973 budget was the first of a series of five in a sixteen-month period. Even the most orthodox Keynesian might find such zeal for fine tuning excessive, and suspect that all was not well with the conduct of policy during these months. However, the actual aggregate outcome of these budgets bore so little resemblance to the government's expressed intentions at the time of their introduction that the only reasonable conclusion can be that 1974 saw the disintegration of the machinery of macro-economic policymaking in Britain. During the fiscal year 1974–75, the public sector intended to borrow just under 5 percent of *GDP* but in fact ended up borrowing about 10 percent; public sector borrowing for 1975–76 is running at about 12 percent of *GDP* and over one-quarter of this borrowing again was not forecast. This unintentionally highly expansionary fiscal policy ran against a continued tight monetary policy, and the unemployment statistics for 1974–75 are eloquent testimony as to which policy tool proved the more powerful.

At this stage there can be no definitive account of what went wrong with the budgetary process in 1974–75, but two broad factors seem to have contributed to the debacle, the first political and the second technical. The Labor government elected in early 1974 replaced statutory wage controls with a voluntary program known first as the "Social Compact" and later as the "Social Contract." Its essence was that the trade unions agreed to limit their demand for increased wages to the rate of inflation, while the government in turn agreed to maintain for a while the price control program of their predecessors, to freeze certain key prices such as rents, and to subsidize certain basic foodstuffs. Since it was never specified whether the rate of inflation to which wage demands were to be limited was the past rate, the current rate, or the expected rate, it was not even necessary for anyone to resort to subterfuge in order to achieve whatever wage increases market conditions indicated.

General wage inflation coupled with price restraint in the public sector involved nationalized industries in increasing deficits; food subsidies had to be paid; and a rent freeze in an economy where about one-third of households occupy already subsidized publicly owned housing ensured a further open-ended commitment to public expenditure. One cannot lay the social contract at the door of professional economists, either inside or outside of government service.[24] They are more culpable of

[24] However in August 1974 the *NIESR*, though doubting that the Social Contract would achieve all its aims, was nevertheless arguing that it be given a year to run as a prelude however to a new round of statutory controls (p. 6). In House of Commons (1974), responding to a question about the desirability of statutory wage and price controls, Sir Kenneth Berrill, then Chief Economic Advisor at the Treasury, is recorded as having said, with more than a little irony, "I do not think I am able to answer that because the present view of the Government, and, therefore, of the Treasury, is that a voluntary incomes policy will work" (p. 141 in House of Commons, 1975, para. 496).

whatever it was that went wrong with official and unofficial forecasts of inflation and unemployment rates in 1974–75. Public expenditure planning in Britain is carried out in real terms. Government departments are automatically granted funds to cover inflation induced cost increases. There is no current purchasing power cash budget to constrain their expenditure. Such a *modus operandi* means that errors in forecasting the inflation rate and relative prices play havoc with government finances. At the same time, the whole thrust of British government forecasting is geared to predicting real income and unemployment. Forecasts of the inflation rate are ancillary to this goal, so that it is not too surprising that such forecasts are relatively unreliable. The major part of the error in forecasting public sector borrowing in 1974–75 seems to have arisen from underestimates of the effects of inflation on public sector costs.[25]

Even though public sector borrowing climbed steadily in 1974–75, and is doing the same in 1975–76, a relatively low rate of monetary expansion was nevertheless maintained until the end of 1975. Although the current account of the balance of payments remained in heavy though decreasing deficit throughout the period, the exchange rate nevertheless remained stable between the end of 1973 until mid-1975 when it fell abruptly to an effective devaluation of about 30 percent below its Smithsonian parity. The explanation of these facts is straightforward. First, the ratio of sales of public sector debt to the nonbank public to total public sector borrowing remained high throughout 1974 and 1975. Moreover, the oil price increase of 1973 led to large capital inflows to Britain, first as oil producers invested surplus funds in London, and secondly as the increase in the prospective value of North Sea oil attracted development capital. In addition to this the public sector actively raised funds in foreign markets over this period.

The effects of the exchange rate being thus supported by capital inflows and public sector borrowing were to permit real domestic expenditure to remain substantially above domestic output and to ensure that the inflation rate was somewhat lower than it otherwise would have been. Policies to reduce the level of public sector borrowing must form a key part of any strategy that is to restore long-run stability to the British economy, and the period of exchange rate stability during 1974–75 might have played a valuable role in smoothing out the inflation rate a little while such policies were implemented. However, this breathing space was wasted; all that was accomplished by the delay in the decline of the exchange rate was to transfer to late 1975 and early 1976 some inflationary pressure that would otherwise have been felt earlier. In 1974–75, rising unemployment generated by, but not attributed to, monetary policy inhibited the authorities from any serious attempts to tighten up on the fiscal side, though given the breakdown in the machinery of policy implementation already described, it is far from clear that they could have succeeded in this endeavor if they had tried.

## VI

The British economy at the beginning of 1976 presents a confusing picture. The public sector is borrowing over 12 percent of *GDP*, much of this to finance transfers and subsidies. Increasingly this borrowing requirement must be met domestically. At the same time, unemployment, though rather low by current international standards, is still high enough to create a major political problem. The government is un-

[25] See House of Commons (1975) for an account of these and other factors affecting public sector borrowing. I base my account of the role of the inflation rate in official forecasting on the Treasury's evidence to the House of Commons Public Expenditure Committee. See House of Commons (1974, paras. 426–33, pp. 127–30 and paras. 455–63, pp. 134–35).

dertaking all manner of piecemeal job saving and creating schemes to deal with it and these are, of course, adding further to public expenditure. Inflation still seems to be regarded in official circles as mainly a cost-push phenomenon, and recently introduced wage controls are going for a while to seem successful as unemployment, generated by the tight monetary policy set in motion in 1973, has its predictable effect on the inflation rate. The one hopeful aspect of the current situation is that far more attention is now being paid to the behavior of the money supply than in the past, and the government has recently and publicly committed itself not to permit renewed rapid monetary expansion. The question remains, however, as to how durable that commitment will prove to be.

The key to maintaining a reasonable monetary expansion rate in Britain must be a reduction in public sector borrowing. It is inconceivable that this can continue to run at the rate of 12 percent of *GDP* without thereby generating a renewed acceleration in the rate of money creation.[26] The inflation rate is now falling rapidly, and an upturn in real economic activity is forecast for 1976. Both of these factors should help to bring the borrowing requirement down, and there seem to be no insuperable technical problems involved in preventing a large increase in the monetary expansion rate.

The real danger in the present situation is political. There is no sign of any early fall in the unemployment rate, and the government must find itself under increasing pressure to "do something" about this problem. If those in authority are convinced that inflation has been brought down in 1975–76 not by monetary policy, but rather by the use of wage controls, and if they are also persuaded that high unemployment makes such controls less rather than more effective, as is still being argued in some circles,[27] then they will be strongly tempted to implement expansionary fiscal policy, accompanied by wage and price controls, whose consequences for monetary expansion and the inflation rate will be qualitatively similar to those of the 1972–73 episode, even if resort is had to import controls in an attempt to shore up the exchange rate and hence to offset "imported" inflation. In short, whether 1975 has seen the peak in Britain's postwar inflation, or merely an upper turning point in a continuing and explosive series of cycles remains to be seen.

[26] It is fair to record that this seems to be the view of *The Economist*, which now pays much more attention to the role of monetary factors in generating inflation than it did even as late as 1974. See, e.g., January 24, 1976, where it is noted that "Mr. Denis Healey will keep tighter screws on money and demand than any of his postwar predecessors during [1976]. So far so better" (p. 71).

[27] See, for example, Lord Kahn (1976).

# Can a Rise in Import Prices Be Inflationary and Deflationary?

## Economists and U.K. Inflation, 1973-74

*By* Marcus H. Miller*

In June and July of 1974, the influential Expenditure Committee of the House of Commons heard submissions from economists in the public and private sector on "Public Expenditure, Inflation, and the Balance of Payments," House of Commons (1974). The hearings came just a few months after the sharp rise in oil prices, and the demise of a Conservative government whose incomes policy had made no special allowance for a rise in coal miners' income despite the increase in energy prices. The witnesses called to give evidence included prominent British macroeconomists of both Keynesian and Monetarist persuasions; thus, for example, Lord Kahn and David Laidler both spoke before the Committee.

The Committee reported, "We are told that a rise in the price of imports was both inflationary and deflationary" (para. 23), which they understood to mean "price increasing and employment reducing." They also noted that the various witnesses were far from unanimous in what they thought the impact effects would be, and in what they recommended by way of policy. This paper will initially focus on how Keynesians and Monetarists expected the shift in the terms of trade to affect prices and output, and what policy conclusions were derived, using evidence given to the Committee. The main reason for concentrating on this aspect of recent inflation is evident from inspection of Figure 1 which shows how severe was the shock of the rise in import prices over the period 1973–74 (import unit values rose by over 60 percent from 1973-II to 1974-II).

Later I discuss how the inflationary effects of such an external shock may be amplified by what Sir John Hicks (1975b) has dubbed "real wage resistance," so that a bout of "imported" inflation may be followed by a spell of "home-grown" inflation. Some witnesses (including those from the Treasury and the National Institute) had referred to the possibility of inflationary pressures from this source (House of Commons, paras. 49, 50, 136, 498).

I will argue, however, that neither the Committee nor Hicks gave sufficient attention to the role of the incomes policy in operation when the price of oil rose so dramatically. For this policy not only involved confrontation with the coal miners, it also led to the linking of the wages of about one-third of the work force to the retail price index, at a time when the latter rose sharply because of a change in terms of trade. Thus the incomes policy helped to prevent real wages from falling when economic circumstances called for such a change.

Perhaps it is not surprising, therefore, that the report had very little positive to say about incomes policy, confining itself to expressing the view that "a permanent, statutory prices and incomes policy is in modern Britain politically both imprac-

* London School of Economics and Graduate School of Business, University of Chicago. I would like to thank M. J. Artis, T. Burns, S. G. B. Henry, R. A. Jackman, D. Laidler, D. Sargan, and J. Wise for their comments, without implying that they would accept the views expressed here.

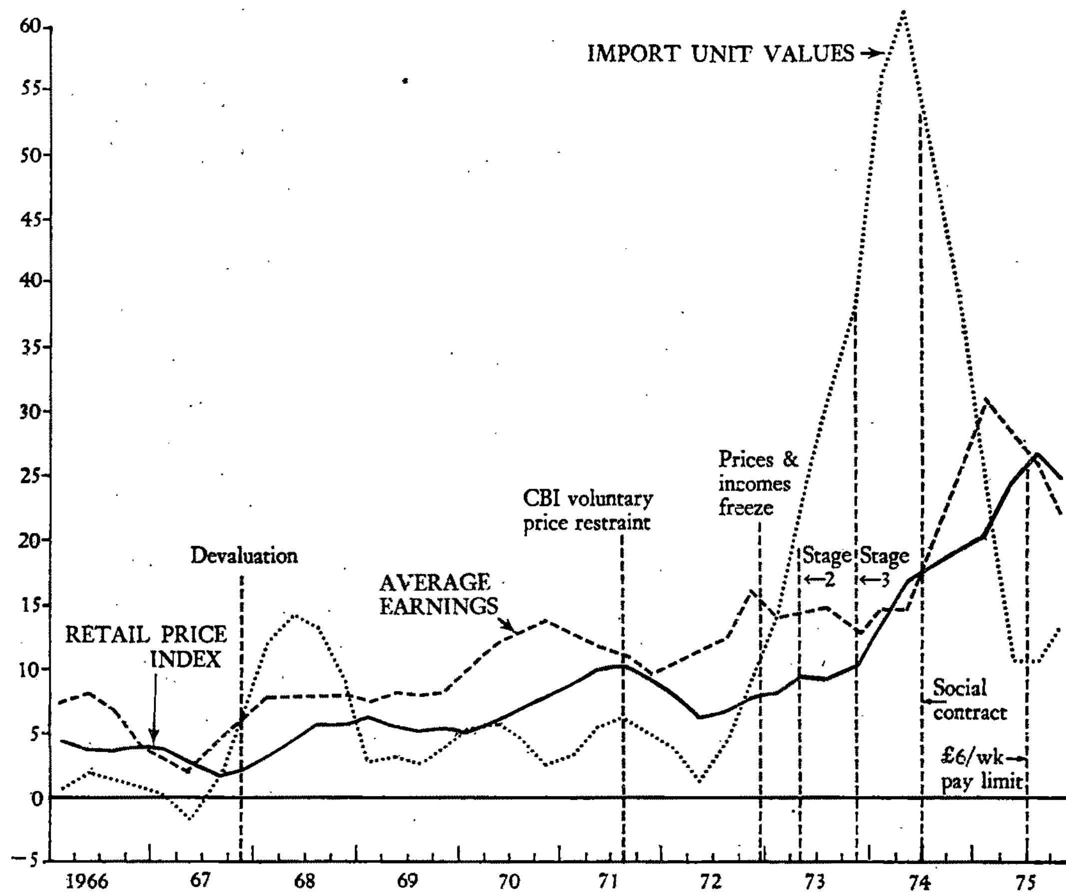

FIGURE 1. RETAIL PRICES, AVERAGE EARNINGS AND IMPORT PRICES (unit values)

ticable and objectionable" (para. 44). An incomes policy calling for a dramatic reduction of nominal wage growth was nevertheless implemented by a Labour administration within a year of the report being published, and the future prospects for the exchange rate appear to depend heavily on the appropriate extension of such a policy beyond July 1976. Though I criticize the policy of indexing wages pursued over the period 1973–74, my examination of the determination of real wages indicates a useful role for incomes policies in mitigating the "cost-push" inflationary pressures that arise from increased taxation and from changes in the terms of trade.

## I. The Economic Situation Prior to the Oil Price Rise

Prior to analyzing the consequences of the rise in import prices from mid-1973 to mid-1974, I must briefly consider the situation before then. The economy as a whole was in what has been referred to as a "super-boom" as a consequence of expansionary action on a number of fronts.

As regards fiscal policy, for example,

there had been a substantial increase in the "adjusted budget deficit" since 1971 (see Table 1). The figures show that the adjusted deficit had risen by about $1\frac{1}{2}$ percent since 1971, despite the fiscal drag to be expected during such a recovery. Monetary policy had also been extremely lax since the reform of the monetary system in 1971.[1] Broad money, $M_3$, grew by over 50 percent from mid-1971 to mid-1973, for example.

Soon after it had become apparent that the economy was set for a period of very rapid expansion, there was a run on sterling with the result that the currency was floated in mid-1972. The immediate adjustment was a 10 percent fall in the "effective" rate from its Smithsonian parity, but this was followed by a further depreciation of 7 percent in the first half of 1973. Not surprisingly, in the circumstances described, unemployment fell from $3\frac{1}{2}$ percent in mid-1972 to $2\frac{1}{2}$ percent in mid-1973.

In an effort to contain the undoubted inflationary pressures generated by this combination of fiscal, monetary, and exchange rate stimuli, the Conservative government, much against its inclinations, instituted a three-stage incomes and prices policy as follows:

> A freeze on wages and salaries was introduced in November 1972 (though not until after a large number of double-figure anticipatory settlements had been rushed through in the preceding months) and lasted until the end of March, although pre-freeze agreements, of which there were many, were allowed to stand. This was followed by Stage 2, in which increases of up to £1 per week plus 4 per cent were permitted (with a ceiling of £250 per annum) and then from November 1973 Stage 3, in which the allowable increase was basically £2.25 per week or 7 per cent (with a ceiling of £350 per annum). [*NIESR Review*, 1974, p. 18.]

In addition, and of vital importance for the subsequent course of events, under Stage 3 wages could be "indexed" for twelve months under a threshold agreement which came into operation when the retail price index (*RPI*) rose by more than 7 percent above its level in October 1973.[2]

With import prices rising by 25 percent over the year to mid-1973, earnings rose by 15 percent and prices by 10 percent over the same period, despite the incomes policies (which did allow for certain costs to be passed on). The deflationary budget and the drastic action to control the money supply taken in November 1973 were designed to offset some of the then existing inflationary pressures and are not to be thought of as the response to the oil crisis. The sort of reaction appropriate to a rise in the oil price itself is considered next.

### II. The Keynesian Diagnosis

I turn to the Keynesian account of how the sharp rise in the price of imports at constant exchange rates was "both inflationary and deflationary." G. D. N. Worswick, Director of the National Institute of Economic and Social Research, endorsed this view before the Committee (paras. 132–35) and I will cite extensively from the National Institute's quarterly review in what follows.

I must first warn the reader that a large change in relative prices of this kind plays tricks with key macro-economic measures. Thus, we may have a rise in the domestic

[1] The program of changes was called "Competition and Credit Control." As part of this program ceilings on bank lending were scrapped and what control there was on bank lending was supposed to come from control of "reserve assets"; but these were in plentiful supply for much of the time, and burgeoning government deficits were taken by the banks to indicate that the supply would continue.

[2] The maximum compensation for inflation was at the rate of 40p per week for every 1 percent rise in the *RPI*, which was designed to represent complete compensation for the average male manual wage earner (but was clearly more than that for the lower paid and less for the better paid).

TABLE 1—ADJUSTED PUBLIC SECTOR DEFICIT: 1970–74[a]

| | Weighted Receipts | Weighted Expenditure | Weighted Deficit | Weighted Deficit Less Impact of Oil Deficit[c] |
|---|---|---|---|---|
| 1970 | 25.3 | 33.0 | 7.7 | — |
| 1971 | 24.3 | 33.0 | 8.8 | — |
| 1972 | 23.3 | 33.4 | 10.1 | — |
| 1973 | 23.4 | 33.6 | 10.2 | — |
| 1974[b] | | | | |
| Mar. I | 24.9 | 34.6 | 9.6 | 7.6 |

| Nov. I | 25.7 | 37.4 | 11.8 | 9.8 |
| Nov. II | 25.2 | 37.4 | 12.2 | 10.2 |

*Source: NIESR Review* (1975, pp. 14–16).

[a] All figures expressed as percentage of current *GDP*; the weights attempt to measure the effect of budget components on aggregated demand; no attempt is made to "standardize" the budget on full employment income.

[b] I before budget changes; II after budget changes.

[c] The impact of the oil deficit on aggregate demand is put at 2 percent *GDP*.

price level without any change in the *GDP* deflator, and a fall in real incomes without any change in *GDP* at constant prices. This may be seen most clearly by leaving on one side any employment effects, and by assuming also that the rise in import prices leaves domestic wages and profits unchanged in nominal terms. Defining nominal income as $Y \equiv PF - P_I M$, where $F$ is the total final sales, $P$ is the associated price index,[3] $M$ is the volume of imports, and $P_I$ is the price index for imports, we may further assume that $M = mF$, so import volumes depend upon the total final sales. (Ignoring the price elasticity of demand for imports is not unreasonable for the case of raw materials and oil.) Given that sales and import volumes are constant, the domestic price level $P$ may rise as higher import costs are passed on, without any change in domestic nominal incomes; hence the *GDP* deflator is not an appropriate index of inflation in these circumstances, when it is "foreign costs" not "home costs" which have risen.

Nor is constant price *GDP* a good measure of real national income since, with volumes unchanged, such a constant price measure will show no change; yet clearly real incomes fall when prices rise relative to constant nominal income, as can be seen from defining[4] real national income as $Y^R \equiv Y^N/P = F - MP_I/P$. The fall in the nation's real income due to the shift in the terms of trade between 1973 (first half) and 1974 (first half) was estimated by the Central Statistical Office to be over 5 percent (see article by J. Hibbert).

The Keynesian account of the *inflationary* impact of the rise in the price of imports can now be expressed simply enough. Real national income has to fall,

[3] Final sales includes exports (as well as government purchases and private consumption and investment). For the sake of simplicity it is assumed that the price of exports moves in line with that of goods sold domestically, so that one index $P$ can be used for all such sales. The important consequences of the price of exports rising relative to other domestic sales are thus not considered in this paper. The Southampton University econometric model being constructed by I. F. Pearce and his colleagues is specifically designed to examine the effects of such changes.

[4] In answer to questions on this point, Wynne Godley answered as follows:

> The real national output is defined as the total value of what we produce valued at constant prices—that is *including* exports at constant prices but *excluding* imports at constant prices. The real national income is defined as the total factor income deflated by the price of domestic expenditure. [House of Commons, para. 89]

but if nominal incomes are rigid downward at a given level of employment, the fall in real incomes must take place by prices rising relative to factor incomes, as import costs are passed on. Nor would appreciating the exchange rate to prevent any rise in the price of final sales $P$ obviate the need for a fall in nominal factor incomes, since the appropriate upward float would only be a fraction of the initial rise in the price of imports; which is one reason why Keynesians were not inclined to recommend exchange rate changes in this context.

We have seen that (even with floating exchange rates) stability of final output prices would only be achieved by a fall in nominal factor incomes relative to what they would have been in the absence of the shift in the terms of trade. Such a fall would, in the Keynesian view, require a rise in unemployment. Now, as we see below, Keynesians were in fact predicting a rise in unemployment in these circumstances, though their policy prescriptions were to offset this and to accept the "imported" rise in the price level.

On the income-expenditure approach, the fall in real income described above will tend to reduce aggregate demand. As the National Institute reported: "The demand-contractionary impact of the new oil prices (akin to a large increase in indirect taxes except that the proceeds accrue to foreigners) was . . . quickly appreciated in this country" (*NIESR Review*, 1975, p. 9). While the fall in national real income will obviously depress domestic aggregate demand, the net effect of such a "transfer" of income depends crucially on the marginal propensity to consume *U.K.* exports on the part of the recipients of the transfer. While this propensity is high for many raw material producers, it was widely accepted that this would not be so for the Arab oil producers; hence, the net impact of the oil price rise was reckoned to be contractionary.[5] Assuming *no* change in exports, the appropriate expansionary action on the income-expenditure approach is for the government to cut taxes by the fall in national real income, so that real national disposable income remains constant, or to increase its own expenditure by the marginal propensity to spend out of the real income loss (see the Appendix).

This is illustrated in Figure 2 which shows total final sales $F$ on the vertical axis as an increasing function of real income $Y^R$ on the horizontal. The cost of imports, whose volume depends on $F$, is subtracted from $F$ to give a measure of domestic-income-creating expenditure (current $GNP$ deflated by the price of total final sales) on the vertical axis. From a position of equilibrium with the current account balance at full employment (with sales at $F_0$), the terms of trade ($h \equiv P_I/P$) shift from $h_0$ to $h_1$, reducing full employment real national income by $M_0 dh$ from $Y_0^R$ to $Y_1^R$. As we can see, there is a deficiency of aggregate demand at this new level of full employment real income. To avoid the unemployment associated with the equilibrium shown at $Y_1^R$ and total final sales of only $F_1$, the authorities must increase the ratio of expenditure to income, as shown by the schedule $F^*(1-h_1 m)$, through an increase in their own spending or a cut in taxes or some combination of the two.

By splitting total final sales into absorption $A$ and exports $X$, and plotting $Y_R - A$ and $X - hM$ against real income as in the lower panel, it is clear that preserving full employment at $F_0$ in this way involves accepting a deterioration in the cur-

[5] The *NIESR Review* (1975) reported that:

> The new Chancellor was quick to point out to his colleagues in other finance ministries the strength of the contractionary forces involved and urged them—especially those with strong external accounts—to take offsetting reflectionary action . . . for nearly the whole year his exhortations fell on stony ground—the Americans, in particular, delayed in the hope of forcing the oil price down again, while in other countries the implication that acceptance of external deficit necessarily meant the acceptance of greater budgetary deficit . . . was not taken to heart. [pp. 9–10]

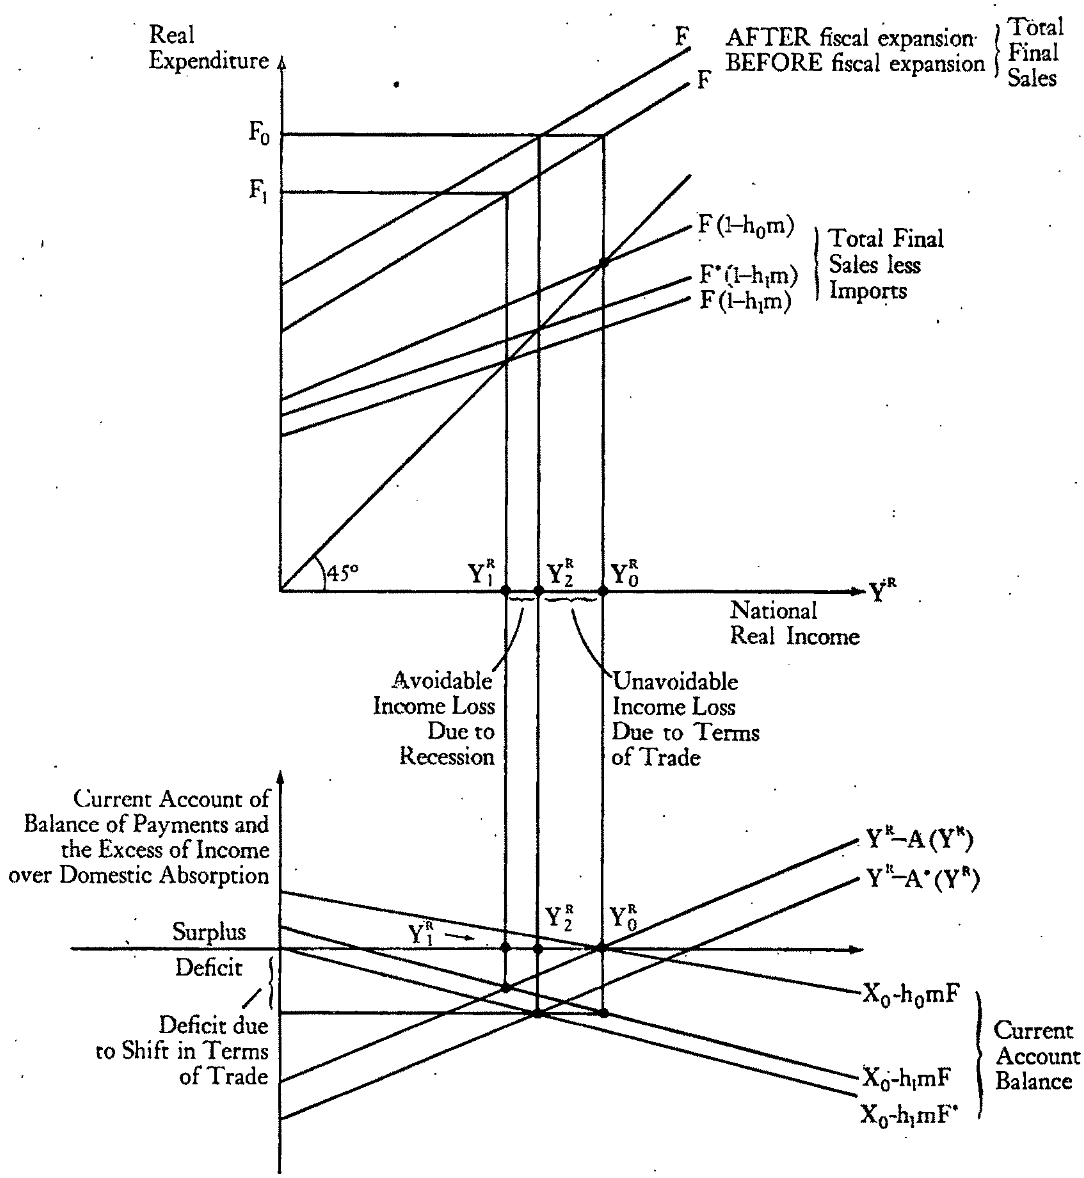

FIGURE 2

rent balance equal to the reduction in real national income.[6]

[6] How much real income will fall in the absence of government action obviously depends on the slopes of the two schedules. One of the principal issues investigated by the committee was the contention by Wynne Godley and Francis Cripps of Cambridge University that the schedule showing the excess of real income over absorption would not increase markedly with real income, implying a large multiplier effect of import price changes on domestic income and employment. The committee concluded only that Godley's hypothesis "was not obviously discredited" (House of Commons, para. 37).

As for the fiscal action actually taken by the *U.K.* authorities in 1974, the *NIESR Review* (1975) noted that:

The Chancellor's intention actually to

> *reduce* the U.K.'s budget deficit in his (admittedly provisional) March budget appeared to run counter to his correct analysis of the situation of the industrial world as a whole. . . . The subsequent budgets of July and November and, most importantly, the revision of the March estimates, restored consistency between the Chancellor's words and his deeds. [p. 10]

As can be seen from Table 1, the increase in the adjusted budget deficit between 1973 and the end of 1974 just matched the deflationary impact of the oil deficit on *U.K.* demand (put at 2 percent by the National Institute). Although the increase in the weighted deficit between March and the end of the year was to a large extent "nondiscretionary," the fact that the authorities did not act to reverse this increase in the November budget shows that they were willing to act in such a way as to offset the contractionary impact of the oil price increase.[7]

### III. The Monetarist Diagnosis

While Keynesians were in favor of letting the rise in prices reduce real incomes and were more exercised about the level of employment, Monetarists scoffed at the idea that there was any need to "import inflation" in this way and recommended a policy of not increasing "monetary demand" in response to the adverse change in the terms of trade. But if final prices are not to rise when, as a result of the change in the terms of trade, real incomes have fallen, then, as we have seen, nominal incomes must fall below the path that they would otherwise have followed. This is not to say that Monetarists expected money wages to fall; simply that their principal policy recommendations, if they were not to lead to unemployment, required that money wages would rise *less*—in the presence of a shift in the terms of trade—than they would otherwise have done.

Monetarists were, moreover, not particularly concerned about the effect of such a slowdown in incomes on aggregate demand, since of course for them the principal determinant of nominal expenditure is the money supply, not nominal income. In two crucial and characteristic respects, therefore, the Monetarist approach to events differed from its Keynesian counterpart; first, Monetarists were relatively optimistic about the possibility of deflecting money wages downward from their previous path, and, second, they ascribed much less importance to the effect of incomes on expenditure. To illustrate these differences, we will examine the position taken by Laidler in his evidence to the Expenditure Committee as described in the final report (which was written, it so happened, with the assistance of another Monetarist, Alan Walters, as specialist adviser to the Committee).

On an implicit assumption of flexibility in factor costs, the Monetarist approach[8] proceeded by comparing the "supply" of goods to the home market with the "monetary demand" for them, the latter being related principally to the domestic money stock. For any given level of domestic output, the supply for the home market is defined by what is left over after export demand has been met. As to the level of export demand, the Committee put it to the witnesses that "Realistically they must assume . . . that the full additional cost of

[7] Some of the nondiscretionary increase in government expenditure was the result of public sector wages and salaries rising faster than predicted (over a period in which many such increases were indexed to the retail price index). Some of the adverse cost-inflationary effects of this rise in public sector incomes are considered briefly below.

[8] The approach adopted by *U.K.* Monetarists at that time had little in common with what is now called "the monetary theory of the balance of payments." For more detail of the Monetarist position, reference can be made to the pamphlet by Harry Johnson et al. and especially the Appendix to that piece, which was written by Walters (who had published an earlier version in December 1973).

the increase in the price of oil is borrowed from the suppliers of that oil. Assuming that the same quantity of oil is imported, it follows that the supply of goods on domestic markets is not affected at all by the price rise. The question is then what would happen to the demand for these goods" (para. 48).[9]

Laidler's answer to the question posed was summarized in the next paragraph of the report and we quote this at length:

> Professor Laidler argued that provided there was no increase in the rate of growth of money supply there was no reason to suppose that demand would be further augmented so that there would be no additional inflationary effect. He agreed with all witnesses that there would be an increase in the price of oil and of those goods which use oil intensively relative to the price of other goods. But then in Professor Laidler's terms the rate of inflation of other prices during this period will be somewhat less than the rate of inflation which they would have experienced in the absence of the oil price rise. [para. 49]

So, with the same volume of goods supplied to the domestic market and with no change in the growth of the money supply in response to the change in import prices, we are to expect basically no change in the path of the domestic price index. Some goods will inflate faster, but others less. How about factor incomes? They must, of course, have grown more slowly, because if they showed no change, then the price level would have risen.

The striking difference between the two schools can be graphically illustrated as in Figure 3. In the right-hand panel the principal features of the Keynesian income expenditure treatment are repeated from the previous section. In the left-hand panel, with the price level on the horizontal axis, we portray the essence of the Monetarist account.

We take as a starting point a position of high employment and current account balance with total final sales at $F_0$ and real income at $Y_0^R$. The supply of goods to the domestic market, i.e., for domestic absorption, is total final sales less exports. Together with the initial price level, this "supply" gives the value of domestic expenditure in the initial equilibrium; see point $A$. Through this point is drawn a schedule showing those combinations of domestic absorption and prices which have the same nominal value. Along this schedule, to use Monetarist terminology, "monetary demand" is constant, and as Laidler's account indicates, the level of monetary demand is principally governed by the money stock.

What effect does a change in the terms of trade have *ceteris paribus* on the equilibrium at $A$ where the "demand" and the "supply" schedules intersect? Under the conditions put forward by the Committee, that exports are unchanged and so is the money stock, the answer is, of course, none at all! Hence the strict Monetarist conclusion that with no change in the growth of money, all will be well—no imported inflation and no fall in output or employment.

The Keynesian view was that by appropriate fiscal action, jobs could be preserved, but at the cost of "importing inflation." Hence, with no change in volumes, the value of domestic expenditure would rise as equilibrium shifted (from $A$ to $B$ in the figure) and this would require an appropriately permissive monetary policy. In the absence of fiscal stimulus, however, Keynesians predicted a contraction of aggregate demand which would lower real incomes by more than the fall due to the shift in the terms of trade. In Figure 3 this recession equilibrium is shown at a level of real income labeled $K$, which is associated with a lower level of total final sales ($F_1$) and so a lower supply

[9] The need to borrow overseas is because the exchange rate is assumed to be fixed, and the volume of exports to be constant, and it is for this reason that the supply of goods to the home market is said to be unaffected by the rise in import prices.

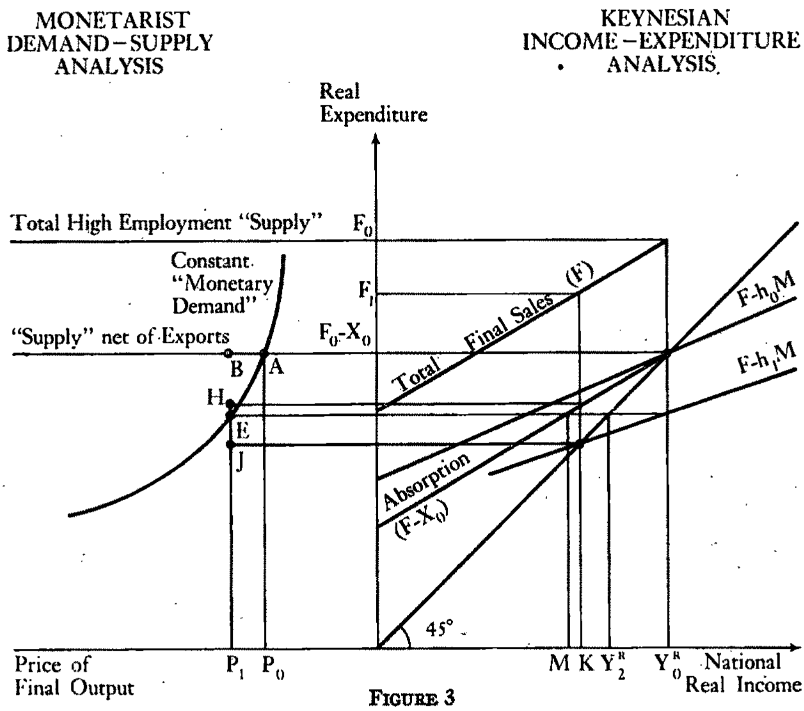

FIGURE 3

of goods to the domestic market. Assuming that prices stay at $P_1$ even in the recession, the value of domestic *expenditure* has risen above its initial level (compare point $H$ with the constant monetary demand schedule), although the value of nominal *income* will have fallen (see point $J$). Since, given a low enough "multiplier," a Keynesian contraction can thus imply a rise in the value of expenditure, a policy of keeping monetary demand constant may require an *even greater* recession. Thus, in the figure, keeping monetary demand constant in the face of prices which do not fall back from $P_1$ would require a contraction of supply to point $E$, which is associated with a fall of real incomes to some point between $K$ and $M$.

So, while Keynesians expected a rise in prices" as an explanation of *U.K.* inflation, and argued for "a gradual return mended expansionary fiscal policy and permissive monetary policy, the Monetarist logic predicted no inflation or recession as a consequence of the change in the terms of trade so long as fiscal and monetary policy were unchanged. Such is the contrast of views and policy recommendations stemming, in my opinion, from the different assumptions as to factor price flexibility and the determinants of aggregate demand mentioned earlier.

It should be mentioned that Laidler did, in his evidence and elsewhere, somewhat qualify the stark Monetarist position portrayed above. Thus he acknowledged that the fall in real income would have some effect on aggregate demand (see House of Commons, para. 187); and he did argue, on the subject of the oil price rise, that "the Government might be wise to permit a temporary inflation in order to help us over these frictions. It *might* be wise and it would have to *permit* it" (see Laidler). It hardly seems likely that Laidler and other Monetarists would wish such qualifications to be taken very far, however, as this would make their position approximate to that of the Keynesians.

However, in early 1974, Johnson, Laidler, Walters, and others signed an open letter to the Prime Minister (see Johnson et al.) which dismissed "the myth of world prices" as an explanation of *U.K.* inflation, and argued for "a gradual return to the aim of a balanced Budget," and recommended cuts in government expenditure and rises in taxation in order to secure a gradual reduction in the rate of increase in the money supply.

In his recent critique of Monetarism, Hicks (1975b) concludes, as I have done, that the Monetarist proposal to prevent imported inflation by controlling aggregate demand would require increased unemployment since domestic factor incomes have to be reduced.[10] "So," he concludes, "a Monetarist policy, applied to the emergency we have been discussing, is strictly deflationary. It involves a contraction of demand, below the level it could have been allowed to reach if the external situation had been more favorable." He goes on to note, "If several countries affected by the shift in the terms of trade all simultaneously adopted the monetarist policy, there is certainly a question whether a contraction, simultaneously adopted in this manner, could be kept under control. It is, therefore, very fortunate that this has not happened. In none of the countries affected has there been an attempt to go so far. But the price of not going so far has been an all-around increase in the rate of inflation" (pp. 8–9).

[10] Members of the Chicago Money and Banking Workshop pointed out that if the demand for nominal balances depended upon nominal *income* ($Y$) (and not nominal domestic *expenditure*, $P(F-X_0)$, as assumed in the above account of the position taken by Laidler and Walters) then a *constant* money stock would in fact "validate" the rise in final output prices due to imported prices. This is the interpretation of the Monetarist position which Hicks followed in his critique. Whether the quantity of money is more stably related to factor incomes or to domestic expenditure on final output appears to be an unsettled issue among Monetarists.

### IV. Real Wage Resistance

The majority of witnesses before the Public Expenditure Committee agreed that the rise in the cost of imported raw materials and oil would increase the price of final output, which would be consistent with nominal wages *not falling* in response to the change in terms of trade. But some witnesses raised the possibility of further rounds of inflation as "people try to offset the increase in their cost of living by asking for more wages" (see comments by Sir Kenneth Berrill in House of Commons report, para. 498). This was put most clearly by G. D. N. Worswick when he argued: "If all of us just took the rise in the price of oil on the chin that would be one thing, but most of us do not; we say, 'Our income is unchanged and prices have risen. We wish to restore our real income.' " (See House of Commons report, para. 136.)

The reason wage earners may resist a fall in the real wages in this manner, according to Hicks (1975b), is that:

> The wage earner's test for fair wages is not simply a matter of comparison with other people's earnings; it is also a matter of comparison with his own experience in the past. It is this which makes him resist a reduction in the purchasing power of his wage, and even a reduction in the growth of that purchasing power to which he has become accustomed." [p. 5]

Hicks has attributed much of the recent *U.K.* inflation to this phenomenon of "real wage resistance."

Now J. D. Sargan (1964) has fitted to *U.K.* data an equation which incorporates this notion that money wage behavior is largely determined by the attempt to restore real wages to a target level which grows steadily through time. Using a modified version of his equations, it is shown in the Appendix how a change in the terms of trade can as a consequence shift the output-inflation tradeoff in the domestic economy.

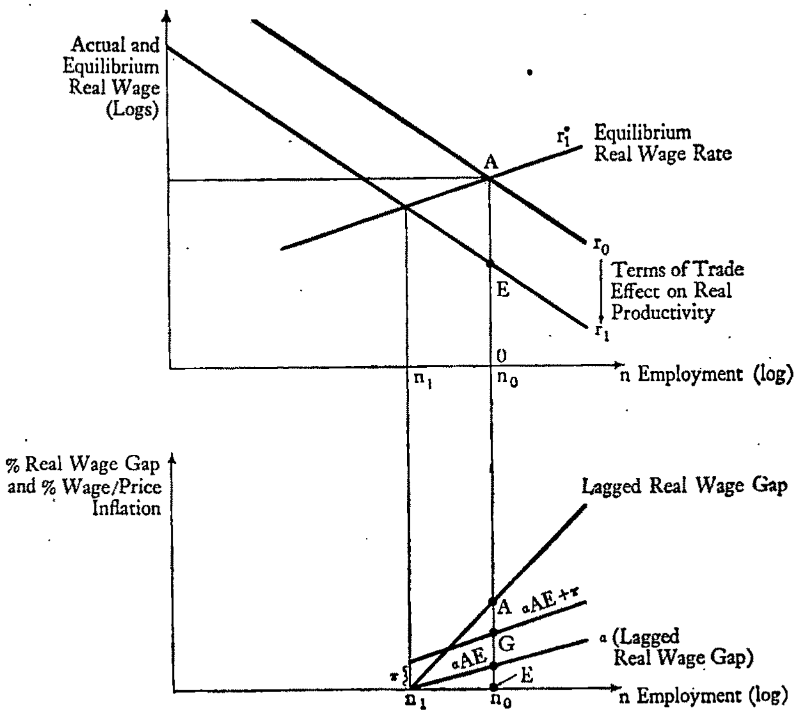

FIGURE 4

The ideas involved are illustrated in Figure 4. The schedule $r_0$ in the top panel shows the marginal product of labor at a point of time as a decreasing function of the number of people employed, $n$, both in *logs*. This marginal product must, in an open economy, be measured net of import requirements. (Thus in the levels it is the addition to the volume of final output *net* of the volume of imports required multiplied by the terms of trade or, to use earlier notation, it is $(dF/dN)(1-mP_I/P)$ where $n=\log N$.) Hence, though a deterioration in the terms of trade will not affect the physical productivity of labor, it will adversely affect the value-added by labor, as shown by the shift from $r_0$ to $r_1$ in the figure. The other schedule $r_1^*$ shows the desired or equilibrium real wage and can be, in the words of Sargan (1964), "interpreted as representing the joint nature of wage-bargaining procedure" (p. 38). The equilibrium real wage was estimated to fall with the number of people employed (relative to a given work force) as the demand for labor and the bargaining strength of the unions declined. It was also reckoned to rise through time (at roughly 2 percent per annum), though there was some evidence that this trend was reduced by the wage freeze at the end of the 1940's. (For simplicity such trends are ignored in the figure.)

The lower panel shows the percentage rate of change of money wages as a fraction $\alpha$ of the percentage "real wage gap" between desired and actual real wages in the period before, *plus* what inflation was then expected. Although inflation expectations were not found to be significant by Sargan (1964, 1971), they are included in this account with a coefficient of one in the light of more recent work on wage determination by J. Johnston and M.

Timbrell.

Of course, if there are no further changes in the exchange rate or foreign prices, then domestic wage/price inflation will in time offset the initial adverse shift in the terms of trade. This, in itself, would have required a considerable rise in British wages and prices after the 1973–74 rise in import prices; but in what follows it seems more appropriate (in the light of what later took place) to assume that the exchange rate depreciates to prevent such domestic inflation reversing the initial change in the terms of trade. Given that there are no subsequent changes in the terms of trade (and ignoring productivity trends), the growth of wages and prices should be the same, and the common rate of wage/price inflation is shown in the bottom panel.

Consider the implications of the initial adverse shift in the terms of trade for inflation in such a model, given that the authorities maintain aggregate demand and "validate" inflation by providing the required money supply. From an initial equilibrium with the real wage at $OA$, and zero inflation (although it could be any other steady-state rate), the system will be moved into disequilibrium with a real wage gap of $AE$, as the level of prices rises relative to wages. As long as there is no change in inflationary expectations, moreover, the rate of wage and price inflation will subsequently be $\alpha\ AE$. If, for example, $\alpha$ is 1/3 and the period is a quarter (see the article by Sargan, 1964), then a 5 percent real wage gap would mean inflation of just under 7 percent per annum. But as is familiar from the debate about the Phillips curve, expectations cannot long remain unchanged in these circumstances, so inflation will tend to accelerate; and, with a unit coefficient on expected inflation with employment at $n_0$ (at point $G$ in Figure 4, for example, actual inflation will exceed what was anticipated).

As can be seen from the figure, the only level of employment where a steady-state rate of inflation is now feasible is at $n_1$. The increase in the level of unemployment required to permit steady-state rates of inflation will depend upon the slope of $r_1$ as well as that of $r_1^*$, but for the latter, Sargan's initial calculations involved doubling the level of unemployment in order to reduce the equilibrium real wage by 3 percent; and subsequent estimates (see Sargan, 1971) have found the equilibrium real wage even less sensitive to the level of unemployment. So the "natural rate of unemployment" implicit in these relationships is quite sensitive to changes in the real wage.[11]

As is evident from the Appendix, this account of inflation as being related to a real wage gap actually bears a strong family resemblance to the "expectations augmented" Phillips curve (differing primarily by the inclusion of the lagged real wage variable). By that token, this explanation is as free of money illusion as the long-run vertical Phillips curve. Thus the nature of equilibrium embodied in the above relationships does not preclude steady-state inflation matched by steady depreciation of the currency and growth in the money stock. Also, as we have noted, under fixed but adjustable exchange rates, a devaluation from a position of initial equilibrium would be offset by domestic inflation, given accommodating monetary policy.

The inclusion of Sargan's lagged real

[11] The natural rate of unemployment here denotes specifically that rate of unemployment associated with the level of employment where the net marginal product of labor equals the bargaining-equilibrium (making steady rates of inflation possible). Note that even if the bargaining-equilibrium real wage at a point of time may be insensitive to the level of unemployment, there is more chance that the *trend* of this equilibrium rate may be lowered by higher unemployment. If this is so the natural rate of unemployment may given time return to the original level, as the net marginal product of labor rises faster than the target real income.

wage variable does make a considerable difference, however, since it explains how there would still be upward pressure on wage costs even if there is no change in the level of employment or in inflationary expectations. It does in this way explain shifts in the natural rate of unemployment (as defined above). These shifts will presumably be reversed in time as the change in the real demand for labor is appreciated by the suppliers of labor, but in the meantime maintenance of high levels of employment will be associated with accelerating inflation.

This description is consistent with Hicks's (1975a) account of the *U.K.* predicament. There he notes that the primary product crisis marked a sharp fall in the real earning power of British labor, and, he continues,

> Now that the veil of money has been so largely stripped off, we have to face it in terms of traditional economics, waking up from the sweet Keynesian dreams that have been with us so long. When the real demand for labor falls (as it has fallen) then, traditional theory says, either there must be a fall in real wages, or there must be unemployment. . . . It is the attempt to bring about such a fall in real wages by a lag in money wages behind money prices—a lag which has by now become quite undependable—that is the principal cause of the acceleration of inflation. [p. 19]

Nor was Hicks optimistic about the capability of fiscal or monetary policy to secure the requisite reduction in the real wage by controlling demand and increasing unemployment. Writing later in the year (1975b), he concluded: "One is therefore led to be more charitable to the 'social contract' and to the '£6 limit'—and to the successors which it is only too likely will have to follow them—than one is tempted to be from one's economist's prejudices" (p. 13).

Unfortunately, however, the operation of Stage 3 of incomes policy over the period November 1973 to July 1974 helped to *offset* any reduction of real wages beneath trend, and so to institutionalize such real wage resistance for a year, as I explain in the next section.

### V. Incomes Policy: Stage 3

Stage 3 was designed under the presumption that the terms of trade would shift in favor of the United Kingdom over the year following October 1973. With wages and salaries subject to a ceiling of 7 percent per annum and productivity growing by 3 percent, it thus appeared reasonable to assume that prices would not rise by as much as 7 percent; hence the policy allowed for compensation to be paid for increases in the price index above 7 percent from the starting date of the policy.

Thus the policy encouraged wage earners to assume that their real incomes would not fall; indeed, since wages were widely expected to "drift" above the 7 percent ceiling up to around 10 percent, the policy was consistent with a rise of 3 percent in real wages (without any triggering of the price threshold payments).

When the terms of trade shifted sharply against the United Kingdom and these higher costs were passed through into the retail price index, the operation of the ceiling on nominal increases had the initial effect of producing the "Keynesian" result that nominal incomes showed no reaction to the price rise and real wages fell. Thus by the first quarter of 1974 real wages had fallen by over 2 percent; see Table 2.

But when three threshold payments were triggered by the Retail Price Index passing the 7 percent mark in April, the situation was transformed completely. For those who had threshold agreements and had settled their annual wage increase, there was no further fall in real wages; for those who had threshold agreements and had yet to settle, the entire

TABLE 2—INCREASES IN AVERAGE REAL WAGES, 1973–75

| Indices 1970=100 | Hourly Wage rates (1) | Retail Prices (2) | Real Wages (1)÷(2) x 100 (3) | Percentage Increase over Quarter: Hourly Wage Rates (4) | Retail Prices (5) | Real Wages (6) |
|---|---|---|---|---|---|---|
| 1973: 1 | 138.4 | 122.2 | 113.3 | — | — | — |
| 2 | 143.6 | 125.3 | 114.6 | 3.8 | 2.5 | 1.3 |

*Source:* for cols. (1) and (2): *NIESR Review*, various issuses.

money wage increase of the settlement was fully indexed. Assuming roughly half the settlements were still to come in the second half of the year following September 1973, an average fully indexed money wage increase of about 10 percent per settlement would raise the national average wage by about 5 percent, which would then offset the 2 percent fall in real wage over the preceding six months to give a rise of 3 percent over the year as a whole. As can be seen from Table 2, real wages did in fact rise by just over 3 percent from third quarter 1973 to third quarter 1974.

In terms of the analysis of the last section, the situation under the incomes policy after April was one of very powerful "real wage resistance" which could be expected to produce a very rapid acceleration of inflation as prices were marked up on wages and so triggered further price increases. This did, of course, happen to some extent, as the 5 percent rise in real wages mentioned above was achieved by a 14 percent rise in wages relative to a 9 percent rise in prices in six months; see Table 2 and Figure 1.

The acceleration of inflation required to *reduce* real wages, under indexation which adjusted wages to prices with a delay of about a month or so, would have been enormous, and as we have seen real wages actually *rose on trend* over the year from 1973 third quarter. This rise was made possible partly by increasing subsidization of prices by the government and partly by a squeeze on company profits as prices were held back under the provision of the Price Code. According to the National Institute (*NIESR Review*, 1975, p. 31) the operation of this Code probably reduced the price level by something of the order of 2 percent below what it might otherwise have been by the third quarter of 1974. The increase in the level of subsidies was by no means sufficient to prevent the real wage rise from reducing profits, and the National Institute (*NIESR Review*, 1975, p. 35) noted that the share of profits (after stock appreciation and depreciation) fell from 12.6 percent of national income in 1973 to 10 percent in third quarter of 1974 (and the Financial Times index of share prices fell by roughly one half over the same interval).

It is apparent that the Government made an error in promoting the indexation of wages to the Retail Price Index (which of course includes import prices and indirect taxes as well as "home costs").[12]

There were those who suggested therefore that the government should shoulder the responsibility of actually *paying* the threshold, giving as it were a wage subsidy, the costs of which could have been borrowed from abroad. Such a scheme, like that discussed by John Flemming would have acted to prevent the cost of labor from rising above its productivity. (Thus in terms of Figure 4, a subsidy of $AE$ per capita could have preserved real wages constant and prevented the profit share from falling.) The assumption behind such proposals was that real wages would not rise (above the level given by the initial subsidy) over a period of a year or more, so the rising productivity of labor would reduce the subsidy required. But subsequent experience has shown that any such subsidy could only have been paid as part of a tough incomes policy. Under the voluntary "Social Contract" prevailing after the end of Stage 3, real wages, far from falling below trend, rose very rapidly, increasing by 7.2 percent in the first quarter of 1975 alone!

It is clear that after Stage 3 real wage resistance as described by Hicks was overtaken by a more determined upward pressure for real wages. Partly, no doubt, labor leaders were encouraged by their ability to negotiate rapidly rising real wages earlier that year, but there was also a lack of will on the part of the Labour government to resist wage rises in the public sector (following the experience of the Conservative Administration with the miners). The transmission of these wage pressures to the private sector was aided by talk of "rescuing" or nationalizing companies which might be unable to pay such increases. Another factor reckoned to have put upward pressure on real wages was the increasing burden of taxation required to pay for the price subsidies, transfers, and spending programs of the Labour government. The Chancellor of the Exchequer appealed to labor unions to take account of the value of these various components of government *spending* when they set their wage demands (arguing that these elements, dubbed the "Social Wage," were worth £20 per week —over a third of the national average wage).

In spite of the Chancellor's appeals, it was increasingly evident that money wage settlements were increased in response to higher taxation *despite* the benefits flowing from the expenditure financed therewith. Dudley Jackson, Herbert Turner, and Frank Wilkinson had in 1972 argued that there existed a wage-tax spiral, and econometric evidence that taxes affected wage settlements was provided by Johnston and Timbrell in 1973.

It thus appeared possible, alarmingly enough, that an increase in taxation could have much the same sort of effect on the inflation-employment relationship as the rise in the price of imports examined in the last section. This would mean that the maintenance of the same level of output and employment by aggregate demand management would be associated with increasing inflation. Preventing wage inflation from raising prices by price controls, moreover, would simply lead to a collapse of profits and so investment. In the article already cited, Johnston and Timbrell noted that the "perverse" positive relationship between wage inflation and unemployment they found there "would be consistent with a theory that suggested variations in unemployment as the *consequence* of changes in wage rates, so that increases in money wages, beyond what current shifts in the production function

[12] The case for choosing the $GDP$ deflator as a more appropriate index for wage contracts in these circumstances is made by Jackman and Kurt Klappholz. In this they depart from what Milton Friedman had to say when he spoke about $U.K.$ inflation on B.B.C. radio soon after the oil price rise and appeared to endorse index linking to a general price index, as under the threshold arrangement.

and current market conditions . . . would bear, result in lower employment and higher prices" (p. 165). Such a consequence has indeed followed the rapid rise in real wages in 1974 and 1975, when it was found that merely maintaining aggregate demand was not sufficient to ensure the employment of labor whose cost to employers exceeded its productivity as increasing labor costs outstripped price inflation.

## VI. Conclusion

I conclude first that it was virtually inevitable that the steep rise in the price of imports from 1973 to 1974 should have resulted in a sharp rise in domestic prices. In this, I am in agreement with the majority of witnesses giving evidence before the Public Expenditure Committee. Furthermore, so long as wage and salary earners were unwilling to reduce their real income beneath the path they would have followed without the shift in the terms of trade, there existed pressures to perpetuate and amplify this "first round" of price increases. Such latent real wage resistance was undoubtedly strengthened by the prevailing incomes policy which failed to allow for the need to reduce real incomes and encouraged the use of threshold agreements which linked money wages to the Retail Price Index.

How much of the increase in money wages was a consequence of the provisions of the incomes policy (which involved eleven "triggers" of threshold payments in seven months) is, as ever, a matter of assessing what would have happened in their absence; doubtless there would have been pressure for interim pay awards, but I conclude that the incomes policy added significantly to the backlash of prices on wages. If incomes policy can in this way affect wage behavior for the worse, it can also in my view affect it for the better (see, for example, the effect of incomes policy in July 1975 after the real wage explosion under the voluntary social contract).

In the circumstances described, "Keynesian" policy recommendations which focused simply on maintaining the level of aggregate *real* demand failed to foresee the collapse of private investment demand and employment as rising real wages made it increasingly unprofitable to "supply" the goods demanded. The Monestarists' prescriptions for controlling *nominal* demand were, in my opinion, based on an excessively optimistic view as to the flexibility of real and nominal wages; consequently a deeper recession would have been required for Monetarist policy to work in the circumstances than they would have expected.

While the recent inflation in the United Kingdom is hardly something of which one can be proud, I end by noting some benefits which have flowed from the experience. First of all, it has made union leaders more aware of the vulnerability of investment and employment in the private sector to real wage pressures, so that it is now more widely appreciated that large wage increases that do not lead to price increases will probably lead to unemployment. Second, the reaction of money wages to increasing taxation has impressed on politicians the need to weigh against the political benefits of increased government expenditure the political costs of such inflationary reactions to the taxes required to finance them. Finally, it has made the public at large afraid of inflation and more willing to do what is necessary to prevent it.

## Appendix

### 1. *Keynesian Demand Management*

Using *GDP* at current factor cost as a measure of "nominal income," $Y^N$, implies

$$Y^N = PF - P_I M$$

where $F$ is total final sales, $M$ the volume of imports, $P_I$ the price of imports, and $P$ the price of total final sales (*net* of indirect taxes). For simplicity, it is assumed that the

price of exports moves in line with the price index for total domestic expenditure. "Real income" $Y^R$ may be obtained by deflating $Y^N$ by the price of final output, so

$$Y^R \equiv \frac{Y^N}{P} = F - \frac{P_I}{P} M = F - hM$$

where $h$ denotes the ratio of the price of imports to that of domestic output and is thus a measure of the terms of trade.

The most common behavioral assumptions can be summarized as

$$\begin{aligned} M &= mF \\ F &= C + I + G + X \\ &= C(Y^R - T) + I + G + X \end{aligned}$$

using standard notation for the components of expenditure, and letting $T$ denote the real level of direct and indirect taxes. To maintain total final sales constant by demand management in the face of changes in the terms of trade, the appropriate fiscal policies are implied by

$$dF = C'dY^R - C'dT + dG + dX = 0$$

assuming no change in investment (and no relative price elasticity of imports, which is not too inappropriate for raw material and energy imports). The change in real income if total final sales are constant is simply $-mF\ dh$; so if the volume of exports does not respond with any alacrity, the requisite fiscal policy actions on this Keynesian analysis are:

$$\begin{aligned} dG\,\big|_{dT=0} &= -C'dY^R = C'mFdh \\ dT\,\big|_{dG=0} &= dY^R = -mFdh \end{aligned}$$

Splitting taxes between indirect and direct taxes as follows:

$$T = \frac{t_i}{1 + t_i}(F - X) + T_v$$

where $t_i$ is the rate of indirect taxation on total domestic sales, the appropriate change in the indirect tax rate, *ceteris paribus*, is

$$\frac{dt_i}{(1 + t_i)^2} = \frac{mF}{F - X} dh$$

The dependence of taxes on income is ignored in Figure 2 of the text.

2. *Inflation, Real Wages, and Employment*

The following is a modified version of Sargan's equations:

*Target or Bargaining Equilibrium Real Wage*

(A1) $\quad r^* = \beta_0 + \beta_1 n + \beta_2(\mathrm{t} + 1)$

*Expectations-Augmented Wage Adjustment Equation*

(A2) $\quad \Delta w = \alpha(Lr^* - Lw + Lp) + L\pi$

*The Price Equation*

(A3) $\quad p = \gamma_0 + \gamma_1 p_I + (w - R)(1 - \gamma_1) + \gamma_2 T_i$

*The Determination of Output per Capita*

(A4) $\quad R = \gamma_3 + \gamma_4(k - n) + \gamma \mathrm{t}$

where $w = \log$ of index of money wage rate
$p = \log$ of index of retail prices
$p_I = \log$ of index of import prices
$R = \log$ of index of output per capita
$T_i = \log$ of ratio of consumption expenditure at market prices to consumption expenditure at factor cost
$r^* = \log$ of equilibrium or target real wage
$n = \log$ of number of people employed
$k = \log$ of capital stock
$\pi =$ anticipated inflation
$\mathrm{t} =$ time, measured in quarters from some base date
$L =$ the lag operator, $p(\mathrm{t}-1) \equiv Lp(\mathrm{t})$
$\Delta \equiv 1 - L$

Assuming that for $\mathrm{t} > 0$ there is no change in indirect taxes, employment, capital stock, or the relative price of imports and domestic output (as when the exchange rate floats to offset domestic inflation), then we have $\Delta p = \Delta p_I$, $\Delta T_i = 0$, $\Delta R = \gamma$, $\Delta r^* = \beta_2$ for $\mathrm{t} > 0$ and so, from (A3) and (A4),

(A5) $\quad \Delta p = \Delta w - \gamma$

which, if we denote the actual real wage by $r$, can be rewritten as

(A6) $\quad \Delta r = \gamma$

Substitution into (A2) yields

(A7) $\Delta p = \alpha(Lr^* - Lr) - \gamma + L\pi$

so the rate of inflation increases with the lagged gap between the equilibrium real wage $r^*$ and that which is actually paid $r$, and also with lagged inflation expectations $\pi$. (The net negative effect of productivity growth is shown in (A9) below.) Corresponding to (A6) we can describe the *level* of real wages $r(t)$ as

(A8) $r(t) = r(0) + \gamma$

where from (A3) and (A4) we find that the real wage at time zero is $r(0) = \gamma_1(w(0) - p_I(0)) + (1-\gamma_1)(\gamma_3 + \gamma_4(k(0) - n(0))) - \gamma_0 - \gamma_2 T_i(0)$ So $r(0)$ is a decreasing function of $n(0)$, as in Figure 4. By substituting into (A7) we obtain

(A9) $$\Delta p = \alpha(\beta_0 + \beta_1 n(0) - r(0)) - (1-\alpha)\gamma + L\pi$$

on the assumption that the trend in the equilibrium real wage $\beta_2$, matches the trend in output per man $\gamma$. Since $n$ will vary inversely with unemployment, this equation is not unlike an "expectations-augmented Phillips curve," modified to take account of the level of real wages. Assuming that no inflation is expected, then the rate of inflation is simply given by

(A10) $$\Delta p = \alpha(\beta_0 + \beta_1 n(0) - r(0)) - (1-\alpha)\gamma$$

which is the rate discussed in the text; but if $\pi = \phi(L)\Delta p$ where $\phi(1) = 1$, then (A9) implies that inflation will accelerate upwards or downwards depending on the sign of the right-hand side of (A10).

Thus, one could by setting (A10) equal to zero and "solving" for $n(0)$ define a "natural rate of employment" (and correspondingly a "natural rate of unemployment") which would prevent any *changes* in the rate of inflation and so permit expectations defined by $\phi(L)\Delta p$ to be fulfilled. This natural rate of employment will fall if $p_I(0)$ rises, see Figure 4.

Indirect taxes have the effect of lowering the real wage as defined above. To allow for the additional possibility discussed in the text that the speed of adjustment of money wages depends upon the gap between a desired real wage and the real wage *net of income tax*, and assuming for simplicity a proportional rate of income tax, one could modify equation (A7) to read:

(A11) $\Delta p = \alpha(Lr^* - Lr - LT_x)$

where $T_x = log$ (1 − proportional rate of income tax). Assuming the tax rate is unchanged t = 0, this would change (9) to

(A12) $$\Delta p = \alpha(\beta_0 + \beta_1 n(0) - r(0) - T_x(0)) - (1-\alpha)\gamma + L\pi$$

where $r(0)$ is defined as before. It is obvious from this how a rise in rate of income taxation has the same impact on the inflationary process as a reduction in real wages by a change in the terms of trade.

# The British Inflation: Indigenous or Imported?

*By* JOHN WILLIAMSON AND GEOFFREY E. WOOD*

Since 1970 it has been asserted with increasing force that the recent worldwide acceleration of inflation has a common cause (see, for example, Hans Genberg and Alexander Swoboda; David Laidler and Michael Parkin, Section 5; William Nordhaus). This cause is usually found in the expansionary monetary policies pursued in the United States during the period of the Vietnam War. Our principal purpose in this paper is to examine whether this theory provides a convincing explanation for the acceleration of inflation in the United Kingdom in the period since 1967, which would imply that Britain's inflationary problems have in large measure been imposed upon her.

One possible basis for contending that British inflation was caused by global inflation lies in the view that arbitrage in traded goods is sufficiently perfect to prevent the price of British-produced tradeables diverging significantly from the price level set on the world market. We examine, and reject, this view in Section I. This means that British inflation cannot be explained as merely a local reflection of worldwide experience, but needs to be explained in terms of both the operation of the British economy and its reactions to developments in the rest of the world. In Section II we therefore attempt such an explanation on the basis of an examination of recent British economic history. In Section III we state our conclusions about British experience and sketch some implications for the interpretation of global inflation.

* University of Warwick and City University, London.

## I. The Perfect Arbitrage Hypothesis

The hypothesis that the "law of one price" prevents the price of tradeable goods produced in different countries diverging even in the short run has been popularized in many of the simpler monetarist models of the balance of payments, and forms the basis of the "Scandinavian model" of inflation (see, for example Gösta Edgren, Karl-Olaf Faxén, and Clas-Erik Odhner). This hypothesis is to be sharply distinguished from the hypothesis that in the long run the inflation rates in different countries which maintain fixed exchange rates between themselves must move in parallel; the latter can hold, even if short-run substitution elasticities are relatively low, through the income effects and monetary repercussions of trade imbalances which are ultimately induced by the emergence of price discrepancies. The hypothesis of no short-run price independence rests on the presence of very high substitutability between the goods produced in different countries. This is plausible enough where primary products are concerned (and some empirical support has been provided by Genberg, pp. 21–23), but questionable in the case of manufactured goods, which is the case of overwhelming importance for a country such as the United Kingdom.

Table 1 shows three sets of comparisons between British and foreign prices of manufactures. Column (1) compares the unit value index for British exports with that for all countries, while column (2) provides a similar comparison with the *U.K.*'s principal individual trading competitor. Column (3) shows a similar comparison be-

[e] *DM* per pound from trade conversion factors in *International Financial Statistics*.

tween British wholesale prices and the unit value index for imports of all manufactures. All three columns show a degree of variation, with ranges from 13 to 23 percent, that hardly seems consistent with perfect arbitrage. Comparison with columns (4) and (5) suggests that these variations are in part explicable as a response to exchange-rate changes, which, according to the perfect arbitrage hypothesis, should have no impact on relative prices.

It is of course true that unit value indices leave something to be desired as price indices because changes in the quantity composition of trade can cause a change in the index even if no individual price is altered. There is little reason to dismiss the evidence exhibited in Table 1 on this ground, however, since the only systematic bias introduced is that price divergencies are *under*stated inasmuch as goods that become too expensive to sell tend to drop out of the index. Nevertheless, both in order to provide a check on the aggregate comparisons shown in Table 1 and because the subject is of inherent interest, an examination was made of micro price changes in what may plausibly be considered the representative manufactured tradeable good, the automobile. This was done by calculating annual price changes for individual automobile models produced in the United Kingdom and models imported into the United Kingdom from each of the five countries (France, Germany, Italy, Japan, United States) which exported four or more types of automobile to the United Kingdom during the period 1967–75. The outstanding characteristic of these figures was the range of the price increases recorded within each year; the standard deviation of price increases averaged 6.8 percent with a minimum of 4.6 percent, while the range averaged 38.5 percent with a minimum of 25.1 percent. (For British-produced cars the minimum standard deviation was 3.8 percent and the minimum range was 17.4 percent.) These variations in relative prices are inconsistent with the view that there is perfect

TABLE 2—FREQUENCY OF PRICE INCREASE OF FOREIGN-PRODUCED AUTOMOBILES IN *U.K.* MARKET, 1967–75

| | Sterling depreciation greater than 5 percent | Sterling appreciation greater than 5 percent | No "significant" exchange-rate change | Total |
|---|---|---|---|---|
| Range of price increase in terms of price increases of British-produced models | | | | |
| Bottom quartile or below | 11.5 | 8 | 67 | 86.5 |
| Second quartile | 24 | 2 | 30 | 56 |
| Third quartile | 19.5 | 1 | 7 | 27.5 |
| Top quartile or above | 31 | 0 | 13 | 44 |

*Note:* Price data were the manufacturers' recommended retail prices in the United Kingdom, including tax, given in the first issue in May each year of *Motor*. One figure (the first listed) was selected for each maker which supplied identically described models in consecutive years. This procedure gave between 21 and 27 observations for British-produced cars, and between 25 and 28 observations for foreign-produced cars in each year.

arbitrage, and suggest rather that automobiles have to be analyzed as differentiated products whose market conditions permit differential price movements.

These data also permitted a further test of the prediction of the perfect arbitrage hypothesis that prices are unaffected by exchange-rate changes. The observations on the price increases of British-produced models were used to calculate medians and quartiles for the price increases in each year. These figures were then used to classify price increases of foreign models into the four categories shown in the rows of Table 2. The observations of foreign model price increases were also classified into years in which sterling depreciated by more than 5 percent against the currency of the producing country (col. 1), those in which sterling appreciated by more than 5 percent (col. 2), and the remainder, in which there was no significant exchange-rate change (col. 3). The perfect arbitrage hypothesis would suggest that the distributions recorded in the three columns should not differ significantly, while the more traditional view that exchange-rate changes produce at least short-run effects on price competitiveness would lead one to expect a preponderance of observations in the bottom row of column (1) and the top row of column (2), relative to column (3). A *chi*-square test reveals that the tendency in this direction shown in Table 2 is not consistent with the view that the three columns are drawn from a common population.[1] In view of the absence of any attempt to allow for other factors, such as differential inflation, that could in general be expected to offset at least in part the impact of exchange-rate changes, this constitutes decisive refutation of the view that changes in exchange rates do not produce a short-run impact on prices. It follows that a more subtle explanation of the international interdependence of inflation rates is required than the hypothesis that they are rigidly linked together by goods arbitrage.

## II. External Factors in the British Inflation

The analytical framework which we regard as appropriate for analyzing inflation is in most essential respects the same as that endorsed by Laidler and Parkin in Sections 3 and 4 of their admirable survey of inflation theory. Inflation has to be analyzed within a comprehensive macroeconomic model encompassing a theory of

[1] The value of *chi*-square was 55.2 with six degrees of freedom, as against a critical value of 12.6 at the 5 percent confidence level.

the determinants of aggregate demand, a theory of the wage and price determination process, and a theory of the determination of the relevant expectations. Such a framework provides a wide variety of channels through which external factors can impinge on the inflationary process. Table 3 presents data designed to outline the inflationary experience in Britain, and to quantify the major channels through which a comprehensive theory would suggest external factors could have exerted an influence on British inflation.

There is no great difficulty in accounting for British inflation up to the middle of 1969. On average the economy was run at a very high pressure of demand (see col. 4): there existed a rather general consensus that unemployment in excess of $1\frac{3}{4}$ percent —or, to the conservative, $2\frac{1}{4}$ percent—signified a need for prompt demand reflation. The Phillips curve seemed a reasonably well-determined relationship which explained why such an ambitious unemployment target would produce marginally more inflation than was compatible with the maintenance of international price competitiveness, and in fact British prices rose about 1 percent per annum faster than the international norm. There was also, however, a widespread belief that the experience of 1948–50—when government-inspired wage restraint was credited with having produced two observations substantially below the Phillips curve, despite a major devaluation—demonstrated that

the Phillips curve was not an immutable relationship, and this led to hopes that incomes policies might enable inflation to be slowed to the international norm without modifying the employment target, which was near universally regarded as a priority commitment. In the event these hopes were not fulfilled.[2] Export prices became increasingly uncompetitive, and hence the employment target became increasingly incompatible with a satisfactory payments outcome. This process could not go on indefinitely, and was eventually terminated by the devaluation of the pound in 1967.

The immediate and almost mechanical effect of devaluation was to increase import prices, which rose in proportion to devaluation in the case of manufactured imports (col. 10) but substantially less in the case of nonmanufactured imports (col. 9). Since the ratio of imports to *GNP* is about 0.2, the average rise in import prices of 11 percent in 1968 provides a simple cost-push explanation for the higher rate of price inflation in 1968–69 as compared to 1966—a year in which the wage increase was similar (cols. 1 and 2). This initial and modest acceleration of inflation can be regarded as the reimportation of the inflation that had been exported during the years 1960–67, when there was a rise in British export prices some 6 percent greater than the international norm, a cumulative current account deficit of some $2.6 billion, and a cumulative reserve loss of $4.7 billion (which was financed entirely by reserve borrowing). During the years 1968–70, price competitiveness was restored to the level of the early 1960's, the current account surplus totalled some $2.2 billion and the net gain in reserves amounted to $2.1 billion (despite the substantial reserve loss in the first postdevaluation year, 1968).

It is worth pausing at this stage to examine whether, as has often been argued (for example, by Edward Bernstein), the maintenance of a pegged exchange rate prior to 1967 performed the function of making the foreign sector a built-in stabilizer, thus alleviating demand pressures at cyclical peaks and so mitigating inflation. There is a general belief in Britain that this has been the case, although it is usually described as the "problem" of how the balance of payments goes into deficit as full employment is approached. Comparison between the trade balance as usually expressed, in nominal terms, and the state of the cycle suggests that there was some tendency in this direction. For example, the correlation coefficient between year-to-year changes in the trade balance as a percent of *GNP* and the unemployment rate for the four quarters starting in the middle of the year,[3] was 0.62 over the period 1960–67. However, it is not the change in trade balance in nominal terms, but rather its change in real terms that is relevant from the standpoint of providing a built-in stabilizer. The correlation coefficient between the real change in the trade balance (as is shown in col. 5) and unemployment on the same basis over the same period was only 0.39. One must therefore conclude that the existence of a pegged exchange rate provided only a modest alleviation of inflationary pressure through induced changes in the trade balance. The explanation of this surprising result presumably lies in the very high degree of synchronization between the business cycle in the United Kingdom and that in the rest of the world.

Even before the second half of 1969 there were some indications that inflationary pressures were greater than could

[2] While quite a number of the studies that have been conducted on the effectiveness of incomes policies have found at least temporary effects on the rate of inflation from some periods of incomes policy, the particular policies identified as successful have an embarrassing tendency to vary between authors. In addition to this lack of robustness, none of the reported estimates are large.

[3] The time displacement was introduced to allow for the fact that unemployment is a lagging indicator of demand pressure.

be accounted for by the near mechanical cost-push effects of devaluation, in that existing estimates of the Phillips curve predicted lower rate of wage increase than those that actually occurred. In retrospect there are three plausible explanations of this development. First, there were major improvements in the social benefits available to the unemployed in 1966. Second, inflationary expectations were substantially raised by devaluation (col. 3: monthly figures show a sharp jump to 11.9 percent in November 1967, which fell back subsequently, but not to predevaluation levels). Third, the lesser pressure from foreign competition after devaluation presumably increased the willingness of firms to concede wage increases.

However, the major acceleration of British inflation occurred in late 1969, when the first "wage explosion" got under way with conspicuous wage settlements in excess of 15 percent. In the following year wage increases were some 6 percent higher than the 7 to 8 percent range that had previously been the maximum (col. 1). (It seems clear enough that wage increases, rather than price increases, were the initiating factor in the intensification of inflation: the contrary interpretation is inconsistent with the severe squeeze on profits of recent years.)

It is this first wage explosion in 1969–70 which has always posed the greatest challenge to accepted theories of inflation, as expounded by Laidler and Parkin, and hence led many of those who do not question the importance of demand and expectational factors in generating inflation to believe that these do not exhaust the list of important independent influences on the wage-determination process. Unemployment was high by previous, if not by contemporary, standards, and rising. This slack in the economy arose from the impact of the deflationary fiscal policy adopted in 1968, and despite the major diversion of resources into the balance of payments (equivalent in real terms to some $1\frac{3}{4}$ percent of *GNP* as compared to 1967); deliberate fiscal deflation was, incidentally, by far the most important method whereby domestic absorption was curtailed to make room for a payments improvement, vastly outweighing the deflationary impact of devaluation on real money balances which receives so much attention in the monetarist analysis of devaluation (col. 8). Price inflation, though still above the predevaluation level, had declined somewhat from the level reached under the immediate impact of devaluation, which would seem to preclude an adaptive-expectations explanation based on observation of changes in the price level; and this conclusion is confirmed by the decline in the Carlson-Parkin measure of consumer price expectations, which is based on survey data (col. 3). Monetary policy, under the tutelage of the International Monetary Fund (*IMF*), was tight—the money supply grew by only 3.2 percent, and domestic credit expansion was actually negative; which would seem to preclude a rational-expectations explanation based on the observation of monetary aggregates. Hence none of the factors emphasized in the standard theory of inflation in a closed economy offers an explanation for this first wage explosion.[4]

[4] It is only proper to acknowledge that the latest wage equations of the Manchester Inflation Programme, as in the recent paper of Malcolm Gray, Parkin, and Michael Sumner, do not suffer from embarrassing positive residuals in 1969–70 (although the wage equation does contain an *ad hoc* dummy for 1971–72). The lack of a positive residual for 1969 is not surprising, since the equation is based on annual data, and the 1969 annual total was only marginally affected by the wage explosion. The absence of a residual in 1970 does surprise us, in view of the absence from the explanatory variables ($U$, $\Delta U$, and $\Delta p^e$) of any variable that increased prior to the wage explosion. One possible explanation lies in the measure of the expected price increase, which was taken as "*U.K.* firms' expected change in the price of their [own] output estimated at the start of each year" (Data Appendix, p. 4). This is a quite illegitimate measure of price expectations in terms of the Manchester theory, since a high coefficient on this variable is consistent with the most rigorously

One alternative type of explanation points to international factors. It has already been noted that the inflation reimported in 1969 through the current-account surplus and reserve inflows was offset by domestic deflationary fiscal-monetary policies, but there remains the possibility that the improved competitiveness resulting from devaluation served to undermine the resistance to wage claims. Nordhaus, after all, in his comparative study of wage inflation in seven countries, found that the scope for wage increases provided by foreign competition provided the best single explanation of British wage inflation. Comparison of columns 1 and 10 does not suggest that this is an entirely adequate explanation, and there are also three particular problems in placing primary emphasis on this factor. First, the increase in profit margins before the wage explosion does not appear to have been particularly large, as this theory would lead one to expect.[5] Second, the theory does not explain why the wage explosion was delayed as long as late 1969, some two years after the devaluation that is claimed to have precipitated it. Third, there is the problem as to why wage increases were maintained at this new higher plateau in 1971–72, after the competitive gains from devaluation had been eroded (Table 1). This is explicable in terms of inflationary expectations having been adjusted upwards to a new higher level by then as a result of the wage explosion (although the Carlson-Parkin estimates of price expectations shown in col. 3 of Table 3 do not provide strong support for this interpretation), but not in terms of a theory which asserts that the wage-determination process is dominated by a concern to maintain international competitiveness. Hence, while we do not doubt that relative international prices constituted a permissive factor in the initiation of the wage explosion, we find difficulty in placing primary emphasis on this factor.

The other alternative type of explanation points to what Laidler and Parkin term "sociological" theories, such as the frustration of wage earners at having their expectations of real income growth disappointed, or the increasing militancy of trade unions in pursuing a set of mutually inconsistent real income claims. Our one substantive departure from the Laidler-Parkin analysis concerns their rejection of such hypotheses (p. 764). Indeed, if the sociological label is intended to imply that such theories imply economically irrational behavior, we would quarrel with the label. If workers are utility maximizers who perceive that their personal economic welfare can be promoted by acting collectively in trade unions, and if the wage bargains sought by unions are such as to maximize their members' welfare, the wage rise sought will be such as to equate the marginal utility of higher income with the expected marginal disutility of greater unemployment and of longer strikes.[6] Since

cost-push theory of inflation, provided that firms are reasonably competent at forecasting the wage increase that they will be obliged to concede. In particular, if, at the start of 1970, firms were aware that a wage explosion had started, and expected to raise their prices in consequence, one would have an explanation of why the Gray-Parkin-Sumner wage equation has no positive residual, but the equation would in no sense explain the wage explosion.

[5] For example, the ratio of profits of companies and public corporations to income from employment increased only some 7 percent in 1969 as compared to 1967, and was still some 9 percent below the level of 1965 (when, admittedly, capacity utilization was dis-distinctly higher). Source: *NIESR Review*, Table 8.

[6] Thus we disagree with the propriety of the assumption of Parkin, Sumner, and Robert Ward that "... the wage level is set by a bargaining process between labor unions and employers' federations with the objective of achieving and maintaining a cleared market" (p. 7). A union which confined itself to achieving what the market would pay anyway would have no *raison d'être* except to counter monopsony, and would fail to maximize the utility of its members unless it placed an infinite welfare weight on continued employment of the marginal worker. It could in our view be argued more plausibly that the purpose of a well-conceived incomes policy is that of persuading agents to

the marginal utility of income may plausibly be expected to depend on dissatisfaction induced by comparisons with peer groups or expectations based on previous experience with a group's existing level of real income, since the power of trade unions may vary, and since changes in the moral climate may alter the disutility occasioned to an individual by participating in actions that hurt others (specifically, by striking), there would seem ample scope for "sociological" factors to influence the wage claims lodged by rational economic actors. Wage claims are not the same thing as wage awards, but any plausible theory of bargaining suggests that they will be positively associated, particularly in the presence of an accommodating monetary policy.

Despite the pioneering contribution of Albert G. Hines, attempts at econometric verification of such theories have not fared well up to the present. However, this may be because the variables which the theory posits as being important are difficult to measure. What can be said is that this type of explanation seems to offer a more plausible explanation of the wage explosion of late 1969 than does any other. Real incomes had been held down in the preceding two years—not so much because of the terms-of-trade effect of devaluation (col. 12), as because of the need to provide for the improvement in the current balance. Unions did become more militant, as reflected in a readiness to inflict direct hurt on the public in ways that had previously been considered unthinkable.[7] The improvement in the balance of payments, which became a clear fact in the summer of 1969, eased the permanent-crisis atmosphere of the preceding years. There were conspicuous and large salary increases awarded to top salary earners in the public sector. The Labor government, having lost its battle with the unions to reform industrial relations, tacitly allowed its incomes policy to become a dead letter rather than pick another fight with an election approaching. While this explanation is uncomfortably *ad hoc*, it is at least consistent with the facts, which is more than can be claimed for the more aesthetically pleasing theories.

In the absence of major change in monetary-fiscal policies or further shocks from abroad, we would have expected the wage explosion to produce a rise in unemployment to a level above the natural rate and, thereafter, a gradual deceleration of inflation back to the international norm. Persistence of the factors that produced the wage explosion would have resulted in a higher unemployment rate, rather than a permanently higher rate of inflation. Unemployment did indeed rise, peaking in the first quarter of 1972 at 3.8 percent, a level marginally above the latest Manchester estimate of the natural rate.[8] However, from 1970 on, monetary expansion broadly accommodated the increased rate of inflation (col. 6). In 1970–71 monetary growth was financed almost entirely by reserve inflows rather than domestic credit expansion (col. 7); this reflected the speculative flight from the dollar as much as the success of devaluation, and is the one period when it could conceivably be argued

accept settlements that clear the labor market rather than maximize monopoly rents. (By this test the only British incomes policy that might claim to have been well conceived was that of 1964–66—which is not to claim that this policy enjoyed any success in terms of restraining inflation.)

[7] This was first manifested in the dustmen's (garbage collectors') strike of October 1969. In subsequent years there were strikes by electricity supply workers, postmen, teachers, and doctors (in addition to major strikes by groups without a strike-free tradition, such as miners and railwaymen).

[8] The first estimate of the natural rate produced by the Manchester Inflation Programme was 1.7 percent (Parkin, Sumner, and Ward, p. 27), based on 1956–71 data. This has since been revised up to 1.8 percent for the period 1952–67 and 3.7 percent for 1968–74 (Gray, Parkin, and Sumner, p. 43), the break being explained by the more generous social benefits available to the unemployed in the later period.

that the United Kingdom imported inflation through monetary channels.[9] Such an argument is not very convincing, however, inasmuch as when unemployment approached the politically sensitive figure of one million, the government promptly embarked on an extremely expansionary fiscal policy which was financed in large part by monetary expansion. This set the stage for the second acceleration of wage inflation in 1974–75.

There is no difficulty whatsoever in accounting for this second wage explosion. Virtually every model of inflation, other than the naive Phillips curve estimated on the basis of predevaluation data, would have predicted a major acceleration of wage inflation in 1973–74. Monetary expansion was extremely rapid (col. 6), even after making allowance for the offsetting impact of import price increases on the real value of the money supply—which actually produced a noticeable effect in 1973–74 (col. 8). Although the current balance deteriorated in nominal terms, this was attributable to a deterioration in the terms of trade caused principally by the world commodity boom, while the current balance in real terms stabilized in 1973 and improved in 1974, thus doing nothing to ease the pressure of demand (col. 5). In total, demand pressure increased as desired, and unemployment fell rapidly to a minimum of 2.2 percent at the end of 1973. Meanwhile import prices shot up (col. 9–11) as a result of the world commodity boom, the oil price increase, and inflation in other industrialized countries, and also because of the depreciation of the pound following the adoption of a floating exchange rate in June 1972. The floating of the pound was inevitable, given the prior erosion of the gains in price competitiveness achieved by devaluation, and the commitment announced in the spring of 1972 to place "growth" (by which was meant a rapid expansion in demand) ahead of preservation of the Smithsonian parity. Finally, the adverse movement in the terms of trade created a need for a significant curtailment of real consumption (col. 12), thus providing ample grist for frustration theories. In view of this mass of reinforcing inflationary impulses, the fact that requires explanation is not that a second wage explosion occurred, but that it was delayed as long as 1974. The only convincing explanation of this delay is the obvious one: that the statutory and relatively rigorous incomes policy introduced in November 1972 actually did restrain wages, at least until the policy collapsed simultaneously with the government in the wake of the miners' strike in February 1974.

There can be no serious doubt that inflation was aggravated in the period 1973–74 as a result of the increase in the world prices of commodities and of oil (surely the clearest example of cost-push inflation in history). Not only did these cost increases produce a direct impact on the price level, which could not have been avoided by any feasible exchange rate appreciation, but they also exerted indirect effects, through

[9] It has sometimes been suggested (for example, by Robert Mundell, p. 281) that British institutional arrangements preclude reserve flows exerting an influence on the domestic money supply, since the operation of the Exchange Equalisation Account (*EEA*) ensures that all reserve changes will be fully sterilized. This is not quite true. With a net inflow of funds, the *EEA* pays sterling to the banks against foreign exchange, adding to both the cash reserves and the deposits of the banks. Then, as the authorities hold almost no cash, they issue a quantity of Treasury bills roughly equal to the inflow. If these bills are taken up by the banking system, then its liquid assets will increase and the banks can expand their lending, and the money supply is increased. If, however, the issue of bills is taken up outside the banking system, then the impact effect of the foreign currency inflow on the banks' deposit and liquid assets will be offset, and the reserve increase will be sterilized. The reason that in the past sterilization was usual is that the Bank of England has tended to resist the changes in the price of gilt-edged stock that occurred when major bank purchases or sales of gilts were induced by changes in the liquid assets of the banking system. Thus sterilization was a consequence of the policy of stabilizing interest rates, and not of the existence of the *EEA*.

frustrating real income growth (col. 12) and, perhaps, through strengthening the position of the miners in their confrontation with the government. Nevertheless, the claim that Britain imported the bulk of this second wage explosion is singularly unconvincing. First, there is no justification for arguing that increased world prices of manufactured imports contributed to British inflation: had other industrialized countries controlled their inflations better, the result would simply have been a larger depreciation of the pound. Second, demand pressures were excessive by late 1973, unless one is prepared to dismiss the evidence of an increase in the natural rate of unemployment. Third, the expansion of demand was so rapid as to have created strains even if the natural rate had been as low as in the early postwar years.

### III. British and World Inflation

Our examination of the development of British inflation up to 1975 therefore leads us to assign the major responsibility to internal factors. Prior to 1967 Britain was an exporter, not an importer, of inflation. The 1969–70 wage explosion was primarily an internal matter, and such impact as the external sector had (via either the frustration hypothesis or mitigated competitive pressures) was largely a reimportation of inflation in response to devaluation rather than a reflection of the comparatively modest inflation that had by then got under way in the rest of the world, which was still well below the British rate. By 1971–72 inflation had stabilized on a higher plateau, well above that prevailing elsewhere, but the government was unwilling to accept the higher level of unemployment needed to achieve a deceleration. The consequent restimulation of demand led to a downward float of the pound and a rapid build-up of demand; these internally generated pressures were indeed reinforced by imported inflation in the years 1973–74. By 1975 inflation was out of hand, and regarded as a sufficiently serious problem for the level of unemployment to be allowed to rise, and for a new statutory incomes policy to be adopted. Under these twin pressures, inflation has since abated.[10]

The conclusion that British inflation was predominantly internally generated naturally suggests the question as to why Britain pursued policies that led to her suffering the worst inflation in the Western world. On the whole we would not subscribe to the view that this was primarily attributable to economic illiteracy on the part of the authorities, despite the undoubted truth in the charge that they underestimated the long-run importance of monetary factors. Of greater importance, in our judgment, is the fact that price stability has simply not been regarded as an objective of paramount importance, in the way that full employment has been. For many years inflation was feared primarily because of its effect in undermining the balance of payments,[11] and not because of a fear of disruptive domestic consequences, social or economic. As long as it was believed that a little more employment could be bought at the cost of a slightly higher inflation rate, the general view was that the inflation was a price worth paying so long as the balance of payments permitted. And as the evidence accumulated that the cost was not in fact a slightly higher inflation rate but rather a permanently accelerating inflation rate, there was that reluctance to face un-

[10] The unemployment rate passed the latest Manchester estimate of the natural rate the month before the incomes policy was adopted, so no one will be obliged to modify their theory of inflation as a result of the latest deceleration.

[11] Indeed, even after sterling had been floating for three years, the popular explanation of the £6 a week incomes policy sent to every household (*Attack on Inflation: A Policy for Survival*) could still claim that a principal reason for curbing inflation was that "Britain's leading competitors in world markets now have the edge on us. Their prices are increasing at only half the rate of ours. And the gap is widening" (p. 4).

pleasant realities which has been one of the recurring failings of postwar British economic management. Whether inflation reaccelerates in the future is essentially a question of whether it is now sufficiently feared to create a willingness to pay the necessary price.

Our interpretation of British experience is not consistent with the view that world inflation originated entirely in the United States and was transmitted to all other countries through the pegged exchange rate system. Hence one must conclude that it was a coincidence that inflation accelerated at much the same time in both the United States and Britain. In our judgment the acceleration of inflation in France in 1968 was also indigenous, and was a further coincidence. To the presumably rhetorical question as to whether the global acceleration of inflation in the late 1960's can have been a coincidence, we would therefore answer that there was indeed an element of coincidence. On the other hand, we would also judge that the other countries of Northern Europe imported their inflations, through the various channels discussed in the British case in Section II. (We are not sufficiently familiar with the experiences of countries outside Northern Europe to offer a judgment as to whether there were any further coincidences, or whether the experience of all others can be accounted for through international linkages.)

Does this mean that Britain and France must share the blame with the United States for igniting an inflation of global proportions? To that question we would answer "no." While Britain and France generated their own inflations, the fact that they were not reserve centers (in any serious way, that is to say) meant that their capacity to export inflation to the rest of the world was strictly limited. After relatively modest deficits they had no option but to devalue and reimport the inflation that they had previously exported. There was no similar constraint on the United States and, hence, no similar limit to the harm that policy errors on her part could inflict on the rest of the world. It was to remedy this situation that other countries urged adoption of asset settlement in the negotiations in the Committee of Twenty that were intended to reform the international monetary system, and it was primarily because the United States declined to concede this point that the reform negotiations failed. In the event the rest of the world did indeed get its safeguard against a recurrence of global inflation, although in the form of floating exchange rates rather than asset settlement. Not only does this imply that the more stable countries will not be obliged to import inflation as they were in the early 1970's, but it also implies that countries that generate their own inflations will be deprived of an alibi.

# The Welfare Costs of Nonoptimum Pricing and Investment Policies for Freeway Transportation

*By* MARVIN KRAUS, HERBERT MOHRING, AND THOMAS PINFOLD*

A "pure peak load phenomenon" can be defined to exist when (a) the demand for a service varies from hour to hour, day to day, or season to season—periods of time too short for capital stock to be varied so as to keep price continuously equal to long-run marginal cost—and (b) storage costs are so high that no inventories can be held, thus requiring output at any instant of time to equal consumption at that instant. It can be shown (see Section I) that the pricing and investment rules for optimum provision of peak load commodities are essentially the same as those for commodities for which demand shifts, when they occur, take place once and for all. If these rules for efficient resource allocation are violated—and in practice, they almost invariably are—welfare losses result.

The basic objective of this paper is to provide rough estimates of the welfare losses involved in providing freeway transportation, a commodity characterized by both a peak load problem and increasing returns to scale. Section I describes the model, the pricing constraints considered, and the loss measure employed. Sections II and III discuss the results of the pseudo-empirical analysis. The former describes the cost data used and their implications for the characteristics of optimum roads and trip prices in the absence of pricing constraints. The latter presents the demand relationships employed and estimates of the welfare losses resulting from the constraints. The Appendix accounts more fully for the selection of demand and cost data.

## I. The Basic Model[1]

Three commodities are produced in an economy: $X_1$ and $X_2$, one-mile freeway trips during peak and off-peak periods, respectively, and $X_3$, a Hicksian composite commodity representing everything else. The $I$ utility-maximizing consumers have identical tastes and enter identically into an egalitarian social welfare function. Each derives utility from his own consumption of these three goods and owns a stock of $\rho$ units of a general purpose resource which yields a flow of $r$ units (henceforth dollars) per year of resource services. A head tax of $h$ dollars is imposed on each consumer leaving him with a net income of $r-h$ dollars. Head taxes serve only to cover whatever deficits (or to redistribute what-

The research reported was initiated during Mohring's Ford Foundation Faculty Research Fellowship and was subsequently supported by the National Science Foundation, grants by the U.S. Departments of Transportation and Housing and Urban Development to the University of Minnesota, and from the Canadian Transport Commission to the University of Toronto and York University during Mohring's and Kraus's visits there, and by large amounts of free computer time from the University of Minnesota. An earlier version of this paper was presented at the 1972 winter meetings of the Econometric Society in Toronto. Since this paper may be of less interest for its results than for the case study it provides on how *not* to do pseudo-empirical research, we will not embarrass the many who gave us advice and solace by acknowledging their help.

[1] It is described more fully and generally in Mohring (1970).

ever surpluses) may arise in the production of $X_1$ and $X_2$. Regardless of trip production rates, one dollar of resource services can be converted into one unit of $X_3$. Resource services are also used as variable and capital inputs in producing trips.

The total variable cost of producing one-mile trips during period $j$ at an *annual* rate of $X_j/\alpha_j$ is $X_j f(X_j/\alpha_j k) = C_j$; $j = 1, 2$. Here, $\alpha_1$ is the fraction of the year during which peak demand conditions are in effect, $\alpha_2 = 1 - \alpha_1$, and $k$ is freeway capacity, the maximum number of person-miles per year that can be provided on a one-mile expressway with a capital outlay of $K = d + ek$ dollars per year.[2] For all positive $X_j < \alpha_j k$, $f'(\cdot)$ and $f''(\cdot)$ are positive. Thus, with this formulation, increasing returns enter the picture only if $d > 0$ in the capacity cost function.[3]

In taking an automobile trip, a consumer provides all[4] of the variable inputs required—gasoline and other vehicle operating costs and, most important, his own travel time. In addition to these costs, $f(X_j/\alpha_j k)$ per person-mile in period $j$, he faces a toll of $T_j$ dollars per mile. The sum $P_j = f(X_j/\alpha_j k) + T_j$ is the price of a one-mile trip in period $j$.

In maximizing social welfare, society can control four variables: the identical head tax $h$ on each consumer; the peak and off-peak tolls $T_1$ and $T_2$ (or, equivalently, the prices, $P_1$ and $P_2$); and $K$, the annual outlay on freeway capacity. It is subject to the resource constraint $R = Ir = C_1 + C_2 + K + X_3$, and to one or more pricing constraints.

A variant of the peak load model is used to study spatial inefficiency in the pricing of freeway transportation. Interpret $X_1$ and $X_2$ as one-mile trips on freeways with high and low unit capacity costs, respectively. The total variable cost of providing $X_j$ one-mile trips per year on road $j$ is $C_j = X_j f(X_j/k_j)$. Providing $k_j$, the annual capacity of road $j$, requires an annual expenditure of $K_j = d_j + e_j k_j$. We refer to this model as the two-roads model.

Figures 1–3 respectively depict the efficient pricing and investment rules for peak load commodities and the nature of two of the constraints considered—the single toll and deficit constraints.[5] Suppose that peak and off-peak periods each last six months. The specification of annual freeway capacity $k$ implies a six-month short-run marginal cost curve like $EFG$ in Figure 1. Also suppose that peak demand is independent of off-peak price and conversely. (These restrictive assumptions are dropped in the subsequent analysis.) Then peak and off-peak demand schedules can be drawn as $D_1$ and $D_2$, respectively. Efficient utilization of the expressway can be shown to require equating the price of each trip to its short-run marginal cost, $GX_1$ and $FX_2$ in peak and off-peak periods, respectively. With marginal cost

[2] Implicit in this formulation is the assumption that only one technology—one production function—is available to provide trips. This assumption would be harmless in the absence of the peak load phenomenon. With constant output rates, if different technologies can be employed in producing a commodity, the only one of relevance is that which at current factor prices involves the lowest unit cost. With peak loads, however, choice of the lowest cost technology can depend on the extent of seasonal demand variations. For example, the cost of highway capacity increases with increases in the extent to which crossroads involve overpasses rather than intersections at grade. With modest seasonal demand variations, full separation of access may be the cheapest way to provide trips between Here and There. With greater demand variations, cost minimization may dictate increasing the capacity provided per dollar spent by making some or all intersections at grade. The loss calculations described in Section III ignore such possibilities for adjusting variable and capacity cost functions. This being the case, they overstate to some degree the welfare losses involved in the pricing constraints considered.

[3] At least for highway travel, this characterization of costs seems reasonably realistic. See the Appendix discussion of cost function derivations.

[4] More accurately, "essentially all." We ignore those road maintenance costs that are directly attributable to road use.

[5] The pricing and investment rules for optimization subject to these constraints are developed formally in Mohring (1970).

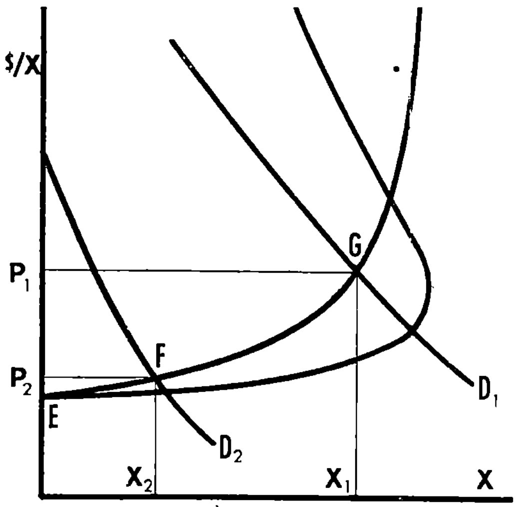

FIGURE 1

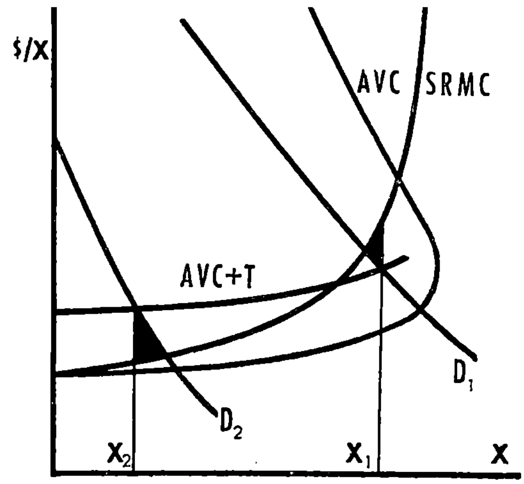

FIGURE 2

pricing, freeway capacity generates annual quasi rents of $EFP_2$ plus $EGP_1$. Efficiency also dictates that capacity be adjusted so as to equate the marginal cost $e$ of providing a unit of capital plant for one year with the annual quasi rents generated by that unit. In such a long-run equilibrium, total revenue just covers total costs if (and only if) the freeway is characterized by constant returns to scale, i.e., if $d=0$ in the capacity cost function.

The welfare costs of the following pricing and investment constraints are considered.

*Peak load—single toll:* The time required—again, probably the most costly input—for an expressway trip depends on the rate at which the expressway is used. However, a traveler is subject only to gasoline and other excise taxes which, per mile traveled, are nearly independent of traffic density. The constraint implied by this characteristic of excise taxes is that the price charged during a demand period must equal average variable cost during that period plus a toll $T$ that does not vary from period to period. If the toll yields a price of $AVC+T$ in Figure 2, too many trips will be taken during the peak period and too few during the off-peak. The resulting loss in real income equals (approximately)[6] the sum of the shaded areas in Figure 2.

*Two roads—single toll:* Efficiency would dictate higher traffic densities and hence higher tolls on high capital cost than on low capital cost freeways. However, gasoline and other excise taxes are invariant not only to the rate of travel on a given freeway but also to its cost. The same gasoline tax is imposed on trips over rural expressways costing perhaps $200 thousand a lane-mile to construct as on urban expressways costing $2 million a lane-mile. The constraint that the same toll per mile be charged on roads for which unit capacity costs differ yields a welfare loss similar to that depicted in Figure 2.

*Peak load—pure deficit:* While expressway construction appears to involve substantial scale economies (see the Appendix), user taxes are set to cover total costs. If demand is invariant over time and price equals average total rather than long-run marginal cost, a loss like $JKL$ in Figure 3 results. A similar conclusion applies when demand does vary from period

[6] The welfare loss measure employed in this study (see the discussion of Figure 4) does not involve the addition of consumers' and producers' surpluses. It does, however, yield similar numerical values.

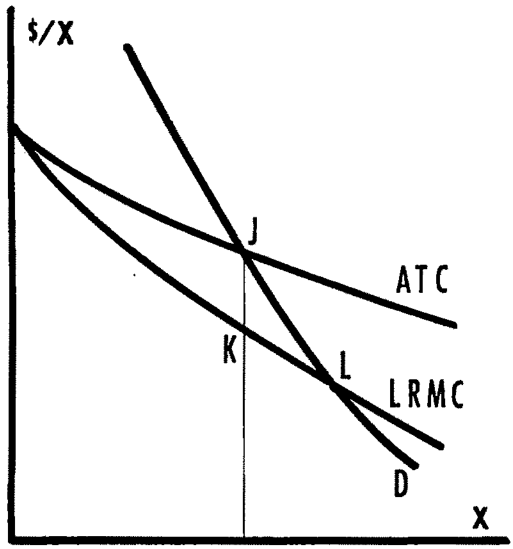

FIGURE 3

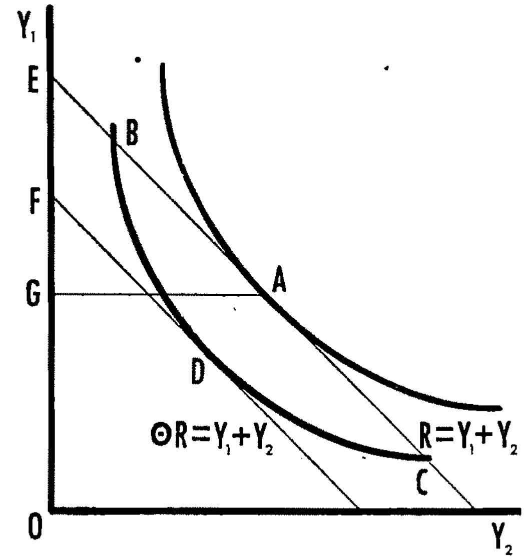

FIGURE 4

to period.

*Peak load—two roads—arbitrary capital input:* In treating the preceding constraints, it is assumed that freeway capacity and prices are optimized subject to the constraint in question. Actually, aggregate expenditures on highway capacity in the United States do not result from formal optimization procedures. Rather, they are largely determined by receipts from highway user taxes which in turn appear to be set arbitrarily. In terms of our model, this procedure implies specification of a single toll sufficient to cover the total cost of the highway(s) when capital inputs are arbitrarily specified.

*Peak load—single toll and deficit:* The peak load—single toll and deficit constraints are simultaneously imposed.

*Two roads—single toll and deficit:* The two roads—single toll constraint is combined with the constraint that total user taxes for the two roads just cover their combined capital costs.

The assumptions of identical tastes and a symmetric, egalitarian social welfare function permit analyzing the welfare costs of these constraints without reference to distributional considerations. For a one-consumer economy, Figure 4 depicts the type of index used to measure resource misallocation. With commodities 1 and 2 priced at marginal cost, a consumer would be in equilibrium at $A$. Imposing a constraint while at the same time adjusting his initial allocation of numeraire ($Y_1$, say) so as to keep him on the linear resource constraint, $R=Y_1+Y_2$, would force the consumer to an inefficient equilibrium such as $B$ or $C$. By simultaneously adjusting the price of good 2 and the consumer's initial endowment of $Y_1$, he could be moved to any other equilibrium on indifference curve $BDC$, $D$ in particular. At $D$, indifference curve $BDC$ is tangent to the budget constraint, $\theta R=Y_1+Y_2$. The loss $1-\theta$ (equals $FE/OE$) is an index similar to those suggested by Harold Hotelling, Arnold Harberger et al. of the proportionate decline in the consumer's real income caused by the pricing constraint. More precisely, $OF$ is the income that, at the prices which would be in effect under optimum conditions, would yield the same utility to the consumer as would $R$ units of resource services when prices are dis-

torted to produce an equilibrium at $B$ or $C$. The distance $FE$ can therefore be interpreted as the loss in his real income (valued at marginal cost prices) attributable to the distortion.[7]

The welfare loss measure employed in Section III is a three-dimensional counterpart of $FE/GE$, not of $1-\theta$ itself. That is, losses are measured as fractions of what the consumer's expenditures on the price-distorted commodities would have been without the distortions, not as fractions of his initial endowment of numeraire.

## II. The Characteristics of Optimum Freeways

Determining the welfare losses resulting from nonoptimum pricing and investment policies for expressways requires, *inter alia*, determining those road prices, operating characteristics, and the like which would optimize the unconstrained system. Specification of only variable and capital cost functions and equilibrium output rates suffices to determine these optimum road characteristics. The Appendix describes the reasoning underlying the specifications made. To summarize, average variable trip cost (in cents/person-mile) during period $j$ is[8] $3.67+V[1+(X_j/\alpha_j k)^{2.5}]$. Here, 3.67 cents is out-of-pocket vehicle operating cost for each of the 1.5 occupants of the average private passenger vehicle, and the bracketed expression is travel time in minutes/person-mile. The value of travel time $V$ is given alternative values equivalent to \$1, \$2.50, and \$4/hour.

Three groups of traffic flow conditions can usefully be distinguished in the typical urban area: morning and afternoon peaks; the period between about midnight and 6 A.M. when very few trips are taken (on the average 1970 weekday, 2.7 percent of the daily total in the Twin Cities area); and the remainder of the day. Rather than work with these three time periods, we have chosen to ignore completely early morning trips. The fraction of the remaining 18 hours of the day during which peak demand conditions prevail, $\alpha_1$, is assigned values of 1/6, 1/4, and 1/3. The values used for the ratio of peak to off-peak (i.e., other than peak and early morning) period trip consumption rates in the absence of pricing constraints, $(X_1/\alpha_1)/(X_2/\alpha_2)$, vary with $\alpha_1$. For $\alpha_1=1/6$, the ratios are 2, 2.5, and 3. For $\alpha_1=1/4$, they are 1.6, 2, and 2.4, while for $\alpha_1=1/3$, they are 1.4, 1.75, and 2.1. These ratios roughly reflect conditions prevailing in the Minneapolis–St. Paul metropolitan area.

If the annual cost of a one-mile freeway with a capacity of $k$ person-miles per year is $d+ek$, marginal cost tolls for a freeway of optimum size would generate annual revenues just sufficient to cover $ek$. An annual capital cost subsidy of $d$ per mile of freeway would therefore be required. If the individual studied is one of $I$ consumers each of whom travels $(X_1+X_2)/I$ miles/year, his "fair share" of this subsidy per mile traveled would be $g=d/(X_1+X_2)$. Three $(e, g)$ pairs are studied. The low pair (0.15¢, 0.5¢) reflects construction costs prevailing in the outer fringes of a large metropolitan area, while the high pair (1.5¢, 2.9¢) reflects costs adjacent to its central business district (*CBD*). The medium pair studied is (0.75¢, 2.1¢).

In the two-roads cases, average variable trip cost on road $j$ is $3.67+V[1+(X_j/k_j)^{2.5}]$ and its capacity cost is $d_j+e_jk_j$.

[7] If the resource constraint is linear and involves constant returns to scale *or* if it involves constant returns to scale and the utility function is homothetic, $\theta$ can also be interpreted as Gerard Debreu's "coefficient of resource utilization." That is, $1-\theta$ is the fraction by which the resources allocated to providing the consumer with goods 1 and 2 could be reduced while still yielding him the utility level associated with $B$ or $C$. In general, however, the Debreu loss measure would not be the same as that employed in this paper.

[8] Contrary to the discussion of Section I, computational considerations led us not to use a cost function which embodies the notion of "capacity" as a maximum flow rate. The function used does, however, reasonably approximate typical empirically derived cost-volume/capacity relationships over the range for which the marginal product of variable inputs is positive. See the Appendix.

TABLE 1—OPTIMUM PEAK LOAD ROAD CHARACTERISTICS

(Value of Travel Time=$2.50/hour)

| Assumed Traffic Pattern: | | Optimum Value of: | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| Peak Period Duration | Travel Ratio[a] | Volume/Capacity[b] Peak | Volume/Capacity[b] Off-Peak | Toll/Person-Mile Peak | Toll/Person-Mile Off-Peak | Price/Person-Mile Peak | Price/Person-Mile Off-Peak | Subsidy/ Other Cost[b] | Subsidy/ Capital Cost[b] |
| | | | | Low Capital Costs | | | | | |
| 1/6 | 2.0 | 45 | 22 | 1.4¢ | 0.2¢ | 9.8¢ | 8.2¢ | 6 | 47 |
| | 3.0 | 48 | 16 | 1.7 | 0.1 | 10.2 | 8.0 | 6 | 42 |

[a] On the assumption that 2.5 times as many trips are taken on urban as on rural roads; shown in percent.
[b] Shown in percent.

Three pairs of $e_j$ and subsidy/trip-mile (i.e., $g_j$) values are studied. One pair ($e_1=2.75¢$, $g_1=3.95¢$, $e_2=0.15¢$, $g_2=0.45¢$) is intended to reflect conditions which might prevail on a Manhattan expressway and a remote suburban freeway, respectively, while the second ($e_1=1.38¢$, $g_1=2.3¢$, $e_2=0.3¢$, $g_2=1.15¢$) and third ($e_1=2.06¢$, $g_1=3.15¢$, $e_2=0.23¢$, $g_2=0.8¢$) are meant to characterize two roads with more modest capacity cost differentials.

Tables 1 and 2 summarize optimum road characteristics for the peak load and two-roads models, respectively. To save space, optimum peak load road characteristics are tabulated only for the medium value of travel time, \$2.50/hour. The entries that would appear in tables based on the other travel time values studied can be determined fairly accurately from those shown in Table 1. If travel time is valued at \$1 an hour, the optimum peak period volume-capacity ratio is between 28–33 percent greater than that shown for the corresponding combination of parameter values. Optimum peak period tolls and prices with a \$1 travel time value are, respectively, 17–25 and 26–31 percent less than the corresponding entries in Table 1. For a \$4 travel time value, optimum volume/capacity ratios are 11–14 percent less while tolls and prices are, respectively, 11–15 and 21–30 percent greater than the corresponding entries in Table 1.

If Table 1 and the data from which it is drawn reasonably reflect real world conditions, tolls are substantially below their optimum peak period levels for most urban freeway travel while volume/capacity ratios are probably—reliable data on the subject are not available—substantially above the optimum levels. The calculations indicate that, if travel time is valued at \$2.50 an hour, a volume/capacity ratio in excess of 90 percent would be optimum only on high capital cost freeway segments and, even then, only when the peak period is brief and the ratio of peak to off-peak traffic flow rates is high. With travel time valued at \$1 an hour, volume/capacity ratios greater than 90 percent would be called for when capital costs are high and, with medium capital costs, when the peak period is of short duration. All other parameter value combinations studied yielded optimum volume/capacity ratios substantially below the near capacity levels which seem common in urban areas during rush hours.

The basic "toll" for highway travel in the United States—the sum of federal and state gasoline taxes—currently averages about 13 cents a gallon. The Bureau of Internal Revenue instructions for deducting state gasoline excises on federal income tax returns appear to be predicated on passenger vehicle gasoline use of 14 miles per gallon. These values suggest an average toll of 0.9–1.0 cent per vehicle mile or about 0.6 cents per person mile if the average private passenger vehicle occupancy rate is 1.5. Table 2 indicates this to be about equal to the efficient toll on an optimally designed rural road. However, with travel time valued at \$2.50 an hour, Table 1 indicates 0.6 cent per person mile to be only 7–15 percent of the efficient peak period toll on an optimally designed freeway near the *CBD* of a major urban area. And if travel time is valued at \$4 an hour, a toll 8–17 times that currently charged—the equivalent of a gasoline tax of \$1.00–2.20 per gallon—would be efficient during peak hours on a near-*CBD* freeway of optimum size.

## III. Welfare Losses

As Hotelling recognized, the welfare loss measure proposed in his famous 1938 article yields ambiguous results when applied to situations in which more than one market is distorted. That is, values of these measures depend on the order in which commodities subject to distortions (the two trip types in the case at hand)

are counted.[9] Provided that demand functions are integrable, the loss measure described in Section I does not suffer from this deficiency.

Unfortunately, the set of integrable systems of demand functions which both allow reasonable flexibility in specifying such attributes as own, cross, and income elasticities of demand *and* can be manipulated with a fair degree of ease appears to be empty.[10] The demand functions used in this study are those generated by the utility function

$$U = [\Sigma\epsilon_i(X_i + \beta_i)^\delta]^{1/\delta}$$

a *CES* function with a displaced origin.[11] For properly shaped indifference surfaces, $-\infty < \delta < 1$, and, without loss of generality, $\Sigma\epsilon_i = 1$. The implied demand functions are

$$(1) \quad X_j = -\beta_j + (w + \Sigma P_i\beta_i)/[(\epsilon_j/P_j)^\gamma Y], \quad j = 1, 2, 3$$

where $w = r - h$ is the consumer's income, $P$ denotes prices, $0 > \gamma = 1/(\delta - 1) > -\infty$, and $Y = \Sigma P_i(P_i/\epsilon_i)^\gamma$.

These demand functions afford considerably less flexibility in the specification of demand attributes than was desired. They do permit seven degrees of freedom in specifying these attributes. However, one of these serves only to fix the system's scale. It was hoped that the remaining degrees of freedom could be used to specify the values that would prevail in the absence of pricing constraints on the ratio of trip consumption rates $(X_1/\alpha_1)/(X_2/\alpha_2)$ and $X_1/X_2$ in peak load and two-roads models, respectively; the share of the consumer's income spent on trips $\rho$; and the own price and income elasticities of demand for the two types of trips, $E_{11}$, $E_{22}$, $E_{1w}$, and $E_{2w}$. However, for given values of the travel ratio and income share, it seems that there do not always exist combinations of utility function parameter values which yield desired combinations of these elasticities. Thus, we were unable to compute welfare losses under as wide a variety of demand conditions as we had hoped.[12]

[9] The same deficiency characterizes similar measures employed by Harberger and others. For a fuller discussion of this problem, see Mohring (1971).

[10] For example, suppose that constant elasticity demand functions apply to commodities one and two in a three-commodity world. With some effort, it can be shown that integrability requires goods one and two to have equal income elasticities of demand and rules out both gross substitutability and gross complementarity between them. Since it seems reasonable to suppose that a change in the price of a peak period trip would affect the quantity of off-peak trips consumed, this system was rejected. Similar analyses with other commonly used demand representations proved no more successful.

[11] This function bears the same relationship to the "linear" utility functions employed in studies by Lawrence Klein and Herman Rubin and by Richard Stone et al. as the *CES* function bears to the Cobb-Douglas.

[12] Using demand attributes to infer parameter values of the utility function which leads to equation (1) requires solving a non-linear equation system. We were unable to develop a reliable numerical procedure for doing so. We then turned to the following procedure for computing welfare losses under desired demand conditions: 1) do a series of preliminary runs to determine ranges of utility function parameter values that yield "reasonable" elasticity, etc., values; 2) draw a random sample of utility function parameter values from independent uniform distributions over these ranges; 3) determine for each combination of parameter values drawn the demand elasticities, etc., that would prevail in the absence of pricing constraints and the welfare loss resulting from each constraint for all possible combinations of high, medium, and low values of cost function parameters; 4) with the welfare losses resulting from the constraints as dependent variables, fit quadratic forms in cost and demand attributes; 5) estimate welfare losses under desired demand and cost conditions by evaluating these equations. The equations revealed demand attributes to be highly collinear. As a result, reliable forecasts could not be obtained under the full set of demand conditions we had hoped to consider. At this point, we concluded that equation (1) is insufficiently flexible and resigned ourselves to limiting the scope of the analysis. It appears, then, that one engaged in this sort of work has two choices, neither very desirable. 1) Employ integrable demand functions. While unambiguous loss values will result, the limited flexibility afforded by the demand specification may seriously limit the scope of the study. 2) Dispense with integrability. Greater flexibility will result, but so will ambiguous loss values. Before we choose 1) again, we will seriously consider 2). It could turn out that the ambiguity is not that great—that different paths yield quite similar loss values. If so, the penalty of ambiguity could well be worth the benefits of greater flexibility.

TABLE 3—DEMAND AND COST PARAMETERS USED IN WELFARE LOSS MODEL

| | Low | Medium | High |
|---|---|---|---|
| Peak Period (High-Cost Road) | | | |
| Elasticities ($E_{11}$, $E_{1w}$)[a] | (0.26, 0.25) | (0.52, 0.50) | (1.00, 1.00) |
| Off-Peak (Low-Cost Road) | | | |
| Elasticities ($E_{22}$, $E_{2w}$)[a] | (0.52, 0.50) | (1.00, 1.00) | (1.88, 2.00) |
| Income Share ($\rho$) | 0.10 | 0.15 | 0.20 |
| Peak Period Duration ($\alpha_1$) | 1/6 | 1/4 | 1/3 |
| Travel Ratio: | | | |
| Peak Load: $\alpha_1=1/6$ | | 2.50 | |
| $\alpha_1=1/4$ | 1.60 | 2.00 | 2.40 |
| $\alpha_1=1/3$ | | 1.75 | |
| Two Roads | 1.35 | 2.50 | 5.00 |
| Capital Costs | | | |
| Peak Load ($e$, $g$) | (0.15, 0.50) | (0.75, 2.10) | (1.50, 2.90) |
| Two Roads ($e_1$, $g_1$, | (1.38, 2.30 | (2.06, 3.15 | (2.75, 3.95 |
| ($e_2$, $g_2$) | 0.30, 1.15) | 0.23, 0.80) | 0.15, 0.45) |
| Travel Time Value ($V$) | 1.00 | 2.50 | 4.00 |

[a] Although concrete evidence on the subject is scanty, the prevailing impression seems to be that peak period demand elasticities are substantially lower than off-peak elasticities. The assumption of a 1:2 ratio seems as plausible as any.

TABLE 4—PEAK LOAD WELFARE LOSSES[a]

(Shown in percent)

| Constraint | Deviation | Peak Period Elasticities | Off-Peak Elasticities | Income Share | Peak Duration | Travel Ratio | Capital Costs | Travel Time Value |
|---|---|---|---|---|---|---|---|---|
| Single Toll | Low | 0.38 | 0.51 | 0.67 | 1.23 | 0.34 | 0.09 | 0.80 |
| 0.66 | High | 1.04 | 0.81 | 0.67 | 0.43 | 0.90 | 1.35 | 0.53 |
| Pure Deficit | Low | 0.61 | 0.85 | 1.19 | 1.12 | 1.26 | 0.10 | 2.26 |
| 1.14 | High | 1.94 | 1.31 | 1.10 | 1.15 | 1.07 | 1.58 | 0.73 |
| Single Toll and | | | | | | | | |
| Deficit | Low | 3.21 | 1.32 | 3.34 | 4.30 | 2.69 | 0.30 | 5.65 |
| 3.20 | High | 3.25 | 10.87 | 3.09 | 2.68 | 3.48 | 5.61 | 2.15 |
| Low Arbitrary | | | | | | | | |
| Capital Input[b] | Low | 22.45 | 16.65 | 18.67 | 19.36 | 17.38 | 7.40 | 22.18 |
| 18.42 | High | 14.12 | 30.20 | 18.09 | 17.98 | 19.20 | 25.17 | 16.03 |
| High Arbitrary | | | | | | | | |
| Capital Input[c] | Low | 8.22 | 5.85 | 8.34 | 9.71 | 7.42 | 2.04 | 11.20 |
| 8.21 | High | 8.32 | [d] | 8.09 | 7.46 | 8.80 | 13.01 | 6.57 |

[a] Ratio of "real income change" loss measure to transportation expenditure under optimum conditions.
[b] Capacity equals 50 percent of the optimum value under the single toll and deficit constraint.
[c] Capacity equals 150 percent of the optimum value under the single toll and deficit constraint.
[d] The iterative procedure used to optimize the constrained system did not converge.

In the sensitivity analysis which follows, welfare losses are computed by first finding a combination of utility function parameter values which, under the specified cost conditions, yields the specified demand conditions.[13] The cost and demand parameter values studied are shown in Table 3.

For the peak load and two-roads models, respectively, Tables 4 and 5 show the welfare losses which result from optimizing the system subject to each pricing constraint when all system attributes assume their medium values and also when system at-

[13] The demand conditions are those which would prevail in the absence of pricing constraints.

TABLE 5—TWO-ROADS WELFARE LOSSES[a]
(Shown in percent)

| Constraint | Deviation | High Cost Road Elasticities | Low Cost Road Elasticities | Income Share | Travel Ratio | Capital Costs | Travel Time Value |
|---|---|---|---|---|---|---|---|
| Single Toll | Low | 0.29 | 0.26 | 0.41 | 0.49 | 0.17 | 0.50 |
| 0.42 | High | 0.52 | 0.59 | 0.42 | 0.29 | 0.69 | 0.34 |
| Single Toll and Deficit | Low | 2.02 | 1.22 | 2.38 | 2.43 | 1.47 | 3.88 |
| 2.28 | High | 2.90 | 4.54 | 2.22 | 2.00 | 3.13 | 1.60 |

| 22.17 | High | 17.18 | [d] | 21.82 | 23.36 | 24.82 | 19.76 |
| High Arbitrary Capital Input[c] | Low | 8.02 | 7.12 | 8.63 | 8.12 | 6.66 | 10.63 |
| 8.53 | High | 10.06 | [d] | 8.48 | 8.63 | 10.24 | 7.22 |

[a] Ratio of "real income change" loss measure to transportation expenditure under optimum conditions.
[b] Total expenditures on the variable component of capacity, $e_1k_1+e_2k_2$, restricted to 50 percent of the optimum value under the single toll-deficit constraint.
[c] Total expenditures on the variable component of capacity restricted to 150 percent of the optimum value under the single toll-deficit constraint.
[d] The iterative procedure used to optimize the constrained system did not converge.

tributes deviate from their medium values individually.[14] In these tables, losses associated with uniformly medium values are found in the column headed "Constraint." Thus, comparison of the uppermost entries in the "Constraint" and "Peak Period Elasticities" columns of Table 4 indicates that, if $E_{11}$ and $E_{1w}$ are lowered from their medium to low values while all other variables are held at their medium values, the single toll constraint welfare loss declines from 0.66 to 0.38 percent.

Three groups of system parameters—capital costs, demand elasticities, and the value of travel time—are by far the most important determinants of welfare losses. An increase in either capital costs or off-peak or low-cost road demand elasticities leads to increases in all loss measures. An increase in the travel time value is associated with increases in *absolute* levels of resource waste, but decreases in the proportionate measures which are tabulated. The effects on losses of the income share, peak duration, and travel ratio parameters are, for the most part, modest and vary in direction from model to model.

Except when capital costs are low or the peak duration is short, the peak load single toll constraint appears to be substantially less consequential than the pure deficit constraint. Excluding from consideration only the low entries in Table 4 for these two parameters, the pure deficit constraint loss ranges between 1.2–3.7 times the corresponding single toll constraint loss for any given combination of

[14] For some parameter combinations, the first-order conditions for optimization subject to some constraints either have no solutions or yield, in peak load models, off-peak trip prices at which the consumer would desire to sell rather than buy them. This is particularly true of models involving deficit limitations when both capital costs and elasticities are high. This result seems attributable to the nature of the demand curves generated by the utility function employed. With this function, demand curves involving high elasticities at any one set of price and income levels are generally rather flat. More precisely, they generally intersect the price axis at a level not much greater than that through which the curve is made to pass in the initial specification of utility function parameter values. Under such circumstances, modest price increases can lead to the equivalent of supply and demand curves intersecting at negative or imaginary output levels.

parameter values.

There is some reason to believe (see Mohring 1965) that urban expressway capacity is substantially below the optimum level in the United States. If this belief is in fact correct, the low arbitrary capital input constraint is the most realistic of those studied. Among the models tested, it yields by far the largest loss values. Actually, these values may well be biased downward. During the height of morning and afternoon peak periods, expressways in many urban areas appear to be operating in the equivalent of the backward bending portion of the average cost curves drawn in Figures 1 and 2. The losses resulting from operating in this range undoubtedly exceed those given by our model—a model in which, to repeat, the marginal product of variable inputs is assumed positive for all positive input levels.

The optimization of freeway capacities subject to the current procedure of financing investments entirely out of gasoline and similar user excises would put the single toll and deficit constraint into effect. Depending on the specific combination of parameter values involved, such a change would reduce losses to 4 to 36 percent of the levels associated with the low arbitrary capital input model.

With rare exceptions, past attempts to measure the welfare costs of various types of resource misallocation have yielded estimates which have seemed trivial, at least in percentage terms. Except for some of the arbitrary capital input model results, this study continues the tradition. For example, the single toll constraint entries in Tables 4 and 5 range between 0.09–1.35 percent. This being the case, it is worth attaching dollar magnitudes to these percentage losses in partial answer to the almost inevitable question, "Why bother?" The highway transportation undertaken by households and business firms in the United States accounts for considerably more than 10 percent of *GNP*, i.e., considerably more than $100 billion. While 0.09–1.35 percent of $100 billion *is* a small fraction of *GNP*, it is also $90–1,350 million, hardly a trivial amount. And this range may well have a downward bias. The value of consumer-supplied travel time does not enter into *GNP* as it is conventionally measured. However travel time is a substantial part of the denominator in the welfare cost-total transportation expenditure ratios shown in Tables 4 and 5. Furthermore, peak load and two-roads pricing constraints are simultaneously in effect in the real world. They are not alternative constraints as assumed in this study. Had these constraints been imposed simultaneously, estimated losses would undoubtedly have increased, perhaps substantially. Finally, the cost figures used in this study apply to expressway transportation. Both the levels of and the differences between optimum peak and off-peak tolls and prices on city streets are substantially greater than those shown in Tables 1 and 2 (see, for example, Mohring, 1964). Thus, the losses associated with this important part of road transportation are undoubtedly greater than those suggested by Table 4.

Would it be worthwhile to take the steps necessary to eliminate the welfare losses identified in this study? It appears that a definite answer awaits further research. Eliminating the arbitrary capacity expenditure part of the low arbitrary capital input constraint would seem most clearly in order. But whether that constraint is in fact applicable to the real world is open to dispute. Neither current highway user charges nor the cost data employed in this study take into account air pollution or the costs that traffic noise and smells impose on those who live and work near traffic arteries.

Eliminating either the pure deficit or the single toll constraint would entail

costs not taken into account in our analysis. As for the former, the welfare loss associated with medium values of all parameters for the peak load-pure deficit constraint model amounts to 1.14 percent of what the consumer would spend on trips under optimum conditions. From Table 1, optimum conditions would involve a subsidy equal to about 20 percent of this expenditure level and hence a welfare gain of about 5.7 cents for the average subsidy dollar. Under the same conditions but with high peak period elasticities an 8.1 cent average gain per subsidy dollar would result from complete absorption by the public of the deficit. The two-roads models yield similar benefit ratios for subsidies.

No political body has available a system of lump sum levies to finance its activities, of course. Existing tax sources themselves introduce distortions. To determine whether a net social gain would result from partial or complete public subsidy of the fixed component of highway capacity costs would require information not presently available on the welfare cost of these tax related distortions.

A similar consideration applies to the single toll constraint. A variety of methods has been proposed to vary highway user charges from place to place and time to time (see, for example, Ministry of Transport). All of these pricing systems would involve administrative and capital costs that could generally be expected to be larger for systems with greater sensitivity. That is, the costs of establishing such a pricing system would almost certainly depend on how close it would come to achieving complete equality between prices and marginal costs through space and time. To specify the fraction of the single toll constraint loss that it would be efficient to eliminate would require information not presently available on the relationship between the costs and the sensitivities of alternative toll systems.

## Appendix

### *The Sources of Cost Functions and Parameter Values*

The highway engineering literature reports a variety of attempts to fit relationships of the general form $c=g(X/k)$ and $t=f(X/k)$ to data on vehicle operating costs $c$, travel time t, and the volume/capacity ratio $X/k$, for various types of roads.[15] Vehicle operating costs appear to be virtually independent of traffic densities on freeways and rural roads. For a vehicle traveling at a constant speed of greater than about 35 mph, gasoline consumption and other operating costs per mile traveled increase with speed. Realized speeds, in turn, decrease with increases in traffic densities. At the same time, however, increased congestion results in an increase in the frequency with which drivers must accelerate and decelerate. According to the American Association of State Highway Officials (*AASHO*) "Red Book," pages 100–25, the costs of these maneuvers tend almost exactly to offset the cost savings associated with lower realized speeds. As a result, regardless of the actual density of traffic, a driver's vehicle operating costs are about those he would incur at the speed he would choose to travel on a road with a zero volume/capacity ratio.

L. L. Liston and R. W. Sherrer report that, in 1973, the sum (net of taxes) of the fuel, oil, tire, plus half of the maintenance and depreciation costs of operating a 1973 standard size automobile in Baltimore was 7.17 cents per vehicle-mile. The corresponding figure for freeway travel would be somewhat less. If operating costs on freeways are on the order of 5.5 cent per vehicle-mile, then adjusting by a vehicle occupancy rate of 1.5 gives 3.67 cents per person-mile.

While the specific functional forms differ, most of the relationships between travel time and volume/capacity ratios in the highway engineering literature agree in two important respects. First, they imply that the law of diminishing marginal productivity holds for the variable input, travel time, at all positive traffic levels. That is, the differ-

[15] For references and a more extended discussion of these studies, see Mohring (1964).

ence between marginal and average travel times per trip is positive at even the lowest traffic densities. Second, these relationships imply that a given stretch of highway does, indeed, have a "capacity" in the sense of being able to produce trips at a rate no greater than some specifiable maximum. If the rate at which travelers attempt to make trips exceeds this level, travel time per trip continues to increase. However, the number of trips completed per time period actually falls; the marginal product of travel time is negative.

The simplest travel time-volume/capacity relationship which approximates those in the highway literature with reasonable accuracy is $X/k=4/\mathrm{t}-4/\mathrm{t}^2$ with t expressed in minutes per trip-mile. This expression underlies Figures 1 and 2. Working with a relationship that allows for the possibility of a negative marginal product for travel time presented computational difficulties that we preferred to avoid. We therefore settled on a relationship suggested by Robert Solow and William Vickrey (p. 436), $\mathrm{t}=a+b(X/k)^d$. For $a=b=1$ and $d=2.5$, this relationship yields travel times per person-mile which closely approximate those from the relationship cited above over the range for which travel time has a positive marginal product. Both relationships, for example, imply speeds of 60, 51, and 30 mph, respectively, at volume/capacity ratios of 0, 0.5, and 1. The ratios of the marginal cost tolls implied by the relationship actually used to those associated with $X/k=4/\mathrm{t}-4/\mathrm{t}^2$ are, however, considerably greater than one for $X/k$ values between about 0.5 and 0.85 and, of course, considerably less than one for $X/k$ ratios in excess of 0.95.

The literature contains no consensus on the rate at which drivers are willing to trade money for reduced travel time. The value most commonly used by the Bureau of Public Roads and state highway departments in benefit-cost studies is $1.55/hour for an assumed 1.8 occupants of the average private passenger vehicle. The seeming precision of this number is misleading. It reflects the view of the Committee responsible for the original 1949 version of the Red Book that $1/hour was as reasonable a number as any that might have been chosen and the fact that both prices and incomes rose between 1949 and 1960, the date of the Red Book's most recent revision.

If drivers choose travel speeds so as to minimize the sum of vehicle operating and travel time costs, data from Robley Winfrey suggest that, c. 1968, desired speeds of 45, 60, and 75 mph imply travel time values of $0.45, $1.73, and $6.08/hour, respectively.[16] By analyzing the choices of a group of British civil servants between slow, cheap, and fast, more expensive means of commuting, Michael Beesley inferred that members of the lowest pay group studied valued their travel time at about 31 percent of their wage rates. This ratio increased with wage rates to a high of 50 percent for the highest pay group analyzed. Similar results were obtained by Thomas Lisco. That is, values of travel time increased as a fraction of income for those with 1966 salaries of less than $10,000 a year. The ratio equaled about 50 percent for annual incomes in excess of $10,000. For an American currently earning $12,000 a year, these ratios would imply travel time values on the order of $2–$3/hour. To take these disparate estimates into account, the implications of alternative travel time values of $1.00, $2.50, and $4/hour are explored in the analysis.

Some rough data developed by John R. Meyer et al., pages 200–11, can be interpreted as indicating that, around 1960, the annual cost at 6 percent interest of the capital invested in right-of-way and construction for one mile of an $N$ lane urban freeway was approximately $Z=\$11{,}200+\$2{,}500D+\$(7{,}200+300D)N$, where $D$, which appears to range between 10–300 in the United States, is the "net residential density" of the area through which the freeway passes, i.e., population per acre of land actually used for residential purposes. In addition, annual right-of-way costs were on the order of

[16] Denoting the value of an hour's travel time by $V$, the total cost of traveling a mile on an uncongested road can be written $c=g(S)+V/S$, where $S$ is the traveler's desired speed. For $c$ to be a minimum, $dc/dS=g'-V/S^2=0$, or $V=S^2g'$. The travel time values given in the text were determined by inserting the appropriate values of $S$ and $g'$ into this equation.

$0.005DZ$. Data privately supplied by the Federal Highway Administration (*FHWA*) indicate that maintenance costs averaged approximately $2,500 per lane-mile of expressway in 1972. Between 1960 and the end of 1973, the *FHWA*'s composite highway construction cost index increased by a factor of 2.1 while its maintenance and operation cost index increased by a factor of 1.1 between 1972 and the end of 1973.

That a substantial proportion of both construction and right-of-way costs are independent of the number of lanes provided reflects the fact that a freeway includes paved shoulders on both sides of each set of traffic lanes, a median strip between opposing traffic streams, and buffer strips between the freeway and adjacent land. As a result, only about 33 to 50 percent, respectively, of the land area used by four- and eight-lane freeways is devoted to freeway lanes themselves.

The capacity of a four- to eight-lane expressway is about 1,800 vehicles per lane-hour or 2,700 passengers per lane hour at an average vehicle occupancy rate of 1.5. Multiplying the Meyer et al. and *FHWA* annual cost data by the appropriate cost indices and dividing by 2,700 passengers per lane-hour times 18 (see below) hours per day times 365 days per year yields, for average and marginal costs per person-mile of capacity:

| Net Residential Density | Marginal Capacity Costs (*MCC*) | Average Capacity Costs (*ACC*) Number of Lanes 4 | 6 | 8 |
|---|---|---|---|---|
| 10 | 0.14¢ | 0.25¢ | 0.21¢ | 0.19¢ |
| 100 | 0.68 | 1.34 | 1.45 | 1.26 |
| 200 | 1.61 | 4.63 | 3.62 | 3.12 |
| 300 | 2.89 | 8.52 | 6.64 | 5.71 |

In the absence of pricing constraints, marginal cost tolls for an optimum highway would generate revenues just sufficient to cover the component of its capacity costs that varies with highway width. The fixed component would be supported by a public subsidy. If the average volume/capacity ratio on the highway is $h$, then $(ACC-MCC)/h$ would be the average subsidy per person-mile traveled.

The calculations summarized in Table 1 yield optimum volume/capacity ratios which, for the medium value of travel time, average 0.25 and 0.49 for marginal capacity costs of 0.15 and 1.5 cents, respectively. These marginal capacity cost values would roughly correspond to those prevailing respectively in the outer suburban fringe and in a near *CBD* area of a large urban region. Highways in such areas would normally be of four and eight lanes, respectively. The respective average subsidies per person-mile associated with these roads—$(ACC-MCC)/h$—would be about $0.13/0.25=0.52$ cents and $1.41/0.49=2.9$ cents. The combinations of marginal capacity cost and subsidy per person-mile actually used in the analysis are: low, $MCC=0.15$ cents and subsidy $=0.5$ cents; medium, 0.75 and 2.1 cents; high, 1.5 and 2.9 cents.

In the two-roads analysis, three sets of values are used for the marginal capacity cost and subsidy parameters. In the first, the *MCC* and subsidy values respectively equal 0.15 and 0.45 cents for the low cost road while *MCC* is 2.75 cents and subsidy 3.95 cents for the high cost road. In the third, least extreme case, $MCC=0.3$ cents and subsidy $=1.15$ cents for the low cost road while $MCC=1.38$ cents and subsidy $=2.30$ cents for the high cost road. In the intermediate case, the respective values are 0.23, 0.8, 2.06, and 3.15 cents.

During the average 1970 work day, about 4.9 million person trips were taken by bus or private passenger vehicle in the Minneapolis-St. Paul metropolitan area. Grouping these trips into those taken during the three hours most heavily used for travel, the second most heavily traveled, and so forth, yields:[17]

| Highest 3 Hours | Second | Third | Fourth |
|---|---|---|---|
| 23.8% | 21.3% | 17.7% | 14.7% |

| Fifth | Sixth | Seventh | Lowest 3 Hours |
|---|---|---|---|
| 12.4% | 7.4% | 2.3% | 0.4% |

In dividing this distribution between "peak" and "off-peak" travel, it seems most

[17] These ratios, it should be noted, reflect suboptimum prices at least during peak hours but also quite likely suboptimum levels of highway investment. The effects of these deficiencies offset each other somewhat in using actual travel ratios to infer those under optimum conditions. The data summarized above were privately supplied by personnel of the Twin Cities area Metropolitan Council.

reasonable to us simply to ignore the 6 early morning hours, 12–6 A.M., which account for only 2.7 percent of average daily traffic ($ADT$), and to regard the highest 6 and next 12 hours as peak and off-peak periods, respectively. If these flow rates apply seven days a week (weekend travel is only slightly lower and slightly less peaked than weekday travel in most urban areas), $\alpha_1$ would equal 1/3 and the relative flow ratio $(X_1/\alpha_1)/(X_2/\alpha_2)$, would equal 1.73. These are approximately the numbers used for the long peak duration–medium flow ratio combination.

The short duration–medium flow ratio combination was derived from the following considerations. Urban peak hour traffic flows typically exhibit a substantial directional imbalance. Traffic is considerably heavier toward than away from the central business district during the morning peak. The reverse is true during the afternoon peak. Suppose that peak period travel in the low flow direction and off-peak travel occur at the same average rate. Reversible center lanes are infrequently employed. This supposition therefore implies that any given expressway lane is subject to peak conditions only 3 rather than 6 hours a day (i.e., $\alpha_1=1/6$ rather than 1/3) and that the difference between peak and off-peak flow rates during this shorter period is twice that suggested by the preceding paragraph, i.e., the relative flow ratio is 2.46 rather than 1.73.

Low and high deviations from this 2.46 flow ratio are based on the alternative assumptions that peak period reverse flows occur at rates characteristic of the highest and lowest three off-peak hours (respectively 17.7 and 7.4 percent of $ADT$ per three hours) rather than the average flow rate of the entire off-peak period. These percentages respectively imply peak hour–peak direction flows of 27.4 and 37.7 percent of $ADT$ per three hours and relative flow rates of 1.95 and 3.16. Approximately the same percentage deviations from medium flow rates are employed for $\alpha_1=1/3$ and an arbitrarily chosen middle value, $\alpha_1=1/4$ with an assumed medium flow ratio of 2.

# Age, Experience, and Wage Growth

By EDWARD LAZEAR*

During the past decade, much has been said about the role that on-the-job training plays in augmenting one's stock of human capital.[1] Up to this point, however, little has been done to distinguish the effect of on-the-job training from that of aging on the increase in human wealth. The reason rests primarily on the fact that it is difficult to observe or even define in some appropriate way the amount of on-the-job training that an individual possesses. In this paper, a method is developed by which one may compare the effects of work experience to those of aging per se. The difference is then attributed to on-the-job training.

The analysis deals with the relationship between an individual's wage growth pattern and his employment history. If, as the human capital framework suggests, individuals increase their wealth by investing in on-the-job training, one might expect workers who spend less time on the job during a given period of time to acquire less human capital. Thus, it is expected that the growth rate of wages will be related not simply to an individual's chronological age, but also to the amount of time spent on the job during the period under consideration. If this is in fact the case, then part of the opportunity cost of being unemployed consists of a nonmeasured human capital component of the wage rate. The total cost of unemployment is then the sum of foregone observed earnings plus the value of the unobserved payment of human capital. By calculating the amount of human capital investment foregone during periods of unemployment, an estimate of the importance of on-the-job training is obtained. The major findings are:

1. Young workers receive approximately one-third of their total employment compensation in the form of human capital. The effect of current work experience on wage growth is therefore substantial.

2. For individuals in the 14–24 year-old age group, aging is an important determinant of wage growth. Its importance, however, declines with age. While for a 19 year old, one year of aging implies about twice as much wage growth as does a year of experience, by the time the individual has reached 25.2 years, the effect of experience exceeds that of aging per se.

3. The finding that wage growth is inversely related to previous work experience casts some doubt on the validity of Yoram Ben-Porath's neutrality assumption.

4. As expected, an increase in formal schooling is associated with more rapid wage growth. It is also found that schooling increases wage growth by slightly more than does the equivalent amount of work experience.

5. Consistent with previous work, it is found that an increase in the number of hours worked implies more rapid wage growth.

* Assistant professor of economics, University of Chicago, and research associate, National Bureau of Economic Research. This research was supported by grants from the National Science Foundation and the Rockefeller Foundation. I wish to thank Charlie Brown, Zvi Griliches, Robert Michael, Jacob Mincer, Sherwin Rosen, and James Smith for comments on an earlier version of this paper. I also thank Janice Platt for excellent research assistance.

[1] See, for example, P. M. Blau and O. D. Duncan, Barry Chiswick, John Hause, James Heckman, L. A. Lillard, Robert Michael and the author, Jacob Mincer (1962, 1974), Mincer and Solomon Polachek, and Sherwin Rosen (1973).

6. It appears that, *ceteris parabus*, nonwhites enjoyed more rapid wage growth over the period in question than did whites. This may be the result of institutional changes or of unobserved quality differences at the time of hiring which work in favor of white workers.

7. Married workers have higher initial wage levels, but slower wage growth than do nonmarried ones. This is presumably a reflection of differences in the life cycle location not captured by the included human capital variables.

8. Union membership at the end of the period is a positive factor in the determination of wage growth.

## I. A Model

Suppose that wage growth over time takes the form of

$$(1)\qquad W_{69i} = AW_{66i}\exp\{\gamma_i t + u_i\} = AW_{66i}\exp\{3\gamma_i + u_i\}$$

where $W_{69i}$ = hourly wage rate in 1969 in cents for individual $i$

$W_{66i}$ = hourly wage rate in 1966 in cents for individual $i$

$\gamma_i$ = average annual growth rate of wages which varies across individuals

$A$ = a wage shift parameter unique to this three-year period, but invariant across individuals. "$A$" should be thought of as a nonmeasured cohort and business cycle effect

$u_i$ = the random error term where $u \sim N(0, \sigma^2 I)$

The growth rate $\gamma_i$ depends on a number of other parameters, the most fundamental of which relate to aging and the acquisition of human capital. Let us then start with

$$(2)\qquad \gamma_i = \alpha_0 + \alpha_1(S_{69i} - S_{66i}) + \alpha_2(OJT_{69i} - OJT_{66i})$$

where $S_{69i}$ = highest grade of schooling completed in 1969 by individual $i$

$S_{66i}$ = highest grade of schooling completed in 1966 by individual $i$

$OJT_{69i}$ = individual's stock of on-the-job training in 1969

$OJT_{66i}$ = individual's stock of on-the-job training in 1966

with $\alpha_0$, $\alpha_1$, and $\alpha_2$ all positive

Although the data to be used in this analysis are quite explicit with respect to job experience, it still remains impossible to directly measure with any confidence the amount of on-the-job training acquired over this three-year period. It is possible, however, to approximate the change in the stock of on-the-job training if it is assumed that

$$(3)\qquad OJT_{69i} - OJT_{66i} = \delta_1(E_{69i} - E_{66i}) + \delta_2 E_{66i} + \delta_3 S_{66i} + \delta_4 Age_i$$

where $E_{66i}$ = initial amount of job experience in years held by individual $i$[2]

$E_{69i}$ = amount of job experience in 1969 for individual $i$, equal to $E_{66i}$ plus the years worked between 1966 and 1969 where a year is defined[3] as (weeks worked/52)

[2] For individuals whose job in 1966 was obtained immediately after school, $E_{66i}$ is exact in years. For individuals whose job in 1966 was the same as the job worked in the final year of high school, $E_{66i}$ equals the number of years since school completion to the survey in 1966 plus .33 years. For all other individuals, $E_{66i}$ equals the number of years between school completion and the survey. Stratifying these groups yielded results which did not differ significantly from those obtained below.

[3] Since experience is measured in terms of years, and since it can be argued that the human capital production during any given year of experience varies with age, the amount of previous experience, and schooling, it might be suggested that equation (3) includes some type of interaction which segments the $(E_{69}-E_{66})$ variable. It was found that when (3) was specified to include multiplicative interaction terms, the resulting equation did not differ significantly from the one obtained when (3) is used as specified.

$Age_i$ = the individual's age in years in 1966.

The coefficient $\delta_1$ is expected to be positive since individuals who spend more time working are more likely to acquire on-the-job training (this essentially is the requirement that the cost of learning be a convex function of the learning rate).[4] The coefficient $\delta_2$ should be negative since it pays an individual who plans to invest in on-the-job training to do so during his first years on the job. As previous experience increases, incremental investment in on-the-job training for a given year of experience should fall.[5] The sign of $\delta_3$ depends upon the marginal complementarity or substitutability of formal schooling and on-the-job training. Finally, $\delta_4$ is negative since, given schooling and experience, older individuals are less likely to invest in human capital.

The term $(E_{69i}-E_{66i})$ may be rewritten as $(3-TN_i)$ where $TN_i$ is the total number of weeks during the three-year period in which the individual did not engage in work divided by 52. Upon substitution, we obtain

$$(4)\quad OJT_{69} - OJT_{66} = 3\delta_1 - \delta_1 TN_i + \delta_2 E_{66i} + \delta_3 S_{66i} + \delta_4\, Age_i$$

so that

$$(5)\quad \gamma_i = \alpha_0 + \alpha_1(S_{69i} - S_{66i}) + \alpha_2[\delta_1(3) - \delta_1 TN_i + \delta_2 E_{66i} + \delta_3 S_{66j} + \delta_4\, Age_i]$$

or

$$(6)\quad \gamma_i = \theta_0 + \theta_1 S_{66i} + \theta_2 E_{66i} + \theta_3(S_{69i} - S_{66i}) + \theta_4 TN_i + \theta_5\, Age_i$$

where

$$\theta_0 = \alpha_0 + \alpha_2\delta_1(3) > 0 \qquad \theta_1 = \alpha_2\delta_3 > 0$$
$$\theta_2 = \alpha_2\delta_2 < 0 \qquad \theta_3 = \alpha_1 > 0$$
$$\theta_4 = \alpha_2(-\delta_1) < 0 \qquad \theta_5 = \alpha_2\delta_4 < 0$$

Substituting (6) into (1) and taking the *log* of both sides yields

$$(7)\quad ln\, W_{69i} = ln\, A + ln\, W_{66i} + 3[\theta_0 + \theta_1 S_{66i} + \theta_2 E_{66i} + \theta_3(S_{69i} - S_{66i}) + \theta_4 TN_i + \theta_5\, Age_i] + u_i$$

or

$$(8)\quad ln\, W_{69i} - ln\, W_{66i} = \eta_0 + \eta_1 S_{66i} + \eta_2 E_{66i} + \eta_3(S_{69i} - S_{66i}) + \eta_4 TN_i + \eta_5\, Age_i + u_i$$

where

$$\eta_0 = ln\, A + 3\alpha_0 + 9\alpha_2\delta_1 > 0$$
$$\eta_1 = 3\alpha_2\delta_3 > 0$$
$$\eta_2 = 3\alpha_2\delta_2 < 0$$
$$\eta_3 = 3\alpha_1 > 0$$
$$\eta_4 = 3\alpha_2(-\delta_1) < 0$$
$$\eta_5 = 3\alpha_2\delta_4 < 0$$

The "effect of aging" may be defined as that wage growth which, in the absence of work experience or investment in formal schooling, occurs simply as the result of the passage of chronological time[6] independent of cohort and business cycle effects. Thus, define $\gamma'$ as the rate at which wages would grow if $(E_{69}-E_{66})$ and $(S_{69}-S_{66})$ were both set equal to zero. Then

$$(9)\quad \gamma' = \gamma - \eta_3(S_{69} - S_{66}) + 3\eta_4$$

since when $TN=3$, $(E_{69}-E_{66})=0$.

From (1), (8), and (9) one may write that

[4] See my 1975 paper, and Rosen (1973) for a more complete discussion of this issue.

[5] This is the usual result of an optimal investment plan in a life cycle context. Both Ben-Porath (1967) and Rosen (1972) derive this implication. Heckman, and Mincer and Polachek, on the other hand, show that under reasonable assumptions this result will not hold.

[6] This is essentially nonmarket acquisition of human capital which the individual acquires as he ages. With enough data on nonwork activities, one could presumably define in some precise way exactly what "aging" is.

$$(10)\quad \gamma' = (\eta_0 + \eta_1 S_{66} + \eta_2 E_{66} + 3\eta_4 + \eta_5\, Age)/3 - (ln\ A)/3$$

Equation (10) is not identified if we are unable to estimate $ln\ A$. However, since it is reasonable that $A \geq 1$, it must be the case that

$$(11)\quad \gamma' \leq (\eta_0 + \eta_1 S_{66} + \eta_2 E_{66} + 3\eta_4 + \eta_5\, Age)/3$$

Thus, an upper bound to the effect of aging may be obtained.

Up to this point, only human capital variables of the most traditional types have been included in the wage growth equation. However, there are reasons to expect that wage growth will depend on other factors as well. Employers may be willing to pay more per hour to workers who work longer hours because of, say, daily set up costs. In light of the work by C. M. Lindsay, Jacob Mincer and Solomon Polachek, and Donald Parsons, it is reasonable to suppose that wage growth will be a function of the change in the number of hours worked between 1966 and 1969. In addition, to the extent that military experience offers an alternative method of acquiring human capital, the change in the amount of military experience should be included. Also, since there are many reasons why blacks may have different incentives to invest in on-the-job training than whites, race may be a factor in determining wage growth. Similarly, one may expect that marital status and union membership may affect wage growth. These variables are added to (8) so that it becomes

$$(12)\quad ln\ W_{69i} - ln\ W_{66i} = \eta_0 + \eta_1 S_{66i} + \eta_2 E_{66i} + \eta_3(S_{693} - S_{66i}) + \eta_4 TN_i + \eta_5\, Age_i + \eta_6 CH_i + \eta_7 D + \eta_8 CM_i + \eta_9 M + \eta_{10} U$$

where $D$ is a dummy variable set equal to 1 for white individuals,

$M$ is set equal to 1 for individuals who were married during 1966,

$U$ is set equal to 1 for individuals who belonged to a union in 1969,

$CH$ is the "usual" number of hours worked in 1969 minus the usual number of hours worked in 1966,

$CM$ is the number of years of military experience in 1969 minus the number of years of military experience in 1966.

## II. Estimation

This equation can be easily estimated with longitudinal data obtainable from the National Longitudinal Survey (*NLS*). The data selected for this study were on young men, 14 to 24 years old. Since we are trying to estimate the effect of experience on wage growth, postulating that missed work time represents missed on-the-job training, we would like to examine a group of individuals who undertake substantial investment in human capital. Since men tend to invest in on-the-job training more than do women, and the young invest more than the old, the desired effects are most likely to be observed when looking at young men. The estimated effects will therefore tend to be stronger for the group in question than for the working population as a whole.[7]

The original sample has records on 5,225 individuals. This had to be reduced to 1,996 observations to meet the following criteria: First, it was necessary that individuals in the sample have wage rates reported in both 1966 and 1969. Second, individuals who reported that their wage rate was either less than 50¢ per hour or greater than $10 were dropped on the grounds that reported wages in those cases were unlikely to be correct. Finally, observations were dropped for which there was incomplete information on variables used in this analysis.

[7] Specifically, the magnitude of the *OJT* effects should be larger for this group. To the extent, however, that variance is reduced by truncating the sample, the precision of estimation may be reduced as the standard errors increase.

Equation (12) was estimated by ordinary least squares (*OLS*).[8] The results were:

$$(13)\quad \ln W_{69} - \ln W_{66} = .87948 \underset{(.00617)}{+ .00548\, S_{66}} \underset{(.00644)}{- .02014\, E_{66}} \underset{(.01202)}{+ .04895\,(S_{69} - S_{66})} \underset{(.01456)}{- .04784\, TN} \underset{(.00653)}{- .02266\, Age} \underset{(.00068)}{+ .00276\, CH} \underset{(.02377)}{- .05173\, D} \underset{(.11183)}{+ .05668\, CM} \underset{(.02738)}{- .11089\, M} \underset{(.02318)}{+ .16406\, U}$$

$R^2 = .156$; $SEE = .4367$; $F(10, 1985) = 36.8$

(The figures enclosed in parentheses are standard errors.)

The equation yields a number of interesting results. First, the coefficient on $TN$ is negative and significant. This is consistent with the theory. Individuals who spend less time in the work force acquire less human capital in the form of on-the-job training. Since this equation holds formal schooling constant, this coefficient is not biased by the substitution of formal schooling for on-the-job training during the nonworked period. The term reflects the net foregone investment in human capital associated with dropping out of the work force.[9] The coefficients are more easily interpreted when converted by the following computation: Taking the *antilog* of (12), we may write

$$(14)\quad W_{69} = W_{66} \exp \{\eta_0 + \eta_1 S_{66} + \ldots + \eta_{10} U\}$$

Differentiating (14) with respect to $TN$ gives

$$(15)\quad \frac{\partial W_{69}}{\partial TN} = W_{66} \exp \{\eta_0 + \eta_1 S_{66} + \ldots + \eta_{10} U\}\eta_4$$

so that

$$(16)\quad \frac{\partial W_{69}}{\partial TN} = -14.8$$

for a single white nonunion worker who was not in the military between 1966 and 1969. (All other variables assume their mean values.)

Equation (16) implies that being out of the work force for a period of one year between 1966 and 1969 will cost the individual 14.8¢ per hour reflected as lower earning power in 1969.That is, the value of the individual's stock of human capital will be 14.8¢ lower from 1969 onward than it would have been had he not missed the year. During the year, the individual earns his observed pecuniary salary plus the value of this human capital. The present value of the human capital component of wages is easily calculated. Since earning power is increased by 14.8¢ per hour by a year's investment, and since this increase is enjoyed on every hour worked (or spent investing) until retirement, the present

[8] By hypothesizing that the change in hours worked enters the wage change equation we introduce simultaneity bias. The wage growth equation writes wage growth as a function of the change in hours. The supply of labor, however, would relate hours worked to wages and thus change in hours worked to the change in wages. Because of this, *OLS* yields biased estimates of the effects. The reader may be somewhat reassured to learn that when the *CH* term was deleted from the equation, none of the remaining coefficients were significantly altered.

[9] It might be argued that this coefficient is a reflection of differences in ability rather than in human capital stock levels. An attempt was made to standardize for the component of ability not held constant by inclusion of schooling, previous experience, and age. The *NLS* has information on virtually every individual in the sample which gives their test scores on an examination which was designed to test their "knowledge of the world of work." If this can be considered a proxy for ability, inclusion of this variable into equation (12) should affect the *TN* coefficient if the ability argument were correct. Estimation of this equation yielded results which were virtually identical in all respects to equation (13). In particular, the coefficient on the ability proxy was insignificant.

value of the human capital component of earnings is

$$(17)\quad PV = (2000)(14.8)\int_{0}^{T-1969} e^{-rt}dt$$

where $T$ is the date of retirement and the individual works 2000 hours per year.[10] If $r=10$ percent, $(T-1969)=45$, then the human capital earned during the year previous to 1969 is worth \$2927.11. An individual with observed earnings in 1968 of, say, \$5,000 would in reality be receiving \$7927.11 since he earns \$2927.11 worth of human capital.[11]

When computing the cost of a given amount of unemployment, one should add the value of foregone human capital to observed foregone earnings. The foregone earnings associated with being unemployed during 1968–69 can be estimated for this individual. If

$$(18)\quad \begin{aligned} W_{69} &= W_{66}\exp\{.42927\} \\ &= W_{66}\exp\{3\gamma\} \end{aligned}$$

then

$$(19)\quad \gamma = .143090$$

so that

$$(20)\quad \begin{aligned} W_{68} &= W_{66}\exp\{2(.143090)\} \\ &= \$2.67 \text{ per hour} \end{aligned}$$

Foregone earnings associated with missing 1968–69 amount to 2000 (\$2.67) or \$5340. Total foregone earnings are then \$5340+\$2927=\$8267 rather than the observed \$5340. The unobserved human capital component of earnings therefore is over one-half the size of observed earnings, or about one-third of total income. This is a very significant part of young men's salaries.

These results are important in that they reveal the existence of an experience effect. Work experience (or its complement) is related to wage growth independent of aging. Individuals who spend more time at work over the three-year period seem to experience more rapid wage growth which, it may be inferred, reflects on-the-job training. One may compare the effects of experience with that of aging per se. From (11) the upper bound of the aging effect was shown to be obtainable. After altering (11) to include the additional variables introduced in (12), we find that at the mean age of 19.334 years, the effect of aging on wage growth is at most

$$(21)\quad \begin{aligned} \gamma' &\leq (.27726)/3 \\ &\leq .09242 \end{aligned}$$

for a white unmarried nonunion worker. (All variables other than the dummies and $TN$ and $S_{69}-S_{66}$ assume mean values.) Thus, at age 19 the maximum effect of aging on wage growth is about twice that of experience (.09242/.04784=1.93).

One may obtain an approximation of $(ln\, A)/3$, which is the difference between the upper bound and true value of $\gamma'$, by the following procedure. In Table 1, regressions 1 and 2, wage level equations are estimated for 1966 and 1969. Since $A$ is a cohort effect which is not captured by variables included in (12), define

$$(22)\quad A = \frac{\hat{W}_{69}}{\hat{W}_{66}}$$

where $\hat{W}_{66}$ is the predicted value of wages allowing all right-hand variables in regression 1 to assume their mean values

[10] If foregone human capital affects nonmarket productivity as well as market productivity, this present value calculation will tend to understate the loss associated with unemployment. It is not likely that this understatement will be significant, however, since on-the-job training tends to be market specific in the type of human capital it provides.

[11] The individual might attempt to "catch up" with his uninterrupted age-earnings profile. However, if Ben-Porath's assumption of neutrality were correct, there would be no reason to engage in any type of catch-up behavior. The marginal cost of human capital would be independent of whether 1968–1969 were worked or not. As long as the date of retirement is not significantly altered, the marginal return to a unit of human capital would be left unchanged as well so that there would be no reason to alter the optimal investment plan.

TABLE 1—SUPPLEMENTARY REGRESSIONS

| Variable | Regression 1 Dependent Variable= $lnW_{66}$ | Variable | Regression 2 Dependent Variable= $lnW_{69}$ |
|---|---|---|---|

(except for dummies) and where $\hat{W}_{69}$ is obtained by plugging the 1966 means into the 1969 equation. This estimates what the typical young man in 1966 would earn if he were transplanted into 1969 and experienced the corresponding vintage effects. This procedure yielded an $\hat{A}=1.04$ so that $(ln\ A)/3$ equals .013. Thus, the upper bound of the aging effect does not differ substantially from our estimate of the true value of $\gamma'$.

Part of the aging effect may be attributed to a measurement bias. Since older individuals are less likely to invest in on-the-job training than are their younger counterparts, the observed wage understates the true wage (which includes compensation in the form of human capital) by a greater amount for younger individuals than it does for older ones. If so, a portion of the observed returns to aging would be illusory, resulting from this systematic bias in observed wages.

The last few paragraphs should not be taken to imply that experience is unimportant. It is clear that aging is important and understandably so for individuals in the 14–24 year-old age group. However, aging is parametric whereas experience is not. Experience has been shown to be important both in an absolute sense and relative to current wages. The fact that the effect of aging is so pronounced for the group in question is an interesting and useful result; it does not, however, negate the importance of the experience effect.

Age (not aging) enters negatively and significantly. Since the date of retirement is so far in the future, it is unreasonable to infer that the age coefficient reflects the difference in marginal returns to investment in human capital across individuals. Two explanations seem more plausible. First, the age component may reflect the influence of nonmarket time accruing previous to 1966. That is,

$$(23)\qquad Age \approx S_{66} + E_{66} + R_{66} + 6$$

where $R_{66}$ is defined as nonmarket time before 1966. The age coefficient is essen-

tially the effect of not attending school or working previous to 1966 on wage growth. However, its effect is an indirect one since most of the influence of $R_{66}$ should be captured by the initial wage $W_{66}$. The effect of $R_{66}$, therefore, relates to a quality component not held constant by the included variables. That is, a 24 year old who has the same amount of experience and schooling as an 18 year old (and thus has a higher value of $R$) obviously uses his time differently. If past work history is correlated with future labor force behavior, the older individual has a lower probability of being employed throughout the full year than does the younger one. The age coefficient then picks up the desire to spend a smaller proportion of each working year on the job and the consequent reduced investment in on-the-job training.

Alternatively, one may interpret the negative coefficient as an interaction term which reduces the effect of *aging* on wage growth as the individual ages. That is, the rate of wage growth which cannot be attributed to work experience or formal schooling ($\gamma'$) declines with age as shown above (although not necessarily relative to that which can be explained by experience and schooling). This is consistent with casual notions of physical and emotional maturation. The difference between a 15 and 16 year old may be considerably more pronounced than that between a 23 and 24 year old. The following calculation reveals the magnitude of this difference. At age 16, the upper bound of ($\gamma'$) is equal to .11760, (with all other variables excepting dummies assuming their mean values). By age 24, the upper bound of ($\gamma'$) is reduced to .05716 and by 26, $\partial W_{69}/\partial(E_{69}-E_{66}) > \partial W_{69}/\partial\ Aging\ (=\gamma')$. The importance of job experience relative to aging grows as the individual matures and overtakes the upper bound of the aging effect by age 25. Thus, the effect of *aging* on wage growth depends on age, but they are not analytically the same. The age coefficient should not be interpreted as the aging effect.

In the same vein, one can distinguish the effect of experience on wage growth from that of previous experience on wage growth. The effect of the former as reflected by the $TN$ coefficient represents the amount by which wages increase with additional work experience in the current period. The latter relates to the rate at which individuals will acquire on-the-job training in the current period for each unit of current experience. It was anticipated that individuals with greater amounts of previous experience will invest in less on-the-job training in the current period since it (generally) pays to invest in larger amounts of training during the initial years of work. Thus, two individuals who differ only in their amounts of previous experience are expected to have different investment rates simply because previous investment is likely to be a substitute for current investment. Since

$$\frac{\partial W_{69}}{\partial E_{66}} = \left.\frac{\partial W_{69}}{\partial E_{66}}\right|_{Age} + \frac{\partial W_{69}}{\partial\ Age}\cdot\frac{\partial\ Age}{\partial E_{66}} \tag{24}$$

and since $\partial Age/\partial E_{66}$ may be taken to be generally equal to one (see equation (23)),

$$\frac{\partial W_{69}}{\partial E_{66}} = [W_{66}\exp\{\eta_0 + \ldots + \eta_{10}U\}] \cdot(\eta_2+\eta_5) < 0 \tag{25}$$

Thus, the effect of previous experience is as anticipated.

This also sheds light on the question of neutrality. If the rental price of human capital were constant over all units of human capital once age is given,[12] and if the marginal cost of human capital were not a function of previous investment (i.e., Ben-Porath's neutrality assumption),

[12] This amounts to assuming that retirement is a function of age alone and is independent of the amount of time spent working over the lifetime. In light of the work done by W. G. Bowen and T. A. Finegan which shows that labor force participation tends to vary positively with the level of education for older workers, it is unlikely that the assumption is a valid one.

the effect of previous experience on the (absolute) change in wages would be zero. More simply, if neither the marginal cost nor marginal return to investment in human capital varies with previous experience, there is no reason for the experienced worker to behave any differently than the unexperienced one. The fact that experience does have a negative effect on $(ln\ W_{69} - ln\ W_{66})$ seems to imply that the neutrality assumption is invalid or that retirement (or more generally, time in the labor force) is a function of previous experience. This latter effect would be unlikely to account for much of the observed negative relationship since the retirement date for these individuals is expected to occur about forty years hence.[13]

There is an alternative explanation. Since the specification in (13) does not permit us to identify the effect of previous experience on on-the-job training from that of aging, it may be that the $E_{66}$ variable is a term which reflects the interaction between previous experience and current aging. If previous experience were in some sense substitutable for aging in the production of human capital, the negative relationship would be consistent.

The coefficient on incremental schooling is positive and significant. As has been argued elsewhere,[14] this should not be interpreted as a rate of return to education. It is, however, interesting to ask what the net effect is of dropping out of the labor force to attend school. The results in (13) permit this calculation. Since

$$(26) \quad TN = .75(S_{69} - S_{66}) + TO$$

where $TO$ is nonschool time not worked and the school year is assumed to be .75 years long. We may substitute so that

$$(27) \quad \left[\frac{\partial(ln\ W_{69} - ln\ W_{66})}{\partial(S_{69} - S_{66})}\right]^* = \frac{\partial(ln\ W_{69} - ln\ W_{66})}{\partial(S_{69} - S_{66})} + \frac{\partial(ln\ W_{69} - ln\ W_{66})}{\partial TN} \cdot \frac{\partial TN}{\partial(S_{69} - S_{66})}$$

where the expression on the left-hand side is the gross partial associated with an increase in schooling that occurs by dropping out of the labor force. Then

$$(28) \quad \left[\frac{(ln\ W_{69} - ln\ W_{66})}{(S_{69} - S_{66})}\right]^* = .04106 - (.04784)(.75) = \underset{(.0158)}{.00518}$$

where (.0158) is the standard error computed from the variance-covariance matrix.

Attending school is then slightly more productive in terms of wage growth than is on-the-job training. This is as it should be since the costs associated with the former are larger than those associated with the latter. In fact, the difference between the two may appear to be too small. This can be explained by the fact that the estimates relate to the average rather than marginal effects over the three-year period. If the ratio of average to marginal effects of schooling are less than the ratio of average to marginal effects of on-the-job training, then the estimate of the schooling effect overstates the marginal schooling effect by less than the estimate of the on-the-job training effect overstates the marginal on-the-job training effect. Under circumstances where the effect of schooling (on-the-job training) on the difference in the *log* of wages was a negative, convex function of previous schooling (on-the-job training), this would be the expected result since individuals in this group are at relatively high levels of formal schooling, but at low levels of on-the-job training.

Changes in the initial level of schooling have very small (and insignificant) effects on wage growth. To the extent that level

[13] See Brown for a more detailed discussion of the neutrality question.

[14] See Rosen (1973).

and increment are correlated, omission of the increment variable would lead to biases and to the incorrect conclusion that the rate of wage growth depended upon initial levels of schooling.[15]

As anticipated, an increase in the number of hours per week worked has a positive effect on wage growth. The partial effect is

$$(29)\quad \frac{\partial W_{69}}{\partial CH} = W_{66} \exp\{\eta_0 + \ldots + \eta_{10}U\}\ \eta_6 = .8521$$

so that increasing average weekly hours by 20 (i.e., moving from the typical part-time to the typical full-time job) increases wages in 1969 by about 17¢ per hour.

One rather interesting result is that, *ceteris paribus*, white workers experienced less rapid wage growth over this period than did black workers. This probably reflects the fact that 1966–69 witnessed rather significant changes in the institutional structure, one of the results of which was a narrowing of the black-white differential.[16] The signalling hypothesis provides another explanation.[17] It may be the case that blacks with equal schooling and job experience as whites may, by self-selection, be higher quality workers than are the corresponding whites. Employers who fail to discriminate in their reading of signals at the time of hiring will tend to pay the higher quality nonwhites the same wage as the lower quality white workers. Over time, however, employers learn about the nonwhite's relative advantages and the nonwhite worker's wages increase accordingly. (This would not be expected to persist over time, though, since employers who discriminated in favor of nonwhites with equal schooling and experience at the time of hiring would drive their less efficient competitors out of business.)

An equally bizarre result is that married workers experience less rapid wage growth than do unmarried ones. It is also the case, however, that their initial wage levels are higher (see Table 1, regressions 1 and 2). Since for this group (young men), holding age, schooling, and past experience constant, married men are in some sense farther along the life cycle path than are unmarried ones, the marriage dummy may reflect previous investment in human capital not captured by the included human capital stock variables. This would account for the higher initial wage level as well as for the lower wage growth since previous investment in human capital may result in less current investment as the outcome of nonneutrality.

Less surprising, perhaps, is the finding that individuals who belonged to a union in 1969 experienced more rapid wage growth. Part of this probably reflects higher wage levels for union workers since some of those who were union members in 1969 were nonmembers in 1966.[18]

Finally, the coefficient on incremental military experience is positive and of roughly the same magnitude as incremental schooling. The standard error here is large, probably because only 52 out of 1,996 individuals had a nonzero value for this variable. To the extent that the estimate is taken to be close to the true value, it appears as though one year in the military contributes as much to the stock of human capital as one year of formal schooling.

## III. Conclusion

This paper has estimated the human capital component of earnings and found it to be about one-third of total compensation for young workers. Although this im-

[15] David Wise examines the effect of schooling levels on wage growth. His analysis deals, however, with a very different sample and the findings are not easily compared.

[16] See Finis Welch for additional evidence on this point.

[17] See Kenneth Arrow and Michael Spence for a more complete discussion of the signalling hypothesis.

[18] Unfortunately, no information on union status in 1966 was available.

plies that human capital obtained through work experience is substantial at young ages, "aging" per se also accounts for a significant proportion of wage growth. This aging effect becomes relatively less important as the individual ages.

# Bond Share Yield Spreads Under Uncertain Inflation

By MYRON J. GORDON AND PAUL J. HALPERN*

It is generally accepted that individuals are concerned with the real and not the nominal values of income and wealth. Accordingly, Irving Fisher argued that the nominal rate of interest should be equal to the real rate plus the market's expected inflation rate; the real rate of interest is a function of production possibilities for the economy and individual's degree of time preference; in equilibrium, the real rate of interest is equal to the marginal productivity of capital.

However, Fisher's work did not recognize uncertainty and aversion to risk in the evaluation of investment opportunities. The work on capital asset pricing theory by William Sharpe, John Lintner, Jan Mossin (1966), and others explains the structure of asset yields and portfolio allocation decisions under uncertainty and aversion to risk, but their development of the theory has been based on nominal values of the variables. The implicit assumption is that the price level is stable or that the inflation rate is known with certainty. Either assumption is untenable in the current economic environment.

During the last few years a number of papers have appeared on the consequences of uncertain inflation for capital asset pricing theory. Marshall Sarnat has shown that linked bonds improve the efficiency of capital markets. Nahum Biger has examined the consequences for optimal portfolio selection. Richard Roll, and Andrew Chen and James Boness have extended the capital asset pricing model to recognize uncertain inflation, with a real riskless asset in one case and without it in the other.

This paper examines the consequences of inflation for the allocation of wealth between a monetary and a real asset and for the relation between the yields, both nominal and real, on the two types of assets. Section I defines the variables included in the analysis and states precisely the simplifying assumptions under which the problem is examined. Section II demonstrates that the allocation of an investor's wealth between a one-period government bond and a nonmonetary risky asset, for example, a share of stock, is a function of the uncertainty as to the inflation rate. Specifically, with the expected values of the real returns on the two assets given, the fraction of wealth invested in the bond decreases as the uncertainty of the inflation rate increases. Section III investigates what happens to the relation between the nominal and real yields on the two types of assets as the inflation rate uncertainty rises. We find that investors can only be persuaded to hold a given stock of monetary and nonmonetary (real) assets by a rise in the real return on the monetary asset in relation to the real return on the nonmonetary asset. In other words, the real return spread between the two assets decreases as the uncertainty as to the inflation rate rises.

Section IV examines the historical data on inflation over time and in different countries to obtain information on uncertainty as to the rate of inflation. These data are consistent with the hypothesis that uncertainty as to the inflation rate is an increasing function of the expected rate

* Professor and associate professor of finance, respectively, Faculty of Management Studies, University of Toronto.

of inflation. Hence, the mean realized inflation rate may be used as an index of the uncertainty as to the inflation rate. Finally, Section V examines some of the implications of the analysis.

Before proceeding to the analysis it may be noted that an interesting feature of it is the application of capital asset pricing theory to the macro problem of the structure of asset yields. Further work along the same lines may have considerable value for the analysis of macro problems of investment, income, and asset yields.

## I. Definitions

In the analysis we will assume that there are only two assets available to investors, a one-period government bond denominated in nominal terms with no default risk and a stock issued by a company.[1] In addition, we assume that the company has no debt in its capital structure, and its product pricing policies are flexible.

In the Fisher tradition we take the nominal return on a bond as the real rate of interest on the bond plus the rate of inflation, i.e., the percentage rate of change in the price level.

$$r_{Nb} = r_b + \Delta \tag{1}$$

where $\Delta \equiv$ the rate of change in the price level; $\Delta$ is a random variable with expected value $E(\Delta)$ and variance $\sigma^2(\Delta)$.

$r_{Nb} \equiv$ the nominal rate of interest on a bond.

$r_b \equiv$ the real rate of interest on a bond; $r_b$ is a random variable with expected value $E(r_b)$ and variance $\sigma^2(r_b)$.

Since the bond is a one-period bond denominated in nominal terms, its nominal rate of interest is not a random variable.

An analogous distinction between real and nominal yields on stocks can be drawn. The nominal yield on the stock, $r_{Ns}$, is equal to the real yield $r_s$ plus the rate of inflation. The expected value of the nominal return is

$$E(r_{Ns}) = E(r_s) + E(\Delta) \tag{2}$$

The variance of the nominal yield on stocks is

$$\sigma^2(r_{Ns}) = E\{[r_{Ns} - E(r_{Ns})]\}^2$$

But the realized nominal return on a stock is equal to the realized real return plus the actual rate of inflation. Therefore

$$\begin{aligned}\sigma^2(r_{Ns}) &= E[\{r_s + \Delta - E(r_s) - E(\Delta)\}]^2 \\ &= \sigma^2(r_s) + \sigma^2(\Delta) + 2\, cov\, (r_s, \Delta)\end{aligned}$$

where $\sigma^2(r_s)$ is the variance of the real rate of return on the stock.

We will assume here that $cov\, (r_s, \Delta) = 0$, which makes the stock a perfect inflation hedge.[2] Since we have assumed that the company has no debt, wealth transfers due to unanticipated inflation will not occur. The assumption further requires that the real return on the stock depends only on real risk factors which are independent of inflation. The consequence is that nominal earnings and stock price will vary with inflation, and

$$\sigma^2(r_{Ns}) = \sigma^2(r_s) + \sigma^2(\Delta) \tag{3}$$

One further concept is introduced here that will be used later. The assumption that $cov\, (r_s, \Delta) = 0$ logically implies that $cov\, (r_s, r_b) = 0$. Intuitively, variations in $r_b$ result only from variability in the inflation rate. However, fluctuations in $r_s$ are independent of the inflation rate. Therefore, $r_s$ is independent of $r_b$.

## II. Allocation of Wealth

Our purpose in this section is to establish the impact of inflation uncertainty on

[1] The stock can be thought of as a security representative of the market portfolio and a proxy for real or nonmonetary assets.

[2] This covariance is unlikely to be zero in fact. Withdrawing the assumption is an area for further research, but the qualitative nature of the conclusions reached is likely to hold except when the nominal return on the share is independent of the inflation rate.

an investor's wealth allocation between the stock and the bond. The investor is assumed to maximize expected utility and the form of his utility function is

$$u_i(r) = 1 - e^{-2\alpha_i r} \tag{4}$$

where $r$ is the real rate of return on the investor's wealth, $\alpha_i$ reflects the degree of risk aversion for investor $i$, and $\alpha_i > 0$. Bertram Schoner has shown that expected utility is given by the expression

$$E[u_i(r)] = 1 - e^{-2\alpha_i [E(r) - \alpha_i \sigma^2(r)]} \tag{5}$$

Therefore, maximizing expected utility is equivalent to maximizing

$$H(r) = E(r) - \alpha_i \sigma^2(r) \tag{6}$$

The choice of utility function was dictated by the following considerations. To keep the analysis mathematically tractable, it is necessary that expected utility be a function of the first two moments of the probability distribution of terminal wealth. To be realistic, the utility function should exhibit constant relative risk aversion. That is, the allocation of wealth between the bond and the share should be independent of the level of initial wealth. This utility function satisfies both conditions since $r = ((Y - W)/W)$, where $Y$ is random terminal wealth and $W$ is fixed initial wealth.[3]

Let $\lambda$ be the proportion of wealth invested in the stock and $(1-\lambda)$ be the proportion invested in the bond. The mean and covariance of the real return on the investor's wealth are

$$E(r_p) = \lambda E(r_s) + (1 - \lambda) E(r_b) \tag{7}$$

$$\sigma^2(r_p) = \lambda^2 \sigma^2(r_s) + (1 - \lambda)^2 \sigma^2(r_b) + 2\lambda(1 - \lambda)\, cov\,(r_s, r_b) \tag{8}$$

However, $cov\,(r_s, r_b)$, the covariance between the real returns on the bond and the share, is equal to zero.

Hence, to find the optimal proportions of wealth invested in each asset, we maximize expected utility or $H(r)$.

$$\max H(r) = \lambda E(r_s) + (1 - \lambda) E(r_b) - \alpha_i [\lambda^2 \sigma^2(r_s) + (1 - \lambda)^2 \sigma^2(r_b)] \tag{9}$$

The derivative of $H(r)$ with respect to $\lambda$ is

$$\frac{\partial H(r)}{\partial \lambda} = E(r_s) - E(r_b) - 2\alpha_i \lambda \sigma^2(r_s) + 2\alpha_i (1 - \lambda) \sigma^2(r_b) = 0 \tag{10}$$

and the optimal proportion of wealth invested in stock is

$$\lambda^* = \frac{E(r_s) - E(r_b) + 2\alpha_i \sigma^2(r_b)}{2\alpha_i [\sigma^2(r_s) + \sigma^2(r_b)]} \tag{11}$$

We are interested in investigating the impact of inflation risk on the allocation of wealth between stocks and bonds. The risk of inflation can be measured by the variance of the real rate of return on bonds. In the spirit of a partial equilibrium analysis, we assume that $E(r_b)$, $E(r_s)$, and $\sigma^2(r_s)$ are fixed and vary the uncertainty in

[3] Our use of equation (4) for a utility function has been questioned on the grounds that it exhibited constant absolute risk aversion and that the use of rate of return as the argument of the function is wrong. Precedents for these objections can be found in the literature. See Michael Jensen (p. 390) and Mossin (1973, pp. 39–40). However, we are at a loss to understand the grounds for these objections to equation (4). It can be written

$$u(Y) = 1 - e^{-\alpha((Y-W)/W)}$$

Taking the first and second derivatives of $u(Y)$ with respect to $Y$, we obtain for the Pratt measure of absolute risk aversion

$$Q = -\frac{u''(Y)}{u'(Y)} = \alpha/W$$

The Pratt measure of relative risk aversion is $\alpha$, which is independent of wealth. That is, the allocation of wealth between a risky and risk-free asset is independent of the investor's initial wealth. Initial and not terminal wealth is the relevant variable for the decision problem we are modeling and for which the Pratt measure is typically used. Finally it should be noted that the Pratt measure is a shortcut method for determining how an investor's investment in the risky asset varies with his wealth. Carrying out the numerical analysis with our utility function confirms the above description of it.

the inflation rate.[4] Since $\sigma^2(\Delta)=\sigma^2(r_b)$, we investigate whether $\partial\lambda^*/\partial\sigma^2(r_b)\gtreqless 0$ for small changes, where

$$(12)\quad \partial\lambda^*/\partial\sigma^2(r_b) = \frac{2\alpha_i\sigma^2(r_s) - E(r_s) + E(r_b)}{2\alpha_i[\sigma^2(r_s) + \sigma^2(r_b)]^2}$$

The impact on $\lambda^*$ can be seen most clearly if we consider different initial values of $\lambda^*$.

CASE 1: The investor is invested entirely in stock, i.e., $\lambda^*=1$. Then it is obvious that $\partial\lambda^*/\partial\sigma^2(r_b)=0$; the investor will not alter the proportion of wealth invested in the stock as inflation risk changes.

CASE 2: The investor holds both stocks and bonds in his portfolio, i.e., $\lambda^*<1$. Substituting this inequality into (11) we obtain $2\alpha_i\sigma^2(r_s)>E(r_s)-E(r_b)$. Substituting this inequality into (11) and noting that the denominator in (12) is positive, $\partial\lambda^*/\partial\sigma^2(r_b)>0$. Therefore, as inflation risk increases, the investor will increase the proportion of wealth invested in the stock.

CASE 3: The investor has shorted bonds to invest in the stock, i.e., $\lambda^*>1$. Using the same type of algebraic manipulations as Cases 1 and 2, it can be shown that $\partial\lambda^*/\partial\sigma^2(r_b)<0$. The investor will reduce the proportion of wealth invested in stocks by selling some stock and repaying the bonds he has created. As bonds become riskier, the debt he has undertaken becomes riskier and he reduces his involvement.

Therefore, in Cases 2 and 3, if an investor is in bonds as either a borrower or a lender, an increase in the variability of the inflation rate makes it attractive to him to borrow less if a borrower, or lend less if a lender.

### III. Impact on Yields of Both Stocks and Bonds

In the preceding analysis we assumed $E(r_b)$ and $E(r_s)$ were unchanged as $\sigma^2(r_b)$ increased. However, there will be a change in the yields on debt and equity as individual investors restructure their portfolios in response to a change in the variability of the inflation rate.

Before presenting a more rigorous analysis of the impact on real yields with a change in $\sigma^2(r_b)$, an intuitive explanation may be helpful. If individuals are unable to issue debt and the only debt outstanding is issued by the government, then $\lambda^*<1$ must hold and $\partial\lambda^*/\partial\sigma^2(r_b)>0$. Therefore, individual investors will move out of debt into stock. However, to persuade individuals to hold the exogenously given, unchanged quantity of debt and shares, the real yields on debt must rise and the real yield on the shares must fall.

The more realistic assumption that both individuals and government issue debt does not change the conclusion, since the net amount of debt in aggregate is the government debt. As $\sigma^2(r_b)$ increases, the real demand for bonds falls for investors with values of $\lambda^*<1$, and, for investors with $\lambda^*>1$, the real supply of bonds falls. The shift in the demand schedule will be larger in absolute amount than the shift in the supply schedule. Thus, the real rate on bonds will increase.

To investigate this more analytically, let $\bar{\lambda}$ be the allocation of market wealth which is a function of the weighted average of the individual investor risk-aversion parameters $\alpha_i$. Thus, from (11),

$$(13)\qquad \bar{\lambda} = \frac{E(r_s) - E(r_b) + 2\bar{\alpha}\sigma^2(r_b)}{2\bar{\alpha}[\sigma^2(r_s) + \sigma^2(r_b)]}$$

But $\bar{\lambda}$ is equal to the market value of the stock divided by the market value of stock plus debt since all assets must be held in equilibrium. The prices of the stock and the bond can be written $D/E(r_s)$ and $M/[1+E(r_b)]$, where $D$ is the expected value of the real dividend per share and $M$ is the expected value of the coupon plus principal on the bond. For simplicity, the

[4] The constraint that $E(r_b)$ remains fixed will be removed in Section III.

share's real dividend is not expected to grow, and the bond is assumed to be a one-period note. Thus,

$$(14) \quad \bar{\lambda} = \frac{n_s D/E(r_s)}{n_s D/E(r_s) + n_b M/[1 + E(r_b)]}$$

where $n_b$ and $n_s$ are the number of bonds and the number of shares outstanding.

If we assume further that the real coupon on the bond is equal to the real rate of interest, the bond is selling at par which is equal to unity. Therefore, (14) can be rewritten

$$(15) \qquad \bar{\lambda} = \frac{n_s D/E(r_s)}{n_s D/E(r_s) + n_b}$$

On the macro level, $n_s$, $n_b$, $D$, and $\bar{\lambda}$ are given. Equating the right-hand side of both equations (13) and (15) and solving we obtain

$$(16) \quad E(r_b) = E(r_s) + 2\bar{\alpha}\sigma^2(r_b) - 2\bar{\alpha}[\sigma^2(r_b) + \sigma^2(r_s)] \frac{n_s D}{n_s D + n_b E(r_s)}$$

To find the impact on yields as inflation risk increases, the derivative of equation (16) with respect to $\sigma^2(r_b)$ is taken.

$$(17) \quad \frac{\partial E(r_b)}{\partial \sigma^2(r_b)} = \frac{\partial E(r_s)}{\partial \sigma^2(r_b)} \left[1 + 2\bar{\alpha} \frac{n_s D}{[n_s D + n_b E(r_s)]^2} n_b[\sigma^2(r_b) + \sigma^2(r_s)]\right] + 2\bar{\alpha}\left[1 - \frac{n_s D}{n_s D + n_b E(r_s)}\right]$$

The quantities in the first and second set of brackets on the right-hand side of equation (17) are both positive.

To find the impact on the real return on bonds as inflation risk changes, *ceteris paribus*, set $\partial E(r_s)/\partial \sigma^2(r_b) = 0$. This results in $\partial E(r_b)/\partial \sigma^2(r_b) > 0$. Therefore, an increase in the uncertainty concerning the inflation rate will *increase* the real rate of return on bonds.

To determine the impact of inflation risk on the real return on stock, set $\partial E(r_b)/\partial \sigma^2(r_b) = 0$; this results in $\partial E(r_s)/\partial \sigma^2(r_b) < 0$.

Therefore, an increase in the uncertainty of the inflation rate will result in a reduction of the expected risk premium measured in terms of real rates of return.[5] By adding the expected rates of inflation to the real rates of return on stock and debt we can obtain the nominal yields.[6]

## IV. Relation Between Mean and Variance of Inflation Rate

This paper has demonstrated that the real rate of return on bonds is an increasing function of the variability of the inflation rate, and not the inflation rate itself. It is immaterial to the risk of a bondholder if inflation is 5 or 50 percent as long as the actual rate of inflation is equal to the expected rate of inflation. However, it is possible that the expected real yield on bonds is related to the expected inflation rate if there is a positive relationship between the expected inflation rate and the variability of inflation.

To investigate this possibility, values of the Consumer Price Index (*CPI*) were obtained for a sample of 33 countries for the period 1952 to 1972 inclusive.[7] The source for the data was *International Financial Statistics*. The countries were chosen so as

[5] Instead of assuming a one-period bond we could have analyzed the impact of changes in the inflation rate by using a consol. Although we did not perform the analysis it is clear that the impact would be in the same direction, but probably larger in magnitude because the impact of unanticipated inflation will be larger on a consol than on a one-period bond since the price of a consol is very sensitive to changes in the interest rate.

[6] It may be thought there is a logical contradiction in the statements that the nominal return on the bond is risk free and its nominal interest rate changes over time. This contradiction may be reconciled by assuming that all trading takes place only on the first day of each holding period, e.g., three months. Alternatively, with continuous trading the three-month return on a three-month bond is always certain, while the intra three-month return is uncertain. Investors nonetheless continuously look at the three-month return and treat the bond as risk free.

[7] A list of the countries used in the sample is presented in the Appendix.

to obtain a full spectrum of inflation rates. Annual percentage changes in the *CPI* were calculated for each year as well as the mean and standard deviation of the percentage change in the *CPI* for each country. The correlation between the mean percentage price change and the standard deviation over the 33 countries was .9081, and significant at the .001 level. The average annual realized rate of inflation for all countries over the sample period was .0848 and the average standard deviation was .0707.

Therefore, the differential between the expected real returns on bonds and stocks will narrow with increases in the expected rate of inflation. It is possible that in countries with hyperinflation, the expected real rate of return on bonds may exceed that on stocks. Since the nominal yields are obtained by adding the expected rate of inflation, similar conclusions on nominal yield differentials can be made.

## V. Implications

Two related conclusions follow from the previous analysis. One is that as uncertainty as to the inflation rate increases, investors move towards an all nonmonetary asset portfolio. The other conclusion is that insofar as the relative real quantities of bonds and nonmonetary assets fail to adjust to investor preferences, the spread between the yields on bonds and shares will narrow.

However, the analysis was carried out under a number of simplifying assumptions of which the following may be the most important. It was assumed that the uncertainty of the inflation rate is independent of its expected value. The previous section, however, established that the variability of inflation increases with its average rate. Hence, the portfolio adjustments investors desire as uncertainty increases are brought about more or less with no explicit portfolio revision by the declining real value of monetary wealth as the average inflation rate rises.

The other critical assumption was that the real return on nonmonetary assets is independent of the inflation rate. If the nominal returns on shares as well as bonds are independent of the inflation rate, there will be no desired movement between the two types of assets and no change in their relative yields. Under the more reasonable assumption that nonmonetary assets are at least a partial inflation hedge, the conclusions reached still hold, but with less force.

We may conclude with the question, what has happened to the spread between bond and share yields? Answering the question is made difficult by the problems of measuring share yields, but these problems are relatively modest for public utility shares. In the early 1960's, Aaa rated bond yields were about 4.5 percent, and electric utility share yields, measured by dividend yield plus expected dividend growth were about 8.5 percent; see Gordon (p. 99). Both authors have testified in recent utility rate of return cases, and we estimate current share yields for strong public utilities as being in the range of 12–13 percent. With Aaa rated bond yields around 9 percent, the absolute as well as the relative spread between nominal bond and share yields has fallen over the last decade.

# The Two-Sector Open Economy and the Real Exchange Rate

By Michael Bruno*

This study arose from dissatisfaction with the multiplicity of models and separate theory compartments within which we usually teach and analyze the main aspects of trade, aggregate demand, capital inflow, and accumulation. It is proposed that in an open economy these can be tackled in one, rather simple, two-sector framework. It hopefully lends itself to a clearer exposition in some cases and possibly may also give new insights into some real phenomena. But first there are at least three mental hurdles to be overcome.

Traditional trade theory mainly assumed a world in which all goods (or the stylized "two goods") are in principle tradable and the main *relative* price involved is the international terms of trade. A third nontradable good sometimes appears as a relatively unimportant appendage to the standard two-tradable goods description. For most countries, however, international prices of imports and exports are given and a much more important relative price (or price vector) is the terms of trade between a composite foreign-exchange earning or foreign exchange using good and domestic nontradables. After all, the latter form over half of *GNP* even in the most open economies.

The importance of the tradable/nontradable distinction and the emphasis on the exchange rate as representing a real relative price have long been recognized in the development planning literature. But only in recent years have these aspects begun to play an important role in pure trade theory, particularly in the analysis of aggregate expenditure.[1] One elementary but essential difference between the two types of goods is that the market for nontradables must always balance *ex post*, that for tradables need not. The two-sector composition of excess demand is thus important for the understanding of the role of absorption and exchange-rate changes in short-run analysis of economic activity and inflation. This brings us to the next point.

Equilibrium in trade theory is usually identified with a balance on current account. There is extensive theoretical treatment of short-run deficits and surpluses, ways to correct imbalances, and the-once-and-for-all transfer problem, but there is much less systematic analysis of the prolonged (and often planned) *structural* imbalances that are a necessary by-product of substantial foreign borrowing. This can be viewed as an efficient way of relaxing

* Falk Institute and Hebrew University. The growth part of this paper is partly based on a more extensive unpublished M.I.T. discussion paper written in 1970. The static economy model (Section I) has been added since then. For financial support at the earlier stage I am indebted to the Ford Foundation (grants to M.I.T. and to the Israel Foundation Trustees) and to the Development Research Center of IBRD. I am greatly indebted to numerous colleagues for discussion and comments on earlier drafts; in particular I should mention Mordechai Fraenkel, T. N. Srinivasan, George Borts, and an anonymous referee.

[1] In a historical note on the survey by Anne Krueger, P. M. Oppenheimer traces the original introduction of nontraded goods to authors preceding I. F. Pearce's important contribution and going back to the late 1920's (Ohlin, Keynes). But I believe it fair to say that it never became central to the basic trade theory approach. Among the most recent studies with which the present one partly overlaps I should mention Rudiger Dornbusch, Eitan Berglas and Assaf Razin, and Elhanan Helpman.

period-by-period constraints on the market for tradables and replacing them by a single multiperiod foreign currency constraint.

The next point relates to the interface between pure growth theory and international trade. Once you allow trade, the consumption-investment goods distinction, so central to the closed-economy growth model, no longer retains its previous overriding importance. After all, exports or import substitutes are produced in order to earn (or save) badly needed foreign currency which can be put to many uses and can be borrowed and lent, so what does it matter whether one trades in nylon stockings or bulldozers?

Conforming to a common two-dimensional bias we start our analysis with a new, but essentially simple two-good descriptive model for an open economy. One good, measured in foreign exchange, is made to perform the multiple duty of juggling all tradable goods for consumption, physical accumulation, and storage of real financial debt. The other is a nontradable good that can be consumed or invested domestically. Given the production possibilities and consumption-demand patterns, the composition of output, price changes, and the balance of payments are essentially determined through absorption and exchange-rate policy decisions. Section I lays out the first, static-economy model and some of the policy implications for inflation and the deficit are analyzed. This is followed in Section II by an extension to a growth process, in which production possibilities and the real exchange rate are allowed to vary over time. Finally, the question of intertemporal optimality is considered (and a mathematical Appendix is given at the end). This has some practical implications for pricing and the rate of interest in public investment decisions.

## I. The Balance of Payments and Inflation in a Static Two-Sector Economy

Consider an open economy that uses and produces two basic types of goods: *nontradable goods* ($X_0$), which are only domestically produced, at the unit price $p_0$, and *tradable goods* ($X_1$), which can be purchased and sold abroad, at unit international price $P_1$ or domestic price $p_1$, where

$$p_1 = P_1 e \tag{1}$$

and $e$ is the nominal exchange rate.

The economy is here assumed to be small, and its international prices are given,[2] and also assumed to remain constant in relation to each other. This allows us to consider $X_1$ as a single composite good (rather than a vector of goods),[3] and $P_1$ as a given scalar which can be normalized so that $P_1=1$. In that case $X_1$ will also measure the potential supply of foreign exchange by the productive system.

The assumption of a single nontradable good (rather than a vector) can be defended on practical grounds if one remembers that nontradable goods (such as construction and services) are usually large users of domestic labor so that their prices are highly correlated with unit wage costs.[4] Both $X_i$ ($i=0$, 1) are measured in terms of value-added (total nominal $GDP=p_0X_0+p_1X_1$).[5] Any intermediate goods in the input-output sense are assumed to have been suitably netted out and added to $X_0$ and $X_1$, respectively, wherever appropriate.

At any moment of time (t) the supply is given of fixed reproducible factors (say nontradable and tradable assets $K_0$ and $K_1$, to be introduced in Section II) and of pri-

[2] This assumption can be relaxed.

[3] Transport costs are ignored here. Thus import substitutes and exports can formally be treated the same. Disaggregation is taken up in Section II.

[4] There may, of course, be some exceptions (e.g., electric power) but it still seems empirically reasonable for the bulk of the group consisting of services and construction, as long as productivity growth is fairly evenly spread within the group.

[5] $GNP$ can be derived by subtracting net interest payments on foreign debt (see below).

mary factors ($L$ being labor and/or land). Production possibilities in terms of $X_0$ and $X_1$ can be presented by the economy's transformation or production possibility curve ($PPC$) assumed to have a well-behaved convex shape:[6]

$$F(X_0, X_1; Z) = 0 \tag{2}$$

$Z$ is a shorthand notation for the vector of all factors that are fixed in the short run but may change in a long-run growth situation. The elements of the vector may include the momentarily given sectoral distribution of nonshiftable capital goods ($K_i$), the total supply of shiftable primary factors (such as $L$), and time (t), representing exogenous shifts such as "technical progress."[7] Underlying the aggregate $PPC$ (2) there must be short-run optimization of intersectoral allocation for at least one factor of production (say, $L$).[8]

The negative slope of the $PPC$, $\partial X_0/\partial X_1|_Z$ at any point measures the marginal rate of substitution in aggregate production between $X_0$ and $X_1$, which has the dimension of a real rate of exchange (domestic currency per unit of foreign currency) $q=p_1/p_0=e/p_0$.

Suppose now that the government can enforce a momentary rate $q$ in production at point $\tilde{M}$ on the $PPC$ (see $PP_1$ in Figure 1 and the line $BB_1$ touching the $PPC$ at point $\tilde{M}$). Total real $GDP(Y)$ can be read from the distance $OB$ in Figure 1 since we have (in units of the nontradable good):

$$Y = X_0 + qX_1 \tag{3}$$

(or $OB=OM+qOM_1$, since $q=MB/M\tilde{M}=OB/OB_1$).

For a given $Z$, $q$ uniquely determines the outputs $X_i$ ($i=0, 1$). For an increase in $q$, keeping $Z$ constant, we get the following price response (using subscripts for partial derivatives): $X_{0q}<0$, $X_{1q}>0$, $Y_q=X_1>0$ (we have $X_{0q}/X_{1q}=-q$).

Next consider household consumption demand. Denote total real household consumption by $C$ measured in nontradable units, and assume it is a portion $(1-s)$ of real $GDP$:

$$C = (1 - s)Y \tag{4}$$

$s$ is a measure of the private-sector contribution to the surplus, combining voluntary savings as well as government (direct) taxation. While government can be assumed to control overall $s$, the division of total $C$ between nontradables ($C_0$) and tradables ($C_1$) is based on consumer choice. Either we start from maximization of a utility function $U(C_0, C_1)$ subject to an expenditure budget constraint $C=C_0+qC_1$ or else by direct assumption, aggregate consumption functions can be written:

$$C_i = C_i(C, q) \qquad (i = 0, 1) \tag{5}$$

We have nonnegative marginal propensity to consume ($MPC$) (out of total consumption), i.e., $C_{ic}\geq 0$ ($i=0, 1$) if both goods are normal (and $C_{0c}+qC_{1c}=1$) and we also assume $C_{0q}\geq 0$, $C_{1q}\leq 0$ for the corresponding partial price responses.[9] Given $q$ (and thus $Y$) and given $s$ (and thus total $C$), the consumption basket ($C_0$, $C_1$) is determined uniquely. In Figure 1 this is represented at point $\tilde{N}(C_1, C_0)$ on the budget line $AA_1$, where $AB/OB=s$, $OA=C$. The projection of the consumption and production points on the respective axes give a measure of the residual commodity supplies (or surpluses) $S_i=X_i-C_i$, $NM$ and $N_1M_1$, respectively, for $i=0, 1$. For the response of these net supplies to changes in the policy parameters $s$ and $q$, we write:

$$S_i = X_i(q) - C_i[(1 - s)(X_0 + qX_1), q] \tag{6}$$

[6] Such a curve can be constructed empirically, e.g., from a detailed multisectoral linear programming system (see, for example, my 1967 paper). In that case $PPC$ will consist of a series of piecewise linear segments.

[7] It might also reflect shifts in world markets.

[8] The simplest model for which this can be derived is the standard two-sector production function model in which the sectoral $K$ are nonshiftable and $L$ is optimally allocated between the two sectors.

[9] Note that $C_0$ and $C_1$ need not be interpreted as final goods only, e.g., we can have total consumption ($C$) nontradable but using importables ($C_1$) in its production.

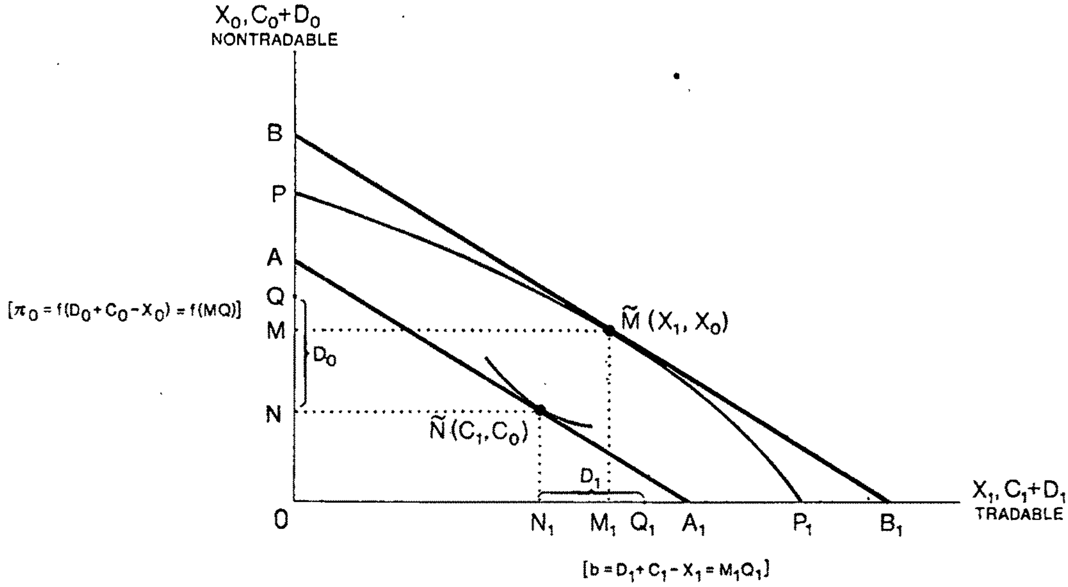

FIGURE 1

and obtain $S_{is}=C_{ic}Y>0$; i.e., there is a positive response to an increase in $s$ for both commodities. Likewise $S_{0q}=X_{0q}-C_{0q}-C_{0c}(1-s)X_1>0$; i.e., the net supply of nontradables unambiguously decreases with an increase in $q$. For tradables, the substitution and income effects work in the opposite directions, and the result is therefore more ambiguous. We get

$$S_{1q} = \frac{X_1}{q}\left(\epsilon_1 + \eta_1 \frac{C_1}{X_1} - \mu_1\right)$$

where $\epsilon_1 = qX_{1q}/X_1$ is the supply elasticity of tradables,

$\eta_1 = -qC_{1q}/C_1$ is the consumption demand elasticity for tradables,

$\mu_1 = (1-s)qC_{1c}$ is the marginal propensity to consume $C_1$ out of $Y$.

Thus $S_{1q}>0$ if and only if

$$\epsilon_1 + \eta_1\left(\frac{C_1}{X_1}\right) - \mu_1 > 0 \tag{7}$$

This formula is, of course, reminiscent of some balance-of-payments stability conditions discussed in the trade literature for the combined classical and Keynesian approaches.[10] However, the present model is somewhat differently structured, emphasizing the tradables/nontradables supply distinction and having no explicit domestic money variable.

To complete the first model in its market equilibrium aspects we now assume the existence of autonomous demands ($D_i$; $i=0, 1$) upon the net supplies ($S_i$) which may in principle consist of public consumption ($G_i$) and private or public investment ($I_i$). For the moment we only look at the short-run equilibrium aspects of inequality between $D_i$ and $S_i$, and leave the possible long-run growth effects of $I_i$ on changes in the $Z$ vector and the *PPC* to Section II.

The fundamental difference between tradable and nontradable goods markets lies in the way in which inflationary (or deflationary) gaps $D_i-S_i$ resolve themselves. As long as the government can control the exchange rate ($e$ or $q$) but foreign

[10] See, for example, Arnold Harberger and Murray Kemp.

borrowing (or investment) is allowed, the market for tradables clears automatically by having net imports equal to the difference $(D_1-S_1)$ if it is positive, or net exports, if it is negative. Denote the outstanding debt of the economy by $B$, its time change by $\dot{B}$, its debt servicing[11] by $R_B$ and the net balance by $b=\dot{B}-R_B$. We can write the adjustment process for tradables, which is also the negative of the balance of payments on current account, in the form:

$$b = \dot{B} - R_B = D_1 + C_1 - X_1 \tag{8}$$

If in Figure 1 the distance $N_1Q_1$ measures $D_1$ we have $b=D_1-S_1$ represented by the distance $M_1Q_1$.

In the market for nontradables no such automatic quantity adjustment can take place. We shall instead assume that any positive gap $D_0-S_0=D_0+C_0-X_0$ (marked by the distance $MQ$ on the $X_0$ axis, Figure 1) will result in pressure on the price level $p_0$, and we can assume a positive relationship between excess demand and the rate of inflation $\pi_0$:

$$\pi_0 = \frac{\dot{p}_0}{p_0} = f(D_0 + C_0 - X_0) \tag{9}$$

where $f'>0$ and $f(0)=0$.[12]

The comparison of the different adjustment processes in the two markets underscores the importance of the *composition* of autonomous demand changes, such as investment or public consumption, in terms of the derived demand in the tradable and nontradable goods markets. Thus suppose for a moment that $D_0=S_0$ so that $p_0$ remains constant, and that there is an increase in $D_1$. This will result in an equivalent increase in the balance-of-payments deficit $(\Delta b=\Delta D_1)$, leaving the real exchange rate $(q)$ and the market for nontradables unchanged. Thus the points $\tilde{N}$ and $\tilde{M}$ will remain stationary. On the other hand, if there is an increase in $D_0$, say, $\Delta D_0$ (from the balance point $D_0=S_0$, i.e., $MQ=0$), $p_0$ will start increasing. This in itself will decrease $q$ in the next period unless the government at the same time corrects the nominal rate $(e)$ so as to keep $q$ stationary (i.e., by making $\dot{e}/e=\pi_0$). A reduction in $q$ would now bring about an accompanying change in the equilibrium output $(\tilde{M})$ and consumption $(\tilde{N})$ levels and the balance-of-payments deficit will increase (assuming $S_{iq}>0$). Likewise $S_0$ will increase, thus making for a subsequent self-correcting reduction of pressure on $p_0$ in the market for nontradables. The system will eventually end up at a higher stationary $p_0$ (and lower $q$, by the amount $\Delta q=\Delta D_0/S_{0q}$). The cumulative indirect change in the deficit brought about by the initial change in $D_0$ will be given by the derivative

$$\frac{\Delta b}{\Delta D_0}\cdot\frac{1}{q} = 1 + \frac{(1-S)X_1 - C_1}{S_{0q}} \lesseqgtr 1$$

iff $(1-S)X_1 \gtrless C_1$, while $\Delta b/\Delta D_1=1$. It follows that under fixed exchange rates, if $(1-S_1)X_1>C_1$, the higher the share of nontradables, in total excess demand, the more of the inflationary pressure will show itself in $p_0$ increases (and $q$ decreases), and the less in an increase in the balance-of-payments deficit (see also Helpman). This type of analysis also explains why under a demand inflation and sticky exchange rates one would expect the domestic price of nontradables (for example, services, construction) to rise by more than that of tradables (such as agricultural products and manufac-

[11] If, as we shall assume below, the economy faces an upward sloping supply curve of foreign loans at marginal interest cost schedule $r(B)$ we have $R_B=\int_0^B r(x)dx$ (thus $dR_B/dB=r(B)$), (see Section II). Note that $R_B$ is part of $GDP$ and $GNP=GDP-R_B$. It does not affect private behavior directly if handled out of the government budget.

[12] We are here confining ourselves only to *ex ante* inflationary (or balance) situations for which $D_0-C_0\geq 0$. *Ex post*, of course, this market must balance. The model could be expanded to cover the case of Keynesian unemployment by assuming $f=0$ for the case of excess supply $(D_0-C_0<0)$, introducing a minimum wage constraint, and allowing for less than full employment of $L$.

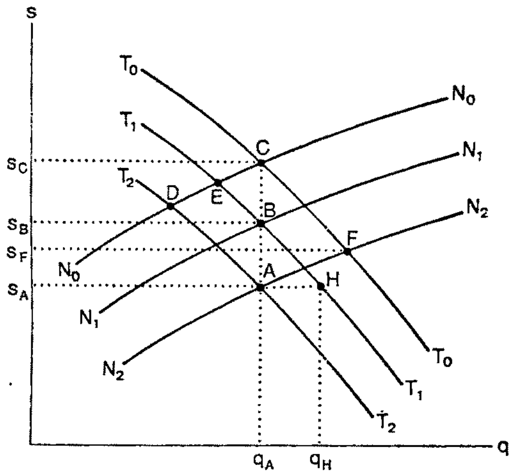

FIGURE 2

tures).[13]

We now use the same set of equations (8) and (9) to elaborate on the interplay of the two basic policy tools, exchange rate policy ($e$ or $q$) and aggregate absorptive measures, summarized under the parameter $s$. For a given level of autonomous demand for tradables ($D_1$), $b$ will decrease if $s$ is increased (since $S_{is}>0$) and if (7) holds it will also be negatively related to an increase in the real exchange rate $q$. The line $T_2T_2$ in Figure 2 represents the various $s-q$ policy combinations keeping $b$ a positive constant. The line $T_1T_1$ represents the same for a lower $b$. The line $T_0T_0$ is drawn for the special case of current account balance (i.e., $\dot{B}=0$). The slope of these lines, which measures the tradeoff between $q$ and $s$, is $[(\partial s/\partial q)_{|b}]=-S_{1q}/S_{1s}$. This is negative if and only if $S_{1q}>0$. If the economy is initially at point $A$ on $T_2T_2$ in Figure 2, a reduction of the deficit to the level corresponding to $T_1T_1$ can be effected, *ceteris paribus*, by pure absorptive measures, keeping $q$ constant at $q_A$ and raising $s$ from $s_A$ (at $A$) to $s_B$ (at $B$) or by exchange rate policy, for given $s$, increasing $q$ from $q_A$ to $q_H$ (at $H$), or by any suitable combination of $s$ and $q$ somewhere between the points $B$ and $H$. However, the nature of the *ceteris paribus* assumption here is critical, because of the simultaneous developments in the other market.[14]

From considerations similar to the above we know that for given autonomous $D_0$ the rate of inflation ($\pi_0$) will fall with an increase in $s$ (since $\partial\pi_0/\partial s=-f'S_{0s}<0$) and rise with an increase in $q$ ($-f'S_{0q}>0$). A devaluation is always inflationary unless coupled with absorptive measures. In analogous fashion the line $N_2N_2$ in Figure 2 represents $s$ and $q$ combinations keeping $\pi_0$ a positive constant. A lower rate of inflation involves a movement of the curve to the left ($N_1N_1$). The curve $N_0N_0$ assumes zero inflation with supply and demand of nontradables balanced at the price level $p_0^*$, say. The slope of the lines $NN$ is always positive since $(\partial s/\partial q)_{|\pi_0}=-S_{0q}/S_{0s}>0$.

The points at which the respective $TT$ and $NN$ lines cross represent pairs of $q$ and $s$ policy combinations that momentarily but simultaneously satisfy the given constraints in terms of allowable inflationary gaps. Moving from $A$ to $B$ and to $C$ here represents a special case of pure absorptive

[13] Let us note that this framework could also be modified to take care of the case in which the market for tradables must balance and we have a flexible rather than a controlled nominal exchange rate. This could be done by replacing equation (8) by an excess demand-price adjustment equation $\dot{e}/e=g(D_1+C_1-X_1)$ where $g'>0$, $g(0)=0$, etc. Alternatively, here as well as for nontradables, domestic money creation could be introduced explicitly whenever there is an *ex ante* gap between $D_i$ and $S_i$. However, the explicit introduction of money (and a real-balance effect) would not change the main aspects of the model for our purpose and they are thus ignored.

[14] Suppose there is a devaluation of $e$ so that $q$ first moves from $q_A$ to $q_H$ (the deficit falling accordingly), and $s$ and $D_i$ are kept constant at their initial values (assuming initially $p_0$ is constant). The price of nontradables ($p_0$) will now start increasing. This process will come to a halt once $p_0$ has increased by the same proportion as $e$. Now $q$ will be back at $q_A$, the deficit will be back at its old level ($T_2T_2$) and all that has happened is an equal rate of increase in the nominal $p_i$ levels, leaving the *relative* price $q$ constant.

policy, keeping $q$ constant (at $q_A$) and affecting both markets simultaneously in the prescribed fashion, by raising $s$ from $s_A$ to $s_B$ and $s_C$. Note that the points $A$ and $B$ (unlike $C$) cannot be sustained unless the nominal exchange rate is being changed at the same rate as the corresponding rate of inflation $\pi_0$ (otherwise $q$ cannot maintain a constant level). Thus strictly speaking a hypothetical movement from $A$ to $B$ really represents a change in the sense of comparative dynamics, switching $\dot{e}/e$ all at once from one steady state to another, at a lower required speed of adjustment.

In the analysis that follows it will be useful to simplify matters by assuming the market for nontradables to remain in balance, say along the line $N_0N_0$, at a constant price level $p_0^*$. In that case a level of $q$ can be maintained by a suitable stationary level of $e$. The combinations of $s$ and $q$ corresponding to successively falling balance-of-payments deficits are represented by the points $D$, $E$, $C$. Note that both $s$ and $q$ must in this case be increased simultaneously because of the need to do away with the accompanying inflationary gap in the market for nontradables. However, a similar effect could alternatively be obtained with a smaller change in $s$ (or none at all) and a larger change in $q$, provided $D_0$ is reduced through either fiscal or monetary measures.[15] The implications of all this for the developments and required policy measures to accompany exchange rate changes (for example, under a "crawling peg") should be clear.

[15] Suppose we start at point $D$ and now move to the point $A$ while reducing $D_0$ to the amount required to keep the nontradable market in balance. This implies that the $N_2N_2$ line is now the line corresponding to constant $p_0$ (and could now be termed $N_0N_0$). For the balance of payments to remain in state $T_2T_2$, $s$ must fall from $s_D$ to $s_A$ while $q$ increases from $q_D$ to $q_A$. Now raise $s$ and $q$ from the point $A$ to the point $F$ at which both markets balance completely. The overall effect is a balance-of-payments correction using a larger increase in $q$ (from $q_D$ to $q_F$ instead of $q_C$) while $s$ falls or increases by less than it would have otherwise ($s_F < s_C$).

## II. Development of the Open Economy

So far we have confined ourselves to price and balance-of-payment changes in the static economy. The incorporation of a growth process into the model can be done by identifying part of the autonomous demands $D_i$ with *investment* in tradables (for example, machines) $I_1$, and/or nontradables (for example, structures) $I_0$, leading to changes in the stocks of assets $K_i$:

$$(10) \qquad \Delta K_i = I_i - h_i K_i \qquad (i = 0, 1)$$

where $h_i$ are the respective depreciation rates.

A change in the stocks of assets will affect the system through the shift vector $Z$, moving the production possibility curve from one "short term" to the next. The precise way in which $Z$ and $PPC$ change depends on a particular specification of the model, for example, whether capital is distributed "optimally" or not. Thus the elements of $Z$ may consist not only of the sum of $K_0$ and $K_1$ but of its particular short-term distribution among industries or firms. For the moment all that we have to assume is that there is some mechanism that makes for $K_i$ formation and allocation and thus for a suitable shift in $PPC$ through the catch-all shift vector $Z$.

We now have to consider $Z$ as a variable together with $q$ in the determination of both outputs $X_i$ and net supplies $S_i$. Denoting by $\Delta$ a total shift from one period to the next and by $\Delta_Z X_i = X_{iZ} \cdot \Delta Z$ (scalar product)[16] a supply shift in $X_i$ due to the long-run factors $Z$ (holding $q$ and $s$ constant) and similarly for $\Delta_Z S_i$ we get:

$$\begin{aligned} \Delta_Z S_i &= S_{iZ} \cdot \Delta Z = X_{iZ} \cdot \Delta Z \\ &\quad - C_{ic}(1-s)(X_{0Z} + qX_{1Z}) \cdot \Delta Z \\ &= \Delta_Z X_i - C_{ic}(1-s)(\Delta_Z X_0 + q\Delta_Z X_i) \end{aligned}$$

[16] $$\Delta_Z X_i = \Delta K_1 \frac{\partial X_i}{\partial K_1} + \Delta K_0 \frac{\partial X_i}{\partial K_0} + \Delta L \frac{\partial X_i}{\partial L} + \Delta t \frac{\partial X_i}{\partial t} \qquad (i = 0, 1)$$

where partial differentiation is performed holding $q$ and $s$ constant.

Denote

$$a = \frac{q\Delta_Z X_1}{\Delta_Z X_0}$$

$$\mu_1 = C_{1e}(1-s)q \qquad \text{(as before)}$$

and $\mu_0 = C_{0e}(1-s)$

where $\mu_i$ are the *MPC* out of gross income and $\mu_0+\mu_1=(1-s)$. We now have

$$\Delta_Z S_1 \gtrless 0 \qquad \text{iff } a \gtrless \frac{\mu_1}{1-\mu_1}$$

$$\Delta_Z S_0 \gtrless 0 \qquad \text{iff } a \lessgtr \frac{1-\mu_0}{\mu_0} = \frac{\mu_1+s}{1-(\mu_1+s)}$$

Since

$$\frac{\mu_1+s}{1-(\mu_1+s)} > \frac{\mu_1}{1-\mu_1} \qquad \text{(as long as } s>0)$$

There are three ranges:

if $\quad a \geq \dfrac{\mu_1+s}{1-(\mu_1+s)},$

$$\Delta_Z S_1 > 0 \quad \text{and} \quad \Delta_Z S_0 \leq 0;$$

if $\quad \dfrac{\mu_1+s}{1-(\mu_1+s)} > a \geq \dfrac{\mu_1}{1-\mu_1},$

$$\Delta_Z S_1 \geq 0 \quad \text{and} \quad \Delta_Z S_0 > 0;$$

if $\quad \dfrac{\mu_1}{1-\mu_1} > a,$

$$\Delta_Z S_1 < 0 \quad \text{and} \quad \Delta_Z S_0 > 0.$$

In particular we note that there will be a secular improvement in the balance of payments for given $s$ and $q$, if and only if:

$$(11) \qquad a > \frac{\mu_1}{1-\mu_1}$$

In words, for given $q$ and $s$, the relative marginal supply shift in tradables over time must be greater than the relative marginal consumer demand for tradables out of income. Note that it is the ratio of the *absolute* size of the increments of $X_1$ and $X_0$ that matters. It will in general depend on past investment and labor training policy, on relative capital intensity in the production of the various goods, and on possible differences in technical progress between the two groups of industries.

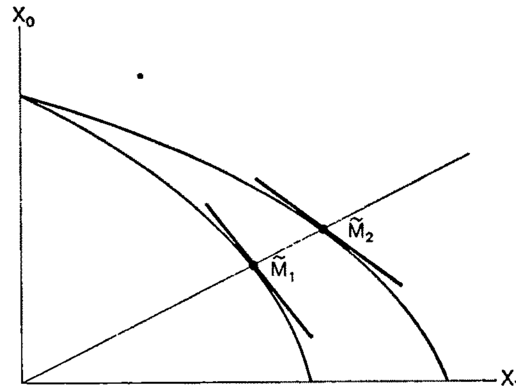

FIGURE 3

A change in $Z$ that is biased toward tradable goods (say, technical progress or investment is biased in that direction or else export prices have increased) will shift the *PPC* so that along a constant relative-output ray from the origin (see Figure 3, movement from $\tilde{M}_1$ to $\tilde{M}_2$) the slope of the *PPC* ($q$) may fall over time, i.e., less of an increase in $q$ will be needed to effect a given *relative* increase in $X_1$.[17] For the analysis of Figure 2 the implication of changes in $Z$ is in terms of a shift of the $TT$ curves to the right and $NN$ curves to the left, with the relative shift depending on the conditions stated above.

We now have the ingredients for a description of development paths in an open economy. At any moment of time $Z$ and *PPC* are given as well as $p_0$, $P_1$, $B$. The choice of $D_i=G_i+I_i$ ($i=0$, 1), $s$, and $q$ (or $e=qp_0/P_1$, assuming government control of the exchange rate) affects the equilibrium in both commodity markets (i.e., $\pi_0$ and $b$) and thus also the domestic

[17] One should be careful in the interpretation of these statements since a rise in $q$ in one period may by itself make the production of tradable goods more profitable and shift factors in that direction in the longer run. Thus the role of $q$ may be underestimated. This is important for empirical estimation of supply responses.

price level $p_0$ and the level of outstanding debt (or exchange reserves) $B$ for the next period. Investment $(I_i)$[18] plus the other factors affecting $Z$ (the amount of exogenously given labor $L$, say, and technical progress) determine a new $PPC$. Now we can start the same process again in the next period.[19] Obviously there is room for many variations on the basic theme, but in principle, this kind of framework could be used to analyze balance-of-payment developments and structural change in a single country over time or as a basis for making comparative analyses of output composition, savings, and balance of payments in different economies.

As an example of explaining international differences in growth patterns consider the characterization of variations in capital inflow across countries. Application of the analysis of the last section suggests that for given $D_1$ and $Z$ we would expect higher $b$ levels to go together with lower $s$ or lower $q$ or both. If extra aid were merely used as a means to finance imports of capital goods $(I_1)$ or defense $(G_1)$, say, variations in $b$ would not be reflected in variations in $S_1$ (since $(D_1-b)$ would not vary). However, one feature of an aid-receiving country should be its ability to smooth its consumption path over time.[20] We would thus expect countries receiving more aid to have, *ceteris paribus* (i.e., for same size and income), a lower savings rate.

One would likewise expect, as long as basic demand patterns in different countries are similar, that countries at the same income level and of the same size, but with a higher relative capital inflow (or the *same* country at a different point in time), would place a lower value on their $q$, i.e., a larger relative share of total production would be in nontradable goods, such as services and construction.

Finally, this framework can be used to rationalize systematic changes in real exchange rates accompanying structural change and balance of payments and capital movements in individual countries over time.

At this stage let me draw attention to another aspect which is of importance when one thinks of this type of framework as a basis for policy. We have so far considered only static optimization. Decisions about savings and investment, foreign borrowing, and the exchange rate were assumed to be taken separately in each period. We know that unless the degrees of freedom on policy making are highly restricted, such behavior will not be optimal from an intertemporal point of view. The ability to dissave and borrow tradable goods first, invest and expand exports (or import substitutes) to repay debts later, must also express itself in proper asset and foreign exchange pricing over time.

In the Appendix I state in greater detail the structure of an optimum intertemporal model. It incorporates the basic assumptions of the general framework under a simple Ramsey-type discounted utility maximand $[\int_0^T e^{-\alpha t}U(C_0, C_1)dt]$ plus a given supply schedule for the foreign debt with marginal cost $r(B)$. The initial and terminal stock levels of capital and debt are given. The solution of such a model as an optimum control problem consists, as one would expect, of two parts. One is a restatement of the static equilibrium conditions under which the marginal rate of substitution in consumption $(U_1/U_0)$ must at each point in time equal that in production $[(\partial F/\partial X_1)/(\partial F/\partial X_0)]$, and both equal the real exchange rate $q$. The second set of relationships is familiar from the theory of optimum capital accumulation (or opti-

[18] It is here assumed that $I_i$ is *ex post* investment, requiring some assumption, at least for nontradables; either $D_0=S_0$ or an *ex ante* imbalance between $D_0$ and $S_0$ is resolved by *ex post* adjustment of $G_0$.

[19] We here identify the "next" period as being the same for investment gestation and for the price change. This, of course, is a simplifying assumption which is not of crucial importance here.

[20] As we shall see below this could also be explained in terms of optimum intertemporal behavior.

mum portfolio choice). If the own net rate of return on each type of asset is denoted by $\rho_i$ ($i=0$) for nontradables and $i=1$ for tradables), then $\rho_i$ measures simultaneously both the marginal net productivity of the capital asset $K_i$ in production as well as the intertemporal rate of substitution of $C_i$ now for a $C_i$ increment in the future. In addition we have:

$$\rho_1 = r(B) \tag{12}$$

$$\frac{\dot{q}}{q} = \rho_0 - \rho_1 = \rho_0 - r(B) \tag{13}$$

These relationships are easy to rationalize intuitively. Equation (12) says that the rate of return on a tradable asset must equal the marginal cost of foreign borrowing. Equation (13) says that at the margin of choice of investing in a tradable asset or in a nontradable asset (or saving for the consumption of nontradables) intertemporal indifference requires the relative capital gain to change at a rate that just equals the difference in the net rates of return of the two assets.

Full analytical characterizations for general models are hard to obtain. On the other hand one can compute numerical solutions for empirically based multisector models having the same basic features as the more general model.[21] However, even in the absence of a full-fledged model the rationale behind these models can be of considerable practical use. For example, the rationale of the more general equation (13) can be used for the choice of a suitable interest rate for public investment decisions.

It is quite common practice to take an estimate of $r(B)$ to represent the accounting rate of interest for public investment decisions. It is a readily available figure and foreign loans naturally represent marginal investment funds. However, as the above theoretical analysis shows, this is definitely a wrong procedure when $q$ is expected to change systematically over time. The correct approach, if one knows the country's balance-of-payments objectives and the relevant supply elasticity of tradable goods, is to get an estimate of expected $\dot{q}/q$. Knowing the marginal cost of foreign borrowing $r(B)$ one can then get an imputed value of the real domestic rate of interest from the sum $\dot{q}/q+r$.[22]

Finally let me point out that the same general framework could also be applied for the rationalization of optimum departures from uniform real exchange rate movements over time. One example for which this can be shown is the case of infant industries or learning effects in the production of some tradables. This calls for a special subsidy to producers. The other is the case of a minimum consumption constraint on some tradables (say low income consumption of a staple food). This calls for a subsidy to the consumer, i.e., an effective exchange rate that lies below the common $q$.

Obviously there are numerous other complications that could be introduced into this basic model. All of this should not distract us from what may be the main implication of the present approach. Far too often exchange rate policy is still seen as a short-term balance-of-payments correcting device and merely as a correction to domestic inflation. This is no doubt strongly tied with the main traditional role of nominal exchange rate adjustments

[21] A detailed programming model that illustrates the application of this kind of framework for Israeli data was given by the author, Dougherty, and Fraenkel. Fraenkel has further developed this model and its theoretical implications, working out time paths for alternative specifications of discount rates and the ability to borrow abroad. His model also provides explicit numerical estimates of the loss of welfare when there exist *absolute* limits on the ability to borrow, a problem no doubt faced in many situations.

[22] In the case of Israel, for example, reasonable orders of magnitude are $r(B)=6$–$8$ percent, $\dot{q}/q=4$–$5$ percent, and thus the real domestic rate of interest (in terms of real domestic resources) should be 10–13 percent.

in well-developed industrialized countries. However, in the process of rapid structural change of an open economy the long-run allocative role of systematic changes in the real exchange rate system may be of much greater importance.

## Appendix

### *The General Optimization Model*

We look at the following general problem:

$$\text{(A1)} \qquad \text{Max} \int_0^T e^{-\alpha t} U(C_0, C_1) dt$$

subject to:

$$\text{(A2)} \qquad F(X_0, X_1; K_0, K_1, L, \text{t}) = 0$$

$$\text{(A3)} \qquad X_0 = C_0 + I_0$$

$$\text{(A4)} \qquad \dot{B} = R_B + C_1 + I_1 - X_1$$

$$\text{(A5)} \qquad \dot{K}_i = I_i - h_i K_i \qquad (i = 0, 1)$$

$$\text{(A6)} \qquad R_B = \int_0^B r(x) dx$$

and $K_i(\text{t})$ $(i=0, 1)$, $B(\text{t})$ are given at $\text{t}=0, T$. The value of $L$ is given at all t.

The formal solution, using the Maximum Principle (see, for example, Robert Dorfman, Kenneth Arrow and Mordecai Kurz), consists of the following necessary conditions:

*Static Maximization:* At *each* point in time the following Hamiltonian must be maximized:

$$\text{(A7)} \quad \text{Max } H = e^{-\alpha t}(U + p_0 \dot{K}_0 + p_1 \dot{K}_1 - p_1' \dot{B})$$

subject to the constraint (A2) where $p_0$, $p_1$, and $p_1'$ are the imputed stock prices, and $H$ can be interpreted as the discounted net domestic product (plus consumers' surplus).[23]

Adding $e^{-\alpha t}\lambda F$ to (A7) with $\lambda$ as a Lagrangian multiplier and substituting from the various equations we must therefore maximize the expression ($H_1$ is the Lagrangian or extended Hamiltonian):

$$e^{\alpha t} H_1 = U(C_0, C_1) + p_0(X_0 - C_0 - h_0 K_0) + p_1(I_1 - h_1 K_1) + p_1'(X_1 - I_1 - C_1 - R_B) + \lambda F(X_0, X_1; K_0, K_1, L, \text{t})$$

with respect to $C_i$, $I_1$, $X_i$ (at given $K_i$, $L$, t).

The first-order conditions are:

$$\text{(A8)} \qquad U_0 = p_0, \qquad U_1 = p_1 = p_1',$$

$$p_0 + \lambda \frac{\partial F}{\partial X_0} = 0, \qquad p_1' + \lambda \frac{\partial F}{\partial X_1} = 0$$

Denoting $q = p_1/p_0$ we get:

$$\text{(A9)} \quad q = \frac{U_1}{U_0} = \frac{p_1'}{p_0} = \frac{p_1}{p_0} = \frac{\partial F/\partial X_1}{\partial F/\partial X_0}$$

We thus get the equality of $q$ and the respective marginal rates of substitution. For (A9) to give a true maximum, concavity of $U(C_0, C_1)$ and convexity of $F(X_0, X_1)$ will be assumed.

*Dynamic Price Equations:* The following dynamic equations must hold for the imputed stock prices:

$$\text{(A10)} \qquad \frac{d(e^{-\alpha t} p_i)}{dt} = -\frac{\partial H_1}{\partial K_i} \qquad (i = 0, 1)$$

$$\text{(A11)} \qquad \frac{d(e^{-\alpha t} p_1')}{dt} = \frac{\partial H_1}{\partial B}$$

Written out, equation (A10) gives

$$\text{(A12)} \quad \frac{\dot{p}_i}{p_i} = \alpha + h_i - \frac{\lambda}{p_i} \frac{\partial F}{\partial K_i} = \alpha - \rho_i$$

where

$$\frac{\lambda}{p_i} \frac{\partial F}{\partial K_i} - h_i = -\frac{\partial F}{\partial K_i} \bigg/ \frac{\partial F}{\partial X_i} - h_i = \rho_i$$

are the own net rates of return.

Similarly, since $p_1' = p_1$ (from (A9)) and $dR_B/dB = r(B)$, we get:

$$\text{(A13)} \qquad \frac{\dot{p}_1}{p_1} = \alpha - r(B)$$

It follows that $r(B) = \rho_1$ (see equation (12)) and finally equation (13) in the text is ob-

[23] Add and subtract $\sum U_i C_i$ in (A7). Consumers' surplus is given by $(U - \sum U_i C_i)$, and net domestic product (in utility units) is given by

$$\left[ \sum_{i=0}^{1} (U_i C_i + p_i \dot{K}_i) - p_1' \dot{B} \right]$$

tained from combining (A12) and (A13).

*Sufficiency:* To have sufficient conditions for an optimum (A1), if it exists, the Lagrangian $H_1$ must be concave in $K_i$, $-B$ (for given $p_i$, t). It follows that $F(\ )$ must be concave in $K_i$ and we must also have $d^2R_B/dB^2 = r'(B) \geq 0$. The above set of equations plus the boundary values on the stocks in principle lead to a complete characterization of an optimum program including the pattern of foreign debt, savings, and prices over time.

Finally we note that in all of the above we have ignored the possibility of corner solutions, otherwise the nonnegativity constraints (for example, on $C_i$ and $I_i$) must be taken into account explicitly in the maximization and the corresponding price variables. The fact that we get $p_1' = p_1$, for example, is connected with an implicit assumption that it will not be optimal to reduce $K_1$ (otherwise $p_1'$ and $p_1$ may differ by a suitable Lagrangian multiple).[24] Also, if $p_1 = p_1'$ an optimum solution may very well imply an initial "jump"[25] (i.e., instantaneous adjustment) in one of the two state variables $K_1$ or $B$ so as to get the two rates of return $r(B)$ and $\rho_1$ equalized. This also implies that in the initial and terminal boundary conditions it is the *difference* $B(t) - K(t)$ that mainly matters for characterization of the path rather than the individual values of $B$ and $K$ separately, at $t=0, T$.

[24] Alternatively, we could *assume* that $K_1$ and $-B$ are freely convertible into each other, in which case $\dot{K}_1 < 0$ could occur.

[25] For a mathematical treatment of such a case, see Karl Vind, Arrow and Kurz.

# A Bargaining Theoretic Approach to Cropsharing Contracts

*By* Clive Bell and Pinhas Zusman*

Sharecropping is a geographically widespread and historically tenacious form of lease. The questions of how the rental share is determined, and how such a form of lease affects resource allocation and the distribution of income pose a challenge to economic theory which has evoked two notable recent attempts to provide an explanation. First, within what may be called the Marshallian tradition, P. K. Bardhan and T. N. Srinivasan (1971) (hereafter B-S) have developed a fairly complete scheme of analysis in which the rental share is regarded by the parties to the contract "as a price-like variable" (1974, p. 1068), i.e., it is parametrically given to all agents. For an exogenously given real wage rate, the supply of and demand for leases determine the rental share. A second approach is that originally formulated by S. N. S. Cheung and subsequently extended and generalized by D. M. G. Newbery (1973a, b), (hereafter C-N). In their system, also claimed to be competitive, both the rental share and the minimum labor input per unit of land are stipulated in all contracts, their values being jointly determined by the landlord's desire to maximize his income subject to the condition that the tenant's income does not fall below his alternative earnings in a perfectly competitive labor market.

True to the spirit of Marshall's analysis (p. 644), B-S show that resource allocation under sharecropping departs from that ruling in a competitive system with fixed rent leases, it being well known that the latter is Pareto optimal. As Newbery (1974) has shown, the fundamental difficulty with B-S's formulation is that there will be excess demand for land for all rental shares less than unity, unless the marginal productivity of land is zero. By contrast, in the C-N scheme of things, the equilibrium which obtains happens to be identical with that ruling in a competitive fixed-rent system and is therefore Pareto efficient. This formulation, however, has two basic and related difficulties of its own. First, there is the dubious enforceability of the minimum labor-intensity provision of the contract. Secondly, if land has to be rationed, both agents are placed in a bargaining situation. Hence, one would expect the rental share which emerges from the bargaining process to reflect the agents' respective bargaining strengths.

Once the overriding importance of the last point is recognized, it is plain that the problem must be reformulated and analyzed within the framework of bargaining theory. This is the salient feature of our approach. Now as Newbery and Joseph Stiglitz have shown, the choice of rental contract is intimately related to the allocation of risk bearing and the provision of incentives in an uncertain world. However, in order to keep the bargaining aspects of the problem in sharp focus, we confine ourselves here to pure cropsharing under certainty.

In addition to these theoretical con-

* Economists, Development Research Center, World Bank. Bell is on leave from the Institute of Development Studies, Sussex, and Zusman from the Hebrew University, Jerusalem. We would like to acknowledge helpful comments by Bela Balassa and an anonymous referee. Errors of analysis are ours alone.

siderations, the foregoing competitive formulations pay little attention to the fact that in addition to his labor, the tenant often possesses land of his own, some capital, and entrepreneurial and management skills. In this connection, it is widely observed that landlord and tenant split the produce in proportions which are close to, if not exactly, 50:50. Any analysis which seeks to explain the latter must take account of the former. All this suggests that the assumptions on which both theories rest must be reconsidered, and that the analysis of the problem must be tailored to the characteristics of the agrarian system in question.

In this paper, we discuss first some empirical evidence concerning the existence and nature of nontradable factors and market imperfections, which play a key role in the bargaining process. The evidence relates mainly to northeast Bihar, but it should survive extension to much of the lower Indo-Gangetic plain. Secondly, we employ John Nash's solution to the bargaining problem, and hence derive the equilibrium rental share. By way of illustration, we calculate the predicted rental and factor shares corresponding to some sets of plausible production parameters. Finally, we analyze briefly the situation in which the marginal productivity of land is zero.

## I. Assumptions and Evidence

The most natural question to begin with concerns the specification of the labor market. The assumption of a perfectly certain and elastic supply of labor and work opportunities at an exogenously determined and parametrically given wage is not really acceptable at the microeconomic (village) level. But it will be retained on account of its simplicity, which eases the task of analyzing the effects of relaxing other less defensible assumptions.

First, the relationship between agricultural worker and tenant status is probably asymmetric. It is always open to the tenant to work for others as well as (or instead of) on the land he has leased in; but the landless laborer cannot just elect to become a tenant if that status requires capital and husbandry skills to which he can get access only with great difficulty, if at all. In this connection, it should be noted that in both India as a whole and Bihar, household operational holdings which are partly owned and partly leased greatly outnumber those which are wholly leased in, and that the former account also for the lion's share of all land leased in.[1] Thus, tenants are drawn mainly not from the mass of landless laborers, but from the ranks of the small peasantry possessing land of their own as well as skills and capital (or access to capital), all of which are traded (if, indeed, they are tradable at all) in imperfect markets.

Moreover, the micro data analyzed by Krishna Bharadwaj for several Indian States and by Bell for northeast Bihar reveal that both categories of tenant households make very extensive use of hired labor for cultural labor operations and harvesting. Thus the costs of supervising cultivation itself (though not the enforcement of a minimum input bundle, of course) fall on the tenant. Moreover, as the work is done by casual laborers, who must be contacted in sufficient numbers at the right time, there are transactions costs of labor hire which are passed on to the tenant by the landlord leasing out his land. Factors such as choice of crop, timeliness of operations, and good husbandry, where the scope for them is large, indicate that purely entrepreneurial skills are also involved (see C. H. H. Rao). All these point to a vital managerial element in the tenant's role—for which he must be sufficiently rewarded.

[1] See, for example, the Indian *National Sample Survey* (nos. 36, 113, 144) and S. K. Chakraverty, p. 99.

The second major query surrounding the stylized competitive models is the absence of nonlabor inputs other than land. Here the principal difficulty stems from the nature of the market for animal draught power, especially on the supply side. In India, there is no historical evidence of human traction (or digging) for land preparation (except for small-scale vegetable cultivation), and there is a broad social disdain for such methods (see Prufulla Sanghvi). Now, if the markets for both this input and credit were perfect, Cheung's contract could be extended to stipulate the minimum draught input per acre as well as the rental share and minimum labor intensity. However, the field data suggest that: (a) hired draught is only a very small fraction of total draught inputs, in marked contrast to labor; and (b) owning at least one pair of bullocks or buffalo is a sine qua non for obtaining a lease, and that this distinguishes tenants owning no land of their own from the general class of landless laborers.

These findings are backed up by the comments of tenants during interviews: although there existed a daily rate for the hire of a bullock team season by season, it was extremely difficult in practice to hire. No cultivator could afford to rely on the hire market, nor, indirectly, could any landlord. Hence the likelihood that tenants would own some land, for land and draught livestock ownership are very highly correlated. Nor are such observations confined to Bihar. In his study of allocative efficiency in an Eastern Uttar Pradesh village, David Hopper was unable to compare the calculated marginal product of bullock labor with its market price because "there was not an active local market for bullock rentals to provide a comparison" (p. 623).

The upshot of this examination of the assumptions underlying the competitive models is that the conclusions drawn from them may be highly misleading. In itself, the generalization of those analyses to many kinds of labor and nonlabor inputs presents no difficulties, provided all markets are perfect. But once it is perceived that tenants are distinguished from ordinary landless laborers by their command over factors whose services are traded (if directly tradable at all) in markets which are inherently and highly imperfect, then major revisions become necessary. First, the equilibrium condition that under perfect certainty the tenant's income must be equal to his alternative earnings as a wage laborer has to be dropped. Secondly, it cannot be replaced by a generalized equivalent to include the alternative earnings of factors other than "worker labor" owned by tenants because the markets for such factors are not even remotely perfect. Thirdly, while it may be safe to assume that the market for unskilled labor is perfect, any formulation of the problem must respect the fact that the crux of the land lease decision lies in the nontradability of managerial skill and draught power.[2]

These imperfections are intimately connected with the issue of whether or not the landlord has the ability to enforce contracts specifying a set of minimum input intensities on sharecropped land. In addition to the a priori arguments advanced by B-S that such contracts are not enforceable, there is empirical evidence to that effect for northeast Bihar. The detailed testing of the competing hypotheses advanced by the two schools[3] has been undertaken elsewhere (Bell), with the Marshallians coming off the better. Although there is no space here to go into much detail, the fact that most tenants also own land allows a search for the influ-

[2] In this connection, it is worth noting Richard H. Day's conclusion that mechanization contributed in a major way to the decline of sharecropping in the *U.S.* South by providing an alternative to tenant-owned draught power.

[3] Four central hypotheses are set up and tested by Cheung (pp. 55–61), who uses evidence from prerevolutionary China, Taiwan, Korea, and Japan.

TABLE 1—MEAN INPUTS AND OUTPUTS PER ACRE ON TENANT HOLDINGS

| | Cropping Intensity | Intermediate Inputs[a] | Hired Labor[a] | Yield[a] |
|---|---|---|---|---|
| Sharecropped plots | 1.40 | 33.0 | 35.6 | 378.3 |
| Owned plots | 1.76 | 64.3 | 46.7 | 561.9 |

*Source:* Bell.
[a] Rupees per net acre sown.

ence exerted by nontradables and other imperfections on the allocation of resources. For each such tenant, his access to inputs (traded or nontraded) and his aversion to risk are common elements in his decisions concerning the allocation of resources between owned and sharecropped plots. These sources of variation across farmers can be eliminated in the following way: for each farmer, form a vector whose elements are the differences between output and inputs per acre on owned and sharecropped land, respectively. This procedure amounts to a "pairing" of observations, a classic and powerful experimental method which has been neglected in the sharecropping literature. Table 1 summarizes mean input and output levels by the tenure status of land cultivated for a sample of 31 farmers, cropping intensity being a proxy for land services (and hence, indirectly, for draught services). Given the multivariate nature of the situation, an appropriate way of testing the significance of the vector of differences on owned and sharecropped land, namely [0.36, 31.3, 11.1, 183.6], is to employ Hotelling's $T^2$ statistic. The computed value of $T^2$ is 31.37, which is significant at the 0.1 percent level.

These findings suggest that the tenants were highly successful in "diverting" both nontradable and tradable resources to the land which they owned, contrary to the competitive theory offered by C-N. While landlords may have had a mind to enforce contracts specifying the mean vector of input intensities and yields for owned land, the task was apparently beyond them in practice.

## II. Bargaining Over the Rental Share

The foregoing discussion suggests a number of fruitful departures from competitive assumptions. We shall confine our attention to just two of them: the inclusion of nontradable factors and the rationing of leases, by landlords. These necessitate the use of a quite different analytical approach, namely, a bargaining game formulation. To keep matters simple, we assume that tenants are landless, but endowed with managerial and husbandry skills, and draught power. The introduction of the tenant's own land would add the complications of an allocation problem to those of finding a solution to the bargaining game.

Suppose just one landlord and $n$ $(<\infty)$ identical tenants reside in each locality and all land is homogeneous. The landlord, who does not cultivate any land himself,[4] possesses $\alpha$ units of land, while each tenant household is endowed with one unit of labor. The labor market is perfect so that the marginal utility of leisure equals the wage rate ($w$) and tenants maximize income net of the imputed cost of labor. Contracts specifying minimum intensities are unenforceable so the bargaining process will determine the rental share ($r$) as the sole provision of the contract. With the existence of nontradable factors, it is reasonable to assume that each tenant's output is a strictly concave, twice continuously differentiable function of his land holding($h$) and unskilled labor inputs ($l$).[5]

[4] This assumption is made for simplicity's sake. The value of the landlord's leisure is then independent of the number and nature of the contracts he concludes, and therefore will not feature in the analysis.

[5] For simplicity, fully traded intermediate inputs such as seed, fertilizer, etc. are lumped together with unskilled labor. Table 1 indicates that this procedure is also empirically defensible.

Consider the landlord's dealings with a single tenant in the situation in which contracts with all other tenants have been closed at a rental rate $\bar{r}$. If these two agents agree on a contract specifying a rental share $r$, their respective incomes (including the value of the tenant's leisure) will be:

$$(1) \quad \begin{aligned} Y^1 &= (1-r)F(h, l_1) - wl_1 + w \\ Y^2 &= (n-1)\bar{r}F[(\alpha-q)/(n-1), l] \\ &\quad + rF(h, l_1) \end{aligned}$$

where $l_1$ is the total labor input (i.e., family plus hired hands) of the tenant in question, and $h \leq q$, $(\alpha - q)$ being the area of land leased out to the other tenants and, because they are identical, equally divided among them. Now suppose that the marginal product of land is positive ($F_1 > 0$) so that there is excess demand for tenancies ($r < 1$), and land is fully utilized ($q = h$) and rationed. Maximization by the single tenant operating $h$ units of land, and by all other tenants, implies also that

$$(2) \quad (1-r)F_2(h, l_1) = (1-\bar{r})F_2[(\alpha-h)/(n-1), l] = w$$

respectively. If, however, the two agents fail to agree, the tenant will fall back on wage labor and the landlord will distribute the $h$ units of land thus freed among the other $(n-1)$ tenants, who change their labor inputs accordingly. In this situation, the tenant's and landlord's incomes become, respectively:

$$(3) \quad \begin{aligned} y^1 &= w \\ y^2 &= (n-1)\bar{r}F(\alpha/(n-1), l') \end{aligned}$$

where the labor input on each of the $(n-1)$ tenancies is now given by $(1-\bar{r})F_2(\alpha/(n-1), l') = w$. The disagreement payoffs ($y^1$ and $y^2$) thus represent the bargaining power of the tenant and the landlord, respectively. The solution of the bargaining problem must reflect the respective bargaining positions of both parties. In this connection, it should be noted that in the event of a disagreement, the landlord's ability to distribute any tenant's parcels among the other claimants makes his position close to what it would be if he were to engage in cultivation himself. Indeed, at the margin, he would be indifferent between such a redistribution and a little extra self-cultivation.

We now employ John Nash's method to arrive at a solution to this bargaining game.[6] Define

$$(4) \quad N = (Y^1 - y^1)(Y^2 - y^2)$$

Then any value of $r$ which maximizes $N$ is a solution. However, since labor utilization by tenants is not part of the contract, tenants' behavior, as given by equation (2), constitutes an external constraint on the bargaining game. That is, the influence that the rental share exerts on labor utilization is recognized by both parties and affects the outcome of the game. Nash's solution also requires that $Y^i - y^i > 0$ for $i = 1, 2$. That is, neither the tenant nor the landlord will enter into nonremunerative contracts. Substituting (1) and (3) into (4), we get the following first-order condition for $N$ to be a maximum:

$$(5) \quad \begin{aligned} \frac{\partial N}{\partial r} = &- F(h, l_1)\{rF(h, l_1) + \bar{r}(n-1) \\ &\cdot [F(h, l) - F(\alpha/(n-1), l')]\} \\ &+ \left[F(h, l_1) + rF_2\frac{dl_1}{dr}\right] \\ &\cdot [(1-r)F(h, l_1) - wl_1] = 0 \end{aligned}$$

where, from (2)

$$\left.\frac{dl_1}{dr}\right|_{w,h} = \frac{F_2}{(1-r)F_{22}} \leq 0$$

[6] In Nash's solution of a two-player cooperative bargaining game, the agreement payoffs to the parties depend on their "disagreement payoffs" and the feasible set of all payoffs. The solution is consistent with the following four axioms: (i) "group rationality"; (ii) von Neumann invariance of the utility indicators; (iii) "independence of irrelevant alternatives"; and (iv) symmetry of players. Alternatively, Nash's solution may be viewed as the outcome of some plausible bargaining processes (see R.D. Luce and H. Raiffa).

Thus, any $r^0$ satisfying (5) is a function of $\bar{r}$. That is, the rental share negotiated in a particular contract depends on the share stipulated in the other $(n-1)$ contracts. The equilibrium configuration of contracts is such that if any contract expires, all other contracts being given, renegotiation will yield the very same contract. Recalling that by assumption all tenants are identical, then symmetry considerations imply $r^0=\bar{r}$. Hence, by (2), $l_1=l$ and $h=\alpha/n$ ( implying, as one would expect, that all tenants would cultivate parcels of equal area). Thus, from (5), we have

$$(6)\quad r^0=[1-\beta_2]\Bigg/\left\{(n+1)-(n-1)\frac{F(')}{F(\cdot)}-\beta_2[1+\epsilon_2(1-\beta_2)]\right\}$$

where $\beta_2$ is the point elasticity of output with respect to labor; $F(\cdot)=F(\alpha/n,\, l)$ is the output on each farm in the event of agreement; $F(')=F(\alpha/(n-1),\, l')$ is the output on each of the other $(n-1)$ tenancies if there is a disagreement; and $\epsilon_2=F_2/l_1F_{22}$ (the inverse of the elasticity of the marginal productivity of labor). Thus equation (6) provides a general determination of $r^0$ once $\alpha$, $n$, $w$, and the technology are specified.

In order to illuminate the influence exerted by these factors on the rental share, we shall now derive solutions for technologies in which the elasticities of substitution between land and unskilled labor are zero, unity, and infinity, respectively.[7]

(A) *Zero elasticity of substitution technology*: $F=\min\,[h^\nu, l^\nu]$, $0<\nu\leq 1$. As tenants are maximizers, $h=l$. Without loss of generality, let $\alpha=n$ so that only family labor is used. By writing down the agreement and disagreement payoffs and maximizing $N$, it may be shown that in a universal cooperative solution, $n=\alpha$, $h^0=l_1^0=1$, and

$$(7)\quad r^0=(1-w)/\{2+(n-1)[1-(1-1/n)^{-\nu}]\}$$

which, for $n$ sufficiently large, becomes

$$(7')\qquad r^0=(1-w)/(2-\nu)\,.$$

Now for the lease contracts to be remunerative, $w<1$ (the level of output on each tenancy). Thus $(1-w)$ is the "surplus" to be divided between the tenant's nontradables and the landlord's land. If there are numerous tenants and constant returns to scale in land and unskilled labor alone $(\nu=1)$, $r^0=1-w$, which is the C-N solution. The competitive share of nontradables is $(1-\nu)$, so that the competitive rental share is $(\nu-w)$, which is less than $r^0$ from (7′) for $\nu<1$, the difference reflecting the landlord's bargaining power.

An important implication of a fixed coefficient technology is that there is no incentive element in the contract, as labor inputs per acre are fixed. The landlord has no enforcement problem, and $r$ acts purely as a distributive instrument. Under these production conditions, it follows immediately that

$$dl_1/dr\,\big|_{w,h}=0$$

Hence, from (3) and (5), $Y^1-y^1=Y^2-y^2$, i.e., the agents' gains over their respective disagreement payoffs are equal.[8]

(B) *Cobb-Douglas technology*: $F=Ah^{\beta_1}l^{\beta_2}$, $A$ constant, $0<\beta_1+\beta_2\leq 1$. Here, consider the limiting case when $\alpha/n(n-1)$ —the extra area received by each of the other $(n-1)$ tenants if the $n$th fails to reach a contract—is small.[9] Then, by expanding $F(')$ as a Taylor series about $F(\cdot)$, and using the condition that the other

[7] It turns out that the derivation using a general *CES* technology does not yield simple interpretable expressions.

[8] For this production technology, the utility possibility frontier $U(Y^1, Y^2)$ for given $\alpha$, $n$, and $w$ is linear.

[9] For example, in a village possessing 1000 acres and 100 tenant households, $\alpha/(n-1)n\simeq 0.1$ acres.

TABLE 2—VALUES OF $r^0$ FOR NUMEROUS TENANTS AND COBB-DOUGLAS TECHNOLOGY

| $\beta_1$ | 0 | 0.2 | 0.4 | 0.6 |
|---|---|---|---|---|
| $\beta_2$ | | | | |
| 0 | 0.50 | 0.56 | 0.62 | 0.71 |
| 0.2 | 0.40 | 0.46 | 0.53 | 0.64 |
| 0.4 | 0.30 | 0.36 | 0.45 | 0.60 |
| 0.6 | 0.20 | 0.27 | 0.40 | — |

tenants alter their labor inputs on receiving an extra $\alpha/n(n-1)$ units of land so as to maintain $F_2=w/(1-r^0)$, some manipulation gives

$$r^0 = (1 - \beta_2)/[2 - \beta_1/(1 - \beta_2)] \tag{8}$$

which is independent of factor endowments and the wage rate. As $l$ decreases with $r$ for given $w$ and $h$, the rental share must now play an allocative as well as a distributive role.

It is instructive to compute $r^0$ from (8) for various pairs of $\beta_1$ and $\beta_2$. If there are constant returns to scale in $h$ and $l$ ($\beta_1+\beta_2=\nu=1$), (8) reduces to $r^0=\beta_1$ which is the C-N solution. However, resource allocation is not Pareto optimal, for $F_2=w/(1-r^0)>w$ when contracts stipulating a minimum labor intensity cannot be enforced and the elasticity of substitution between $h$ and $l$ is nonzero. Thus, while land receives its competitive cost share, labor inputs per unit of land are lower than they would be under fixed rents, and production is not efficient.

More generally, from Table 2, we see first that $r^0$ exceeds the output elasticity of land by a good margin if $F$ is highly concave. This is noteworthy because although the landlord is a potential monopolist, all land is under cultivation. For the assumptions on the technology ensure excess demand for land by tenants ($\beta_1$ and $\beta_2$ are constant, and $F_1>0$ everywhere). Also, when $F$ is strictly concave, a maximizing landlord will not keep land out of cultivation, since $r^0$ is insensitive to changes in $\alpha$ when $\alpha/n(n-1)$ is sufficiently small, and total output will fall if there is a failure to reach agreement with one or more tenants. Secondly, there is a marked tendency for $r^0$ to take values nearer to the magic 0.5 than $\beta_1$ for virtually all but extreme $(\beta_1, \beta_2)$ pairs. Thirdly, for plausible values of $\beta_1$ and $\beta_2$, $r^0$ clusters closely around 0.5. Hopper, for example, reports values of $\beta_1$ in the range 0.2–0.4 and of $\beta_2$ in the range 0–0.2 (p. 615).

A related issue is the structure of factor shares corresponding to the ruling value of $r^0$. The share of (field) labor, whether supplied by the tenant's own household or by the landless is given immediately by equation (2):

$$s_w = wl/F(\cdot) = (1 - r^0)lF_2(\cdot)/F(\cdot) = (1 - r^0)\beta_2$$

Thus, following the Marshallian rule for the use of the variable factor not only depresses employment, but also reduces labor's share in output. The residual output, of course, accrues to the nontradable factor. Denoting the factor shares of land, field labor, and nontradables by $s_l$, $s_w$, and $s_t$, respectively, the most plausible values of $\beta_1$ and $\beta_2$ yield the sets of factor shares shown in Table 3. Taking the competitive structures of factor shares as a benchmark, it is seen that: (a) the landlord exploits the tenant; (b) both the tenant (as manager) and the landlord exploit labor, though only in the fifth case is the landlord's exploitation of the tenant more than offset by the tenant's exploitation of labor.

(C) *Land and labor perfect substitutes:* $F=(h+l)^\nu$, where $\nu\leq 1$. Here, $F_1>0$ everywhere, so there is excess demand for land if $r<1$. Also, from (2), $\nu(1-r)(h+l_1)^{\nu-1}=w$. Thus, if land is redistributed in the event of a disagreement, the labor input employed by each of the other $(n-1)$ tenants will fall so as to keep $(h+l)^{\nu-1}$ constant. Hence production on the other tenancies will not change following a redistribution

TABLE 3—FACTOR SHARES

| | | | | | | |
|---|---|---|---|---|---|---|
| $\beta_1$ | 0.4 | 0.2 | 0.4 | 0.2 | 0.4 | 0.2 |
| $\beta_2$ | 0 | 0 | 0.2 | 0.2 | 0.4 | 0.4 |
| $s_l$ | 0.62 | 0.56 | 0.53 | 0.45 | 0.45 | 0.36 |
| $s_w$ | 0 | 0 | 0.10 | 0.11 | 0.22 | 0.26 |
| $s_t$ | 0.38 | 0.44 | 0.37 | 0.44 | 0.33 | 0.38 |

of land, and the landlord's bargaining position is the weaker thereby. In this case, the Nash function takes the simple form

$$(4') \qquad N = rF(\cdot)[(1 - r)F(\cdot) - wl_1]$$

from which we obtain, at length,

$$(9) \qquad r^0 = \frac{(1 - \beta_2)(1 - \nu)}{(2 - \nu - \beta_2)}$$

where $0 \leq \beta_2 \leq \nu$ and is also a function of $w$.

To round off the analysis, it is instructive to compare the rental shares ruling in the above cases as $w$ varies, but with given factor endowments ($\alpha$, $n$) and returns to scale ($\nu$). In the zero elasticity of substitution case (7′), it is immediate that $r^0$ is linearly decreasing in $w$, with $r^0 = 1/(2-\nu)$ ($\leq 1$ for $\nu \leq 1$) at $w=0$, and $r^0=0$ at $w=1$ ($w \leq 1$ if lease contracts are remunerative to tenants). Now in a Cobb-Douglas technology, $r^0$ is constant and less than unity for $\nu < 1$. It is easily shown by comparing (7′) and (8) that there exists some $0 < w^* < 1$ such that the rental share ruling in a Cobb-Douglas technology is less than that in a Leontief technology if $w < w^*$, and conversely if $w > w^*$.

The perfect substitutes case is more complicated. Here, note first that by (2), $\beta_2(w) = \nu l/(1+l)$, where $h^0 = 1$ ($\alpha = n$). By definition, $0 < \beta_2(w) \leq \nu$. Also $\beta_2(w) \rightarrow 0$ as $l \rightarrow 0$ and $\beta_2(w) \rightarrow \nu$, its upper bound, as $l$ becomes large. As $\beta_2(w) \rightarrow 0$, $r^0 \rightarrow (1-\nu)/(2-\nu)$, and as $\beta_2(w) \rightarrow \nu$, $r^0 \rightarrow (1-\nu)/2$. By differentiating $r^0$ in (9) with respect to $\beta_2$, we see that $dr^0/d\beta_2 < 0$ for $\nu < 1$ so that $r^0$ decreases monotonically as $\beta_2$ increases from 0 to $\nu$. Now as $r^0 \rightarrow (1-\nu)/2$ for large $l$, it follows from the tenants' maximizing behavior $[\nu(1-r)(1+l)^{\nu-1} = w]$ that this is the limiting value of $r^0$ as $w \rightarrow 0$. Moreover, because $r^0 = (1-\nu)/2$ is the maximum of all $r^0$ on $\beta_2 \epsilon [0, \nu]$, and as the Cobb-Douglas value in (8) exceeds this value, the rental share in technology $C$ is less than that in $B$ for all $w > 0$. A further deduction from tenants' decisions regarding labor utilization is that because $r^0 = (1-\nu)/(2-\nu)$ for $\beta_2(w) = 0$ (which implies $l = 0$), then no labor will be used if $w \geq \nu[1 - (1-\nu)/(2-\nu)] = \nu/(2-\nu) < 1$. In this range of $w$, $r^0 = (1-\nu)/(2-\nu)$. Also, we note from (9) that if $\nu = 1$, then $r^0 = 0$ for all $w \geq 0$, a result also obtained by Newbery (1974, p. 1063). The intuitive interpretation of the behavior of the rental shares in different technologies is that for a given wage rate, the higher the elasticity of substitution, the greater the incentives (lower $r$) to use labor the landlord will provide to the tenant. An increase in the wage rate improves the bargaining strength of the tenant and thus tends to lower the rental share. However, the associated fall (if any) in the latter depends in a complicated way on the elasticity of substitution and the wage rate.

## III. Some Land Uncultivated: Causes and Consequences

To complete the analysis, we now consider the cases which may lead to some land remaining unutilized. At first glance, this may come about in two ways: either all tenants are able to choose a parcel size such that $F_1 = 0$ (assuming an appropriate production function); or the parcel size is

also determined in the bargaining process. Let us deal with each of the cases in turn.

Treading a now familiar path, we have in the former case, if a contract is reached, conditions described by equation (1) above. If there is a failure to reach agreement, then we have

$$(10) \quad y^1 = w, \quad y^2 = (n-1)\bar{r}F(\bar{h}, l)$$

In this case,

$$(11) \quad N = [(1-r)F(\cdot) - wl_1][rF(\cdot)]$$

where $F(\cdot) = F(h, l_1)$. Note that $N$ is now independent of the contracts reached with the other tenants. Recall that labor inputs applied by the tenant depend on the rental share—equation (2)—and that tenant maximization implies $F_1(h, l_1) = 0$. Differentiating $N$ partially with respect to $r$, we get

$$(12) \quad \frac{\partial N}{\partial r} = -rF(\cdot)^2 + \left[F(\cdot) + rF_2 \cdot \frac{dl_1}{dr}\right] \cdot [(1-r)F(\cdot) - wl_1]$$

By differentiating totally the tenant's maximizing conditions, viz., $F_1 = 0$ and (2), and hence solving for $dl_1/dr$, we obtain

$$\frac{dl_1}{dr} = \frac{1}{(1-r)} \cdot \frac{F_2 F_{11}}{\Delta}$$

where $\Delta = F_{11}F_{22} - F_{12}^2 > 0$ by the strict concavity of $F$. Hence, for $N$ to be a maximum simultaneously for all contracts, we have, from (12),

$$(13) \quad r^0 = \frac{(1-\beta_2)}{2 - \beta_2[1 + (1-\beta_2)F_2F_{11}/\Delta]}$$

Now, for some $r^0 > 0$, but arbitrarily small, $[(1-r^0)F(\cdot) - wl_1] > 0$ if land is at all cultivated. Also from (12),

$$\left.\frac{\partial N}{\partial r}\right|_{r=0} = F(\cdot)[(1-r)F(\cdot) - wl_1] > 0$$

for the same reason. Then, since $0 \leq r^0 \leq 1$, the maximum value of $N$, and thus the solution to the bargaining game, exists and is associated with a positive rental share. This despite the fact that the marginal productivity of land is zero.

It is important to relate the analysis of this case to the discussion of the competitive formulations in the literature. Recall that, as Newbery has shown, $F_1 = 0$ is the only condition under which a B-S equilibrium will exist. Given fixed factors in limited supply (in this case, nontradables) together with an abundance of land, it is highly plausible that the marginal product of land will fall to zero if the parcel size is made sufficiently large. This may well be the case in some parts of Latin America. What is striking is that our analysis predicts a positive rental share in this situation. That the rental share is positive stems directly from the landlord's power to prevent a would-be tenant from cultivating land if the landlord so chooses.

The second case is one in which both the size of the parcel and the rental share are determined by bargaining. To solve this new bargaining problem we maximize $N$ in (11) with respect to $r$ and $h$, subject to the land availability constraint $h + (n-1)\bar{h} \leq \alpha$, and taking into account the fact that tenants are maximizing on their own account: $(1-r)F_2 = w$ and $(1-r)F_1 \geq 0$. The conditions for a Nash solution (maximum $N$) are obtained by setting

$$(14) \quad \frac{\partial N}{\partial r} = 0$$

$$(15) \quad \left.\begin{aligned} &\frac{\partial N}{\partial h} \geq 0 \\ &h + (n-1)\bar{h} \leq \alpha \end{aligned}\right\} \text{complementarily}$$

Suppose the land availability constraint does not bind and $(1-r)F_1 > 0$. We have, from (15),

$$(16) \quad (1-r)F_1 \cdot F(h, l_1) + \left[F_1 + F_2 \cdot \frac{dl_1}{dh}\right] \cdot [(1-r)F(h, l_1) - wl_1)] = 0$$

Tenants' employment decisions imply $dl_1/dh = -F_{21}/F_{22} > 0$ for well-behaved pro-

duction functions. Also, $(1-r)F(h, l_1) - wl_1 > 0$ if production is at all undertaken. But then condition (16) is not satisfied, for all terms on the left-hand side are positive. Hence, $F_1 = 0$ if the land availability constraint is not binding. By symmetry, the landlord must reach the same contract with all tenants, so that $h = h^0 = \bar{h}$ and $r = r^0 = \bar{r}$, with $F_1[h^0(r^0), l^0(r^0)] = 0$. We are then back to the first case. Alternatively, suppose that the land availability constraint binds; but then we are in our original formulation of the problem, in Section II.

We have thus established that if any land lies uncultivated, then the marginal productivity of land is zero and the rental share is positive. This result contrasts both with the competitive solution, in which the rental share is zero if $F_1 = 0$, and with the monopoly solution, in which both the rental share and $F_1$ are positive in the face of land lying uncultivated.

## IV. Concluding Remarks

In this paper, we have used bargaining theory to derive determinate solutions for the rental share. We have adopted this approach because both the nature of the contract and the features of the agrarian system necessitate it, while competitive formulations must ignore such considerations. In practice, of course, the bargains which are struck need not conform exactly to those predicted by Nash's solution. But if Nash's solution is empirically valid, and given that the bargaining process is repeated year after year in circumstances of unchanging technology and social institutions, then there will be a long-term tendency for contracts to center on some average value. Moreover, if in most situations the solution is not very different from one-half, agents will save themselves the bother of detailed arithmetic and settle for that magic number, which has also the advantage of sounding equitable. Thus that particular rental share is elevated to the status of a social norm.

It goes without saying that some of the drastic simplifications in our formulation may vitiate the analysis. In particular, when a would-be tenant can deal with more than one landlord his bargaining position is stronger than in our formulation. But given the spatial dimensions of agricultural production and the resulting costs of cultivating widely scattered parcels, our neglect of the alternative opportunities stemming from the existence of other landlords may not prove to be too serious. To introduce such considerations into the analysis would entail very considerable complications, which we have chosen not to pursue at this stage.

# Consumer's Surplus Without Apology

By ROBERT D. WILLIG*

The purpose of this paper is to settle the controversy surrounding consumer's surplus[1] and, by so doing, to validate its use as a tool of welfare economics. I will show that observed consumer's surplus can be rigorously utilized to estimate the unobservable compensating and equivalent variations—the correct theoretical measures of the welfare impact of changes in prices and income on an individual.

I derive precise upper and lower bounds on the percentage errors of approximating the compensating and equivalent variations with consumer's surplus. These bounds can be explicitly calculated from observable demand data, and it is clear that in most applications the error of approximation will be very small. In fact, the error will often be overshadowed by the errors involved in estimating the demand curve. The results in no way depend upon arguments about the constancy of the marginal utility of income.

Consequently, this paper supplies specific empirical criteria which can replace the apologetic caveats frequently employed by those who presently apply consumer's surplus. Moreover, the results imply that consumer's surplus is usually a very good approximation to the appropriate welfare measures.

To preview, below I establish the validity of these rules of thumb: For a single[2] price change, if $|\bar{\eta}A/2m^0| \leq .05$, $|\underline{\eta}A/2m^0| \leq .05$, and if $|A/m^0| \leq .9$, then

$$\frac{\underline{\eta}\,|A|}{2m^0} \leq \frac{C-A}{|A|} \leq \frac{\bar{\eta}\,|A|}{2m^0} \tag{1}$$

and

$$\frac{\underline{\eta}\,|A|}{2m^0} \leq \frac{A-E}{|A|} \leq \frac{\bar{\eta}\,|A|}{2m^0} \tag{2}$$

Here, $A$ = consumer's surplus area under the demand curve and between the two prices (positive for a price increase and negative for a price decrease)

$C$ = compensating variation corresponding to the price change

$E$ = equivalent variation corresponding to the price change

$m^0$ = consumer's base income

$\bar{\eta}$ and $\underline{\eta}$ = respectively the largest and smallest values of the income

* Economic Research Department, Bell Laboratories. This paper is drawn from doctoral research done at Stanford University under the guidance of Jim Rosse. I am grateful for his support and for the standards of professional excellence he tried to teach me. I would also like to thank Megina Jack for considerable editorial assistance.

[1] Throughout, the term consumer's surplus is used to refer to the area to the left of an individual's fixed-income (Marshallian) demand curve and between the relevant price horizontals. The concept of consumer's surplus originated in 1844 (see Jules Dupuit) and has been controversial ever since. Alfred Marshall, who popularized the tool, stipulated that for it to be validly used the marginal utility of money must be constant (Marshall, p. 842 or David Katzner, p. 152). However, Harold Hotelling wrote that consumer's surpluses "give a meaningful measure of social value. This breaks down if the variations under consideration are too large a part of the total economy of the person . . . " (p. 289). John Hicks too, stated only a gentle caution: "In order that the Marshallian measure of consumer's surplus should be a good measure, one thing alone is needful—that the income effect should be small" (p. 177). More recently, though, Paul Samuelson (pp. 194–95) concluded that consumer's surplus is a worse than useless concept (because it confuses), and I.M.D. Little (p. 180) agreed, calling it no more than a "theoretical toy." Nonetheless, theorists and cost-benefit analysts have persisted in their use of the tool. For justification they resort (see E. J. Mishan, pp. 337–38, for example), with no formal theoretical support, to statements similar to those quoted above from Hotelling and Hicks.

[2] While I restrict attention to single price changes here, analogous, but more complex formulae are derived for multiple price changes in my papers (1973a, b).

elasticity of demand in the region under consideration.

The formulae place observable bounds on the percentage errors of approximating the $C$ or $E$ conceptual measures with observable $A$. For example, if the consumer's measured income elasticity of demand is 0.8 and if the surplus area under the demand curve between the old and new prices is 5 percent of income, then the compensating variation is within 2 percent of the measured consumer's surplus.

The ratio $|A|/m^0$ can be interpreted as a measure of the proportional change in real income due to the price change.[3] In most applications, the ratio will be very small. Measured income elasticities of demand tend to cluster closely about 1.0, with only rare outliers. Thus it can be expected that $\bar{\eta}|A|/2m^0$, the most important of the terms in (1) and (2), will usually be small enough to permit conscious and unapologetic substitution of $A$ for $C$ or $E$ in studies of individual welfare.[4]

Should $\underline{\eta}|A|/2m^0$ be large, $A$ would not be close to $C$ and $E$. For such rare cases, formulae are provided below in Section IV which enable the estimation of $C$ and $E$ from the observable $\bar{\eta}$, $\underline{\eta}$, $m^0$, and $A$.

## I. The Compensating and Equivalent Variations

In this section, I present definitions of conceptual tools to measure the costs or benefits of price changes to an individual consumer. While these theoretical measures are not directly observable, the analysis that follows in succeeding sections will show that they can be empirically estimated with consumer's surplus.

Throughout I will be assuming that the consumer behaves as though he were choosing his consumption bundle $X=X^1, X^2, \ldots, X^n$ to maximize an increasing strictly quasi-concave ordinal utility function $U(X)$ subject to the budget constraint $\sum p_i X^i = m$. The resulting demand functions, denoted $X^i(p, m)$, are assumed to be differentiable. The indirect utility function, defined by

$$l(p, m) \equiv U[X^1(p, m), X^2(p, m), \ldots, X^n(p, m)]$$

relates the price and income parameters to the maximum level of utility the consumer can achieve under the resulting budget constraint. Clearly, by nonsatiation, $l(p, m)$ is monotone increasing in income $m$, and decreasing in prices $p$.

The indirect utility function can be used to make statements about individual welfare. Let the base, initial situation be characterized by prices $p^0$ and income $m^0$, while an alternative situation can be summarized by $p', m'$. The economic well-being of the consumer in the different situations can be compared by means of the ordinal ranking of the numbers $l(p^0, m^0)$ and $l(p', m')$.

Another way to effect this welfare test is to compare the income change $m'-m^0$ to the smallest income adjustment needed to make the consumer indifferent to the change in prices from $p^0$ to $p'$. If $m'-m^0$ is larger, then welfare is greater in the new situation, and inversely.

This test level of income adjustment is called the compensating income variation, denoted by $C$ below. Symbolically,

$$(3) \qquad l(p^0, m^0) = l(p', m^0 + C)$$

The welfare test above

$$(4) \quad l(p', m') \gtreqless l(p^0, m^0) \quad \text{as} \quad m' - m^0 \gtreqless C$$

follows immediately from (3) by nonsatiation. Thus the compensating variation is an individual's cost-benefit concept which makes price changes perfectly commensurable with changes in

[3] Or the ratio can be interpreted using the words of Hotelling quoted in fn. 1 as the relative size of the variation.

[4] Formulae (1) and (2) reflect the cautions (see fn. 1) of both Hotelling and Hicks.

income.

Similarly, the equivalent variation in income ($E$) can be defined[5] by

$$(5)\qquad l(p^0, m^0 - E) = l(p', m^0)$$

In words, $-E$ is the income change which has the same welfare impact on the consumer in the base situation as have the changes in prices from $p^0$ to $p'$. It reduces the impacts of different price changes down to the single dimension of income. As such, the equivalent variation concept can be used to rank the consumer's levels of well-being under various sets of prices. With the definitions $l(p^0, m^0-E')=l(p', m^0)$ and $l(p^0, m^0-E'')=l(p'', m^0)$, these welfare tests, too, follow from nonsatiation:

$$(6)\qquad \begin{aligned} l(p', m^0) &\gtreqless l(p'', m^0) \quad \text{as} \quad E'' \gtreqless E' \\ l(p', m^0) &\gtreqless l(p^0, m') \quad \text{as} \quad m^0 - E \gtreqless m' \end{aligned}$$

The welfare tests (4) and (6) show that the compensating and equivalent variations are cost-benefit concepts which can be used to evaluate the impact of microeconomic policy on an individual.[6] These concepts derive practical importance from the fact that they can be estimated from observable consumer's surplus.

## II. Consumer's Surplus

The compensating and equivalent variations can be most incisively studied and related to consumer's surplus by means of the income compensation function.[7] This is denoted by $\mu(p|p^0, m^0)$ and is defined to be the least income required by the consumer when he faces prices $p$ to achieve the same utility level he could enjoy (by maximizing behavior) under the parameters $p^0$, $m^0$. Thus, by definition,

$$(7)\qquad l[p, \mu(p|p^0, m^0)] = l(p^0, m^0)$$

Trivially, we have

$$(8)\qquad \mu(p^0|p^0, m^0) = m^0$$

Now, we can see that the compensating and equivalent variations can be expressed or redefined in terms of the income compensation function. From (3), $m^0+C=\mu(p'|p^0, m^0)$, or combining with (8),

$$(9)\qquad C = \mu(p'|p^0, m^0) - \mu(p^0|p^0, m^0)$$

Similarly, from (5), $m^0-E=\mu(p^0|p', m^0)$, or

$$(10)\qquad E = \mu(p'|p', m^0) - \mu(p^0|p', m^0)$$

These relationships serve as the bridge to consumer's surplus.

It is well known[8] that

$$(11)\qquad \frac{\partial\mu(p|p^0, m^0)}{\partial p_i} = X^i(p, \mu(p|p^0, m^0))$$

This system of partial differential equations, together with the boundary condition (8), is the heart of analytical welfare economics.[9] The compensating and equivalent variations, or any measure of individual welfare that accepts the individual's own consumption preferences, can be calculated from the complete demand functions via (11) and (8).

Restricting attention to changes in a single price, $p_1$, let $p^0=(p_1^0, p_2^0, \ldots, p_n^0)$ and $p'=(p_1', p_2^0, \ldots, p_n^0)$. Use the Fundamental Theorem of Calculus and (11) to rewrite (9) and (10) as

[5] The definitions (3) and (5) correspond to those of Hicks, p. 177, and Samuelson, p. 199.

[6] They also can serve as building blocks for methodologies to make social welfare judgments. The Compensation Principle is a well-known example (see Tibor Scitovsky).

[7] This theoretical tool was introduced by Lionel McKenzie, and definitively studied by Leonid Hurwicz and Hirofumi Uzawa.

[8] See Hurwicz and Uzawa for a state-of-the-art derivation. Heuristically, (11) says that the first-order income change, $d\mu$, required to compensate for the price increase, $dp_1$, is just the augmentation needed to buy the old consumption bundle, $X(p, \mu,(p|p^0, m^0))$, at the new prices $p_1+dp_1, p_2, \ldots, p_n$, rather than at the old prices $p$. The irrelevance to this calculation of the concomitant substitution effects is the result of the envelope theorem.

[9] This point of view was taken by Herbert Mohring.

$$(12)\quad C = \int_{p_1^0}^{p_1'} X^1(p_1, \overset{0}{p_2}, \ldots, \overset{0}{p_n}, \mu(p_1, \overset{0}{p_2}, \ldots, \overset{0}{p_n} \,|\, \overset{0}{p_1}, \overset{0}{p_2}, \ldots, \overset{0}{p_n}, \overset{0}{m}))dp_1$$

$$(13)\quad E = \int_{p_1^0}^{p_1'} X^1(p_1, \overset{0}{p_2}, \ldots, \overset{0}{p_n}, \mu(p_1, \overset{0}{p_2}, \ldots, \overset{0}{p_n} \,|\, p_1', \overset{0}{p_2}, \ldots, \overset{0}{p_n}, \overset{0}{m}))dp_1$$

These formulae express the compensating and equivalent variations as areas under demand curves, between the old and new price horizontals. The demand curves are not Marshallian in that the income parameters are not constant. Instead, they are Hicksian compensated demand curves, because the income parameters include compensation which varies with the price to keep the consumer at a constant level of utility. The only distinction between $C$ and $E$ in (12) and (13) is the level of utility the compensation is designed to reach.

Referring to Figure 1, $C$ is the area $p_1^0 p_1' be$ under the demand curve compensated to $l(p^0, m^0)$. This curve crosses the Marshallian curve $X^1(p, m^0)$ at $p_1^0$, since $\mu(p^0 | p^0, m^0) = m^0$. With $p_1' > p_1^0$, if $X^1$ is noninferior ($\partial X^1/\partial m \geq 0$) this compensated curve lies above the Marshallian one for $p_1 > p_1^0$, since $\mu(p_1, p_2^0, \ldots, p_n^2 | p^0, m^0) \geq m^0$ whenever $p_1 > p_1^0$. Similarly, $E$ is the area $p_1^0 p_1' af$ under the demand curve compensated to $l(p', m^0)$. This Hicksian curve crosses the Marshallian one at $p_1'$, and lies below it for $p_1 < p_1'$. The area usually called consumer's surplus is $p_1^0 p_1' ae$, defined by the observable Marshallian demand curve. Denoting this area by $A$, we have, then, $C \geq A \geq E$, for noninferior $X^1$ (the inequalities reverse for $X^1$ inferior). Of course, it also follows immediately that if there is no income effect ($\partial X^1/\partial m \equiv 0$), $C = A = E$.

These qualitative results may be useful for some cost-benefit analyses. For example, suppose a policy would raise both an individual's income and the price of a noninferior good. If the observable con-

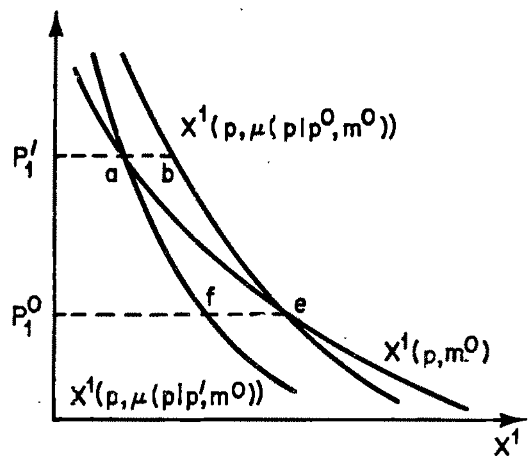

FIGURE 1

sumer's surplus area $A$ were greater than the income boost, it could be inferred from the inequality that $C$ also would be greater. Then, from the welfare test (4), an analyst could conclude that the policy would be injurious to the consumer.

However, usually more information than this is needed about $C$ and $E$. What is required is a methodology to estimate the welfare measures from observable data. In the next section I show how $C$ and $E$ can be explicitly calculated from observables when the income elasticity of demand is constant.

## III. Constant Income Elasticity

Constant income elasticity of demand for $X^1$ means that

$$\frac{\partial X^1(p, m)}{\partial m} \frac{m}{X^1(p, m)} \equiv \eta$$

Then, we have the simple differential equation $dX^1/X^1 = \eta(dm/m)$ which can be integrated from $X^1(p, m^0)$ to yield

$$X^1(p, m) = X^1(p, m^0)\left[\frac{m}{m^0}\right]^\eta$$

The entire income compensation function can be derived by substituting this expression into (11) and solving the result-

ing differential equation with boundary condition (8). We have, suppressing unchanging arguments,

$$\frac{d\mu}{dp_1} = X^1(p_1, \mu) = X^1(p_1, m^0)\left[\frac{\mu}{m^0}\right]^\eta$$

or

$$\mu^{-\eta} d\mu = (m^0)^{-\eta} X^1(p_1, m^0)dp_1$$

Then, integration between $p_1^0$ and $p_1'$, remembering that $\mu(p_1^0) = m^0$, yields

$$(14)\quad \frac{[\mu(p_1')]^{1-\eta} - [m^0]^{1-\eta}}{1-\eta} = (m^0)^{-\eta}\int_{p_1^0}^{p_1'} X^1(p_1, m^0)dp_1$$

for $\eta \neq 1$, and for $\eta = 1$,

$$ln\,\mu(p_1') - ln\, m^0 = \frac{1}{m^0}\int_{p_1^0}^{p_1'} X^1(p_1, m^0)dp_1$$

Hence, after rearranging we have these explicit expressions for the income compensation function:

$$(15)\quad \mu(p_1' \mid p_1^0, m^0) = m^0\left[1 + \left(\frac{1-\eta}{m^0}\right)\int_{p_1^0}^{p_1'} X^1(p_1, m^0)dp_1\right]^{1/1-\eta}$$

$\eta \neq 1$

$$(16)\quad \mu(p_1' \mid p_1^0, m^0) = (m^0)\exp\left[\frac{1}{m^0}\int_{p_1^0}^{p_1'} X^1(p_1, m^0)dp_1\right]$$

$\eta = 1$

These give the welfare measure $\mu$ in terms of the potentially observable constant income elasticity of demand and the consumer's surplus area under the Marshallian demand curve. Let us denote this area by

$$(17)\quad A \equiv \int_{p_1^0}^{p_1'} X^1(p_1, m^0)dp_1$$

From (15), we see that if $\eta = 0$, $\mu(p_1' \mid p_1^0, m^0) = m^0 + A$. However, from (16) we see that if preferences are homothetic, the consequent unitary $\eta$ does not imply any equalities among $C$, $E$, and $A$. Below, for expositional convenience, I ignore the case $\eta = 1$.

Recalling the definitions of $C$ and $E$, (9) and (10), and loosely applying to (15) this Taylor approximation,

$$(1+t)^{1/1-\eta} \approx 1 + \frac{t}{1-\eta} + \frac{\eta t^2}{2(1-\eta)^2}$$

(where $\approx$ means "approximately equal to"), we get:

$$C \approx A + \frac{\eta A^2}{2m^0}, \qquad E \approx A - \frac{\eta A^2}{2m^0}$$

$$\frac{C-A}{A} \approx \frac{\eta A}{2m^0} \quad \text{and} \quad \frac{A-E}{A} \approx \frac{\eta A}{2m^0}$$

This was the striking result on the percentage error of approximating $C$ with $A$ which was previewed in the introduction. The next section will establish this formula rigorously for nonconstant income elasticity of demand.

## IV. Estimation Results

Assume that in the region of price-income space under consideration,[10] $\bar{\eta}$ and $\underline{\eta}$ are upper and lower bounds, respectively, on $(\partial X^1(p, m)/\partial m)(m/X^1(p, m))$, with neither equal to 1.[11] It follows from the Mean Value Theorem that

$$(18)\quad \left(\frac{m_2}{m_1}\right)^{\underline{\eta}} \leq \frac{X^1(p, m_2)}{X^1(p, m_1)} \leq \left(\frac{m_2}{m_1}\right)^{\bar{\eta}} \quad \text{for } m_2 \geq m_1$$

Let us consider the welfare impact of a price increase from $p_1^0$ to $p_1'$. Since $\mu(p_1 \mid p^0, m^0) \geq \mu(p_1^0 \mid p^0, m^0)$ for $p_1 \geq p_1^0$, we can set $m_2 = \mu(p_1)$ and $m_1 = \mu(p_1^0) = m^0$ in (18):

[10] This region is $\{(p, m): p_1 = \alpha p_1^0 + (1-\alpha)p_1', 0 \leq \alpha \leq 1; p_i = p_i^0, i \neq 1; m = \gamma m^0 + (1-\gamma)\mu(p \mid p^0, m^0), 0 \leq \gamma \leq 1;$ and $X^1(p, m) > 0\}$.

[11] Either $\bar{\eta}$ or $\underline{\eta}$ can be arbitrarily close to 1.

$$\left[\frac{\mu(p_1)}{m^0}\right]^{\underline{\eta}} \leq \frac{X^1(p_1, \mu(p_1))}{X^1(p_1, m^0)} \leq \left[\frac{\mu(p_1)}{m^0}\right]^{\bar{\eta}}$$

Rearranging, and substituting from (11) yields

$$0 \leq X^1(p, m^0)^{-\underline{\eta}} \leq \frac{\partial\mu(p)}{\partial p_1}[\mu(p)]^{-\underline{\eta}} = \partial\left[\frac{\mu(p)^{1-\underline{\eta}}}{1-\underline{\eta}}\right] \Big/ \partial p_1$$

and

$$0 \leq \partial\left[\frac{\mu(p)^{1-\bar{\eta}}}{1-\bar{\eta}}\right] \Big/ \partial p_1 = \frac{\partial\mu(p)}{\partial p_1}\mu(p)^{-\bar{\eta}} \leq X^1(p, m^0)(m^0)^{-\bar{\eta}}$$

Integrating these relationships with respect to $p_1$ between $p_1^0$ and $p_1'$ (as in (14)) preserves the inequalities. Rearrangement of the resulting relationships yields these bounds:

$$(19)\quad m^0\left[1 + (1-\underline{\eta})\frac{A}{m^0}\right]^{1/1-\underline{\eta}} \leq \mu(p' \mid p^0, m^0) \leq m^0\left[1 + (1-\bar{\eta})\frac{A}{m^0}\right]^{1/1-\bar{\eta}}$$

provided $\underline{\eta}, \bar{\eta} \neq 1,\ 1 + (1-\underline{\eta})\frac{A}{m^0} > 0$

and $1 + (1-\bar{\eta})\frac{A}{m^0} > 0$

For the case of a price decrease from $p_1^0$ to $p_1'$, since $\mu(p_1 \mid p_1^0, m^0) \leq m^0$ for $p_1 \leq p_1^0$, we can set $m_2 = m^0$ and $m_1 = \mu(p_1)$ in (18), and then follow the same sequence of steps. Once again, (19) emerges, but reference to (17) shows that here $A$ is negative.

Invoking the definition (9), (19) can be rewritten as

$$(20)\quad \frac{\left[1 + (1-\underline{\eta})\frac{A}{m^0}\right]^{1/1-\underline{\eta}} - 1 - \frac{A}{m^0}}{|A|/m^0} \leq \frac{C-A}{|A|} \leq \frac{\left[1 + (1-\bar{\eta})\frac{A}{m^0}\right]^{1/1-\bar{\eta}} - 1 - \frac{A}{m^0}}{|A|/m^0}$$

Also, using (10) and reversing the roles of $p'$ and $p^0$ in (19) (but not in the definition of $A$) gives

$$(21)\quad \frac{\left[1 - (1-\underline{\eta})\frac{A}{m^0}\right]^{1/1-\underline{\eta}} - 1 + \frac{A}{m^0}}{|A|/m^0} \leq \frac{A-E}{|A|} \leq \frac{\left[1 - (1-\bar{\eta})\frac{A}{m^0}\right]^{1/1-\bar{\eta}} - 1 + \frac{A}{m^0}}{|A|/m^0}$$

The measures of a consumer's welfare can be tightly estimated from observables via (19)–(21), regardless of the size of $A/m^0$, if $1 \pm (1-\underline{\eta})A/m^0 > 0$, $1 \pm (1-\bar{\eta})A/m^0 > 0$, and if $\underline{\eta}$, and $\bar{\eta}$ are sufficiently close in value.[12] Of course, in the limit, as $\underline{\eta}$ approaches $\bar{\eta}$, (19) reduces to the constant elasticity formula (15). Moreover, we shall see that if the absolute values of $\underline{\eta}A/2m^0$ and $\bar{\eta}A/2m^0$ are small, then (20) and (21) reduce to elegant rules of thumb.

Table 1 displays the numerical values of the following coefficients for selected choices of $\eta$ and $a$:

[12] The most plausible cause of the negation of these conditions is $(\partial X^1/\partial m)(m/X^1) \to \infty$. However, regions in which $X^1$ is identically zero can be ignored, since there both $\mu$ and $A$ are unchanging. To handle the case in which $X^1 = 0$ and $\partial X^1/\partial m \neq 0$ near the boundary of the relevant region, bounds on $\mu$ can be derived from bounds on $\partial X^1/\partial m$. Because these are generally more gross than (19), the best approach is to take this tack only in the vicinity of the singularity, use (19) on the rest of the path of integration, and splice the sets of inequalities together. The formulae for such procedures can be found in my 1973a, b papers. An explicit solution for $\mu$ when $\partial X^1/\partial m$ is independent of $m$ is also reported there.

[a] Each group of three numbers includes, from the top, $\eta a/2$, $[(1+(1-\eta)a)^{1/1-\eta}-1-a]/a$, and $[(1-(1-\eta)a)^{1/1-\eta}-1+a]/a$. The entry ** indicates that $(1+(1-\eta)a)<0$.

$$\frac{\eta a}{2}, \quad \frac{[1+(1-\eta)a]^{1/1-\eta}-1-a}{a}$$

and

$$\frac{[1-(1-\eta)a]^{1/1-\eta}-1+a}{a}$$

The latter two expressions encompass the forms of the bounds in (20) and (21), when $a$ is interpreted as $|A|/m^0$.[13] It can

[13] For example, the value of the lower bound in (20) when $\eta=2$ and $A/m^0=-.05$ is .048. This can be found in Table 1 as the value of $[(1-(1-\eta)a)^{1/1-\eta}-1+a]/|a|$ when $\eta=2$ and $a=.05$.

be readily seen from the table that for the ranges of parameter values studied,[14] when $|\eta a/2|$ is small (say less than .05), $\eta a/2$ is close enough (within .005) to the actual bounds for most practical purposes. This numerical observation corroborates the loose application to (15) of the Taylor Series expansion in Section III. More importantly, it establishes the rules of thumb previewed in (1) and (2).[15]

Addition of (1) and (2) yields a check on the numerical proximity of $C$ and $E$: when $|\underline{\eta}A/2m^0| \leq .05$, $|\bar{\eta}A/2m^0| \leq .05$, and $|A/m^0| \leq .9$,

$$\frac{\underline{\eta}|A|}{m^0} \leq \frac{C-E}{|A|} \leq \frac{\bar{\eta}|A|}{m^0} \tag{23}$$

So, the analysis hinges on the magnitudes of $\eta$ and $A/m^0$. As discussed in the introduction, in most practical applications $|\eta A/2m^0|$ and $|A/m^0|$ are likely to be small enough for the rules of thumb to apply. If not, equations (19)–(21) and Table 1 will be useful. Even if the calculated error bounds are too large to be ignored, the compensating and equivalent variations may still be usefully estimated from the data via the formulae.

## V. Individual Welfare and Consumer's Surplus

With the approximation results in hand, let us return to the question of how to make statements about individual welfare, based on observable data. Remember from (4) that $l(p', m') \gtreqless l(p^0, m^0)$ as $m' - m^0 \gtreqless C$. With the empirical information that $\underline{C} \leq C \leq \bar{C}$, where $\underline{C}$ and $\bar{C}$ can be calculated from (20) or (22), it can be concluded that

$$\begin{aligned} (24)\quad & l(p', m') > l(p^0, m^0), \quad \text{if } m' - m^0 > \bar{C} \\ & l(p', m') < l(p^0, m^0), \quad \text{if } m' - m^0 < \underline{C} \end{aligned}$$

[14] These seem to include most values that would be found for these parameters in actual applications.

[15] When $|\underline{\eta}A/2m^0| \leq .05$ and $|\bar{\eta}A/2m^0| \leq .05$, it suffices for $1 \pm (1-\underline{\eta})A/m^0 > 0$ and $1 \pm (1-\bar{\eta})A/m^0 > 0$ that $|A/m^0| < .9$.

If $\underline{C}$ and $\bar{C}$ are close in value, (24) provides a welfare test of considerable power.[16] If $|\bar{\eta}A/2m^0|$ and $|\underline{\eta}A/2m^0|$ are small enough, both $\underline{C}$ and $\bar{C}$ can be safely replaced in (24) by $A$. Otherwise, they can be calculated from $\underline{\eta}$, $\bar{\eta}$, $A$, and $m^0$.

To conclude, at the level of the individual consumer, cost-benefit welfare analysis can be performed rigorously and unapologetically by means of consumer's surplus.

[16] Another welfare comparison (which may be useful for an analysis of social welfare with a Bergsonian social welfare function) is made possible by the fact (see Hurwicz and Uzawa) that $\mu(p^0|p, m)$, viewed as a function of $p$ and $m$, is a proper indirect utility function.

$$\mu(p^0|p, m) = E + m$$

where $E$ is the equivalent variation associated with a change from $p^0$ to $p$. Hence this particular ordinal indirect utility function can be exactly expressed by areas under compensated demand curves, as in (13), or it can be estimated from consumer's surplus via (19), (21), or (2).

# Trade and Domestic Effects of the Offshore Assembly Provision in the U.S. Tariff

By J. M. FINGER*

The *U.S.* tariff contains an offshore assembly provision, (*OAP*). The tariff on certain imported goods is charged on the value of such goods *less* the value of incorporated domestically produced components, i.e., the tariff on an assembled product is applied only to the value-added in foreign assembly or processing if domestically produced components are used. Such provisions were included in the 1930 *U.S.* tariff,[1] and they are the subject of continuing controversy. Clauses to repeal the offshore assembly provisions[2] in the *U.S.* tariff were included in the recent Mills and Burke-Hartke trade bills (which were not passed by the Congress), and an unsuccessful attempt was made to include such a repeal clause in the recently passed Trade Reform Act of 1974. The AFL-CIO is actively pursuing the repeal of these provisions.

With an *OAP*, the tariff on an imported good is applied only to the value-added in assembly, *if* domestic components are used. One of its effects then is to reduce the effective rate of protection of the assembly activity, and hence to shift demand from domestic to foreign assemblers. Opponents of the provisions stress the associated displacement of domestic assembly activity and the accompanying negative balance-of-trade impact.[3] They frequently cite the rapid rate of increase of *OAP* imports from developing countries (*LDC*); 60 percent per year over the period 1966–72 as compared with 12 percent for other manufactured imports from *LDC*.[4]

But this "tariff break" is available only if domestic components are used—implying a simultaneous shift of demand from foreign to domestic components. Defenders of the *OAP* stress the associated positive effects on domestic activity and on the balance of payments.

The object of this paper is to estimate the static impact of the *OAP* on domestic economic activity (in assembly and in production of components) and on the balance of trade. Estimates of the effect on domestic economic welfare of the *OAP* will also be presented. The effect on investment flows will be taken into account indirectly by the supply parameters of the model, but will not be explicitly estimated. To measure balance of payments rather than simply the balance-of-trade impact, an

* U.S. Treasury Department.

[1] A history of such provisions is included in the Tariff Commission report.

[2] Item 806.30 of the *U.S.* tariff allows such tariff treatment on metal articles exported by *U.S.* firms for processing abroad by a subsidiary or foreign subcontractor, and returned for further processing by the *U.S.* firm. Item 807.00 allows such tariff treatment on any imported article which contains *U.S.* components, regardless of whether the foreign operation is performed by a *U.S.* subsidiary, a foreign subcontractor, or a foreign firm which purchases *U.S.* components for inclusion in products exported to the United States. Over 90 percent of *OAP* imports enter under item 807.00. There are limits to the sort of processing allowed abroad. For details, see the Tariff Commission report, pp. 9 ff.

[3] Throughout, the "balance-of-payments impact" is understood to be a pressure on the exchange rate under a regime of flexible rates.

[4] For imports from all countries, comparable rates of increase are 24 and 17 percent. *OAP* imports from all countries were \$3.4 billion in 1972—about 9 percent of manufactured imports; *OAP* imports from *LDC* were \$1 billion—22 percent of manufactured imports.

estimate of the effect of *OAP* trade on the profit remittances of foreign subsidiaries would also be required.

In Sections II, III, and IV a comparative statics theory of the incidence of *OAP* is formulated, and expressions for the various effects of their repeal are derived. In Section V the effects are estimated by substituting parameter values into the formulae.

## I. The Model and Assumptions

The model is essentially the fixed coefficients, partial equilibrium, effective protection model with less than perfectly elastic import supplies. In order that the shifts from domestic to foreign assembly and from foreign to domestic components may be analyzed, it must incorporate foreign and domestic assembly and foreign and domestic production of components. It thus consists of five equations: the demand for the finished good,[5] supply functions of foreign and of domestic components, and supply functions of foreign and domestic assembly. The model is completed by aggregating across countries to determine the total supplies of assembly and of components, which are then aggregated vertically to determine the supply of the finished good. The intersection of this curve with the demand function defines market equilibrium.

In analyzing the *OAP* we are looking at final goods which are imported by the United States and contain components exported by the United States. In the language of the model, this makes the United States an exporter of components and an importer of assembly.

Operationally, the distinction between "assembly" and "components" is based on the separation of the dutiable from the duty free value of a finished good imported under the *OAP*. This distinction is then used to specify what is defined as assembly and as components in import replacements (domestic assembly of domestic components) and in non-*OAP* imports of the same final good (foreign assembly of foreign components).[6] *OAP* and non-*OAP* imports and domestic import replacements are assumed perfect substitutes for each other.

For example, suppose shirts imported under *OAP* are made from parts which are cut in the United States from *U.S.* fabric. The parts are then shipped outside of the United States, where they are sewn with foreign thread into shirts. Upon entry into the United States, the tariff is charged on the "final" value of the shirts, less the value of the *U.S.*-made parts. Thus the dutiable value includes foreign-made components as well as assembly cost, in the strict sense of the term. Components therefore refers to the shirt parts and assembly to the thread and the sewing. Because we assume fixed coefficients, and because the same tariff rate (the rate for the finished good) is applied to all segments of the foreign value, it is not necessary to distinguish in the model the thread from the sewing. Imported shirts sewn from foreign cloth (and thus ineligible for *OAP* treatment) contain foreign components (the parts) and foreign assembly (the thread and the sewing). We distinguish in the same way the components from the assembly of domestically produced import replacement shirts.

The "quantity of assembly" is defined as the quantity of finished goods produced (assembled), and the "supply of assembly" relates this quantity to the rate of payment for the assembly process, i.e., to the "piece rate" received by a contract assembler or the difference between the price

[5] "Finished" of course is relative to the process being studied. Whether these are consumption, intermediate, or capital goods is irrelevant for our purposes.

[6] The reason for not assuming that all imports of the finished good contain *U.S.* components (i.e., are *OAP* imports) is empirical. For virtually every 7-digit product for which there are *OAP* imports, there are also non-*OAP* imports.

received for finished articles and the price paid for components by an assembler who works for his own account.[7] Supplies of components are supply functions in the usual sense and the demand for the finished good is a demand function in the usual sense.

The foreign supply functions are defined as export functions—the foreign supply of assembly refers to assembly for export, and the foreign supply of components to the foreign supply net of demand for production for the foreign market.[8]

### A. *Notation*

The notation has been made mnemonic as far as possible. The $P$, $Q$, and $V$ represent prices, quantities, and values, while $T$ is the ad valorem tariff rate applicable to the finished good. The subscripts $d$, $f$, and $t$ distinguish domestic, foreign, and total (sum of foreign and domestic), while $a$ and $c$ identify assembly and components. The subscript $j$ refers to the finished good. Elasticities of supply are represented by $\Phi$; $\Gamma$ is the elasticity of domestic demand for the finished good, defined so as to be negative; $C$ is the component's input-output coefficient, evaluated at foreign prices, i.e., $C=P_{fc}/(P_{fa}+P_{fc})$. The $R_{fa}$ and $R_{fc}$ are shares of imports in total assembly and in total production of components for the *U.S.* market. Starred variables refer to proportionate changes (for example, $V^*=dV/V$) for all variables except $T(T^*=dT/(1+T))$.

### B. *Equations of the Model*

In the case in question, in which domestic components ($DC$) are reimported after assembly abroad, the foreign assembler (or a foreign exporter who buys components and has them assembled into goods for export) can choose between $DC$ and foreign components ($FC$).

If there is no $OAP$, the foreign assembler will always choose the components with the lower price, hence at equilibrium

$$P_{dc} = P_{fc} \tag{1}$$

Because of the domestic economy's tariff on $J$,

$$P_{dj} = (1+T)(P_{fa}+P_{fc}) \tag{2}$$

By definition,

$$P_{da} = P_{dj} - P_{dc} \tag{3}$$

and combining the three equations, we have

$$P_{da} = P_{fa} + T(P_{fa}+P_{fc}) \tag{4}$$

If, however, there is an $OAP$, the foreign assembler can avoid a tariff liability of $T\cdot P_{fc}$ by using $DC$. Hence, at equilibrium (1) is replaced by

$$P_{dc} = (1+T)P_{fc} \tag{5}$$

while (2) and (3) remain relevant, so we have

$$P_{da} = (1+T)P_{fa} \tag{6}$$

Thus the effect of removing the $OAP$ is to "shift" the term $T\cdot P_{fc}$ from the difference between the domestic and foreign prices of components to the difference between the domestic and foreign prices of assembly. This can be treated algebraically by introducing the term $X$, which measures the proportion to which the tariff is a simple tariff on imports of $J$ rather than a tariff with an $OAP$. At one extreme, when $X=1$, the tariff is a "pure" tariff on imports of $J$ without an $OAP$, while at the other extreme when $X=0$, the $OAP$ is in effect. We can thus write

$$P_{dc} = (1+(1-X)T)P_{fc} \tag{7}$$

$$P_{da} = (1+T)P_{fa} + X\cdot T\cdot P_{fc} \tag{8}$$

which with (2) express the equilibrium

[7] The concept of a value-added product basic to such a supply function is explored by Chulsoon Khang.

[8] An equivalent procedure for analytical purposes would be to assume that all production is for *U.S.* consumption, i.e., that products of the type imported under *OAP* are consumed only in the United States.

price relationships of the model, and allow the removal of the $OAP$ (i.e., the comparative statics shift from the "with $OAP$" to the "without $OAP$" case) to be handled by taking the derivative of the model with respect to $X$ ($T$ held constant) and setting $\Delta X=1$.

The behavioral relations of the model are $Hd(P_{da})$ and $Hf(P_{fa})$, the domestic and foreign supplies of assembly; $Gd(P_{dc})$ and $Gf(P_{fc})$, the domestic and foreign supplies of components; and $K(P_j)$, the domestic demand for the finished good.

The total supplies of assembly and components, expressed by substituting for $P_{da}$ and $P_{dc}$ from (7) and (8) as functions of foreign prices are

$$(9) \quad Q_t = G_d[(1+(1-X)T)P_{fc}] + G_f[P_{fc}]$$

$$(10) \quad Q_t = H_d[(1+T)P_{fa} + XTP_{fc}] + H_f[P_{fa}]$$

Note that in (9) and (10) we do not distinguish between the total quantities of assembly and of components. This means that (9) and (10) incorporate the equilibrium condition that these two quantities are equal. Further $Q_t=K(P_j)$ is the equilibrium condition that quantity supplied of $J$ equals quantity demanded.

By definition, $P_j=P_{da}+P_{dc}$. When we substitute for $P_{da}$ and $P_{dc}$ from the equilibrium price relations (7) and (8), we have

$$(11) \quad P_j = (1+T)(P_{fa}+P_{fc})$$

When (11) is substituted into the demand function, we have

$$(12) \quad Q_t = K[(1+T)(P_{fa}+P_{fc})]$$

The initial system contains five behavioral relations (the two $H$, two $G$, and $K$), three definitions (of $P_{da}$, and of the total quantities supplied of assembly and of components), and four equilibrium conditions (equations (7) and (8), plus the implicit equality of the quantity demanded of $J$ with the total quantities supplied of assembly and of components). The variables in this system are $P_{da}$, $Q_{da}$, $P_{dc}$, $Q_{dc}$, $P_{fa}$, $Q_{fa}$, $P_{fc}$, $Q_{fc}$, $P_j$, the quantity demanded of $J$, and total quantities supplied of assembly and of components. In use this system is reduced to the three simultaneous equations (9), (10), and (12) in the variables $P_{fa}$, $P_{fc}$, and $Q_t$. Conceptually, after equilibrium values of these variables are solved for simultaneously, they can be substituted into (7), (8), (11) and the supply functions in order to determine equilibrium values of the other variables.

## II. Effects of the Offshore Assembly Provision

In this model the effects of the $OAP$ are the derivatives with respect to $X$ ($T$ held constant) of the system of equations. The resulting expressions will be evaluated for the case in which $X=0$, initially, but $T>0$. (An $OAP$ cannot be defined when $T=0$.)

After substituting (11) into (12), taking total derivatives of equations (9), (10), and (12), with $T$ held constant, and converting to elasticity terms, we have[9]

$$(13) \quad Q_t^* = \Phi_{tc}P_{fc}^* - \Phi_{dc}R_{dc}\cdot T/(1+T)\cdot dX$$

$$(14) \quad Q_t^* = \Phi_{ta}P_{fa}^* + \Phi_{da}R_{da}(T/(1+T)) \cdot(C/(1-C)dX)$$

$$(15) \quad Q_t^* = (1-C)\Gamma P_{fa}^* + C\Gamma P_{fc}^*$$

### A. *Effects on Prices and Outputs*

The solutions for $P_{fc}^*$ and $P_{fa}^*$ are shown in (16) and (17). If we replace the $dX$ by $\Delta X$ and let $\Delta X=1$, these expressions measure the effects of removing the existing $OAP$, and the assumptions that the $\Phi$ are positive and that $\Gamma$ is negative imply that

[9] From the total supply of components and of assembly functions (9) and (10) we can show that $\Phi_{ta}=R_{da}\cdot\Phi_{da}+R_{fa}\cdot\Phi_{fa}$, and $\Phi_{tc}=R_{dc}\cdot\Phi_{dc}+R_{fc}\cdot\Phi_{fc}$, where $R_{da}=Q_{da}/Q_t$, etc.

$$(16)\quad P^*_{fc} = \left[\frac{-\Gamma[C\cdot\Phi_{da}\cdot R_{da} + (1-C)\Phi_{dc}\cdot R_{dc}] + \Phi_{ta}\cdot\Phi_{dc}\cdot R_{dc}}{-\Gamma[C\cdot\Phi_{ta} + (1-C)\Phi_{tc}] + \Phi_{ta}\cdot\Phi_{tc}}\right]\left(\frac{T}{1+T}\right)dX$$

$$(17)\quad P^*_{fa} = \left[\frac{\Gamma[C\cdot\Phi_{da}\cdot R_{da} + (1-C)\Phi_{dc}\cdot R_{dc}] - \Phi_{tc}\cdot\Phi_{da}\cdot R_{da}}{-\Gamma[C\cdot\Phi_{ta} + (1-C)\Phi_{tc}] + \Phi_{tc}\cdot\Phi_{ta}}\right]\left(\frac{C}{1-C}\right)\left(\frac{T}{1+T}\right)dX$$

$P^*_{fc}>0$ and $P^*_{fa}<0$.

From equations (7), (8), and (11) we derive

$$(18)\quad P^*_{dc} = P^*_{fc} - \left(\frac{T}{1+T}\right)dX$$

$$(19)\quad P^*_{da} = P^*_{fa} + \left(\frac{T}{1+T}\right)\left(\frac{C}{1-C}\right)dX$$

Comparing the numerator and the denominator in both (16) and (17), we see that term by term the numerator of the expression in the square brackets is less in absolute value than the denominator. (For example, $\Phi_{da}\cdot R_{da}<\Phi_{ta}$, $\Phi_{dc}\cdot R_{dc}<\Phi_{tc}$, etc.) The expressions in square brackets in (16) and (17) are thus between 0 and 1 in absolute value, so (18) and (19) imply that $P^*_{dc}<0$, and $P^*_{da}>0$. The solutions for $Q^*_{da}$, $Q^*_{dc}$, $Q^*_{fa}$; $Q^*_{fc}$, have the same sign as the respective price changes, hence there remains only the question of the effect on $P_j$ and $Q_t$ of removing the $OAP$. The expression for the effect on $Q^*_t$ is

$$(20)\quad Q^*_t = \Gamma\cdot C\left[\frac{\Phi_{ta}\cdot\Phi_{dc}\cdot R_{dc} - \Phi_{tc}\cdot\Phi_{da}\cdot R_{da}}{den}\ \frac{T}{1+T}\right]dX$$

The denominator inside the square brackets is the same as in equations (16) and (17).

On closer examination of this expression we find that it is positive or negative as

$$\left(\frac{\Phi_{fa}}{\Phi_{da}}\right)\cdot\left(\frac{R_{fa}}{R_{fc}}\right)\cdot\left(\frac{\Phi_{dc}}{\Phi_{fc}}\right)\cdot\left(\frac{R_{dc}}{R_{da}}\right)$$

is less than or greater than 1.

Because $OAP$ imports contain domestic components and are assembled abroad, we know that $Q_{fc}<Q_{fa}$ and $Q_{da}<Q_{dc}$, i.e., $R_{fc}<R_{fa}$ and $R_{da}<R_{dc}$. This information about the relative positions of the domestic and foreign supply curves does not specify their relative elasticities. But because "assembly" is an activity with a relatively large input of unskilled labor, it seems reasonable to assume that expansion of assembly would require less bidding away of labor from higher paying activities if that expansion took place outside of the United States, i.e., to assume that $\Phi_{fa}>\Phi_{da}$. One is tempted to reason conversely that $\Phi_{fc}<\Phi_{dc}$. The foreign supply of components refers however not only to the labor-rich areas which might have comparative advantage in assembly, but also to industrial countries such as Japan and Germany, and the foreign supply curve is net of foreign demand, hence it is possible that $\Phi_{fc}>\Phi_{dc}$.

We cannot therefore conclude on a priori grounds that $Q^*_t$ is either positive or negative. But because $R_{fa}/R_{fc}$ and $R_{dc}/R_{da}$ are definitely greater than 1, and $\Phi_{fa}/\Phi_{da}$ is likely greater than 1, it seems likely that $Q^*_t/dX$ will be negative and $P^*_t/dX=(1/\Gamma)$. $(Q^*_j/dX)$ will be positive, i.e., that repeal of the $OAP$ will raise the price and reduce domestic consumption of goods imported under the provisions.

### B. *Effect on the Trade Balance*

The supply functions of the model all refer to production of the final good for sale in the U.S. This means that the net value of imports $M$ is equal to $P_{fc}Q_{fc}+P_{fa}Q_{fa}$. From this,

$$(21)\quad M^* = A(1+\Phi_{fa})P^*_{fa} + (1-A)(1+\Phi_{fc})P^*_{fc}$$

where $A$ is the value of assembly as a proportion of net imports. The first term on the right-hand side of (21) measures the effect of the $OAP$ on imports of $FA$; the second term its effect on imports of $FC$.

Because $P^*_{fa}<0$ and $P^*_{fc}>0$, it is clear that the change in the trade balance resulting from elimination of the $OAP$ will not necessarily be positive—the change being larger (in a positive sense) as the elasticities of supply of assembly in the two countries are smaller and as the elasticities of supply of components are larger.

## III. Welfare Effects

Following Harry Johnson's classic article, the net domestic welfare effect of a change in a trade policy variable is the sum of the change of consumers' surplus, the change of producers' surplus, and the transfers of wealth between the domestic and foreign economies associated with the collection of tariff revenue.

### A. *Change of Consumers' Surplus*

The change of consumers' surplus resulting from a policy change is always measured by the change of the area under the demand curve which is above the price paid by the buyer. Thus the gain of consumers' surplus is measured by

$$(-dP_j)Q_t + 1/2(-dP_j)(dQ_t)$$

or in relative terms,

$$(22)\quad \frac{Gain\ of\ CS}{P_jQ_t} = -P_j^*(1 + 1/2\Gamma\cdot P_j^*)$$

where $P_j$, $Q_t$ are the initial values of the variables and the $dP_j$, $dQ_t$ are the results of the change in the policy variables in question.

### B. *Change of Domestic Producers' Surplus*

As an $OAP$ and tariffs with and without $OAP$ will affect the level of $DA$ and of production of $DC$, there will be changes of producers' surplus in each sector. In each sector, the gain of producers' surplus will be equal to

$$(dP)Q + 1/2\,(dP)\cdot(dQ)$$

or, in relative terms

$$(23)\quad \frac{Gain\ of\ PS}{PQ} = P^*(1 + 1/2\,\Phi\cdot P^*)$$

where again $P$ and $Q$ represent initial values, and refer along with $\Phi$ to $DC$ in one case and to $DA$ in the other.

### C. *Transfers Associated with Tariff Revenue*

Figures 1 and 2 will be used to isolate the wealth transfers between the domestic and foreign economies which are associated with the $OAP$. In these figures, the first subscript distinguishes among domestic, foreign, and total (the sum of domestic and foreign) while the second distinguishes among the three policy situations—free trade ($o$), a tariff with $OAP$ ($p$), and a tariff without $OAP(t)$. To reduce the number of lines, the supplies of $DC$ and of $FC$ in Figure 1, and the supplies of $DA$ and $FA$ in Figure 2 have been assumed to be identical.

Because a tariff on $J$ without $OAP$ does not affect the relation between $P_{dc}$ and $P_{fc}$ (see equation (7) with $X=1$), such a tariff will not shift any of the curves in Figure 1. A tariff with an $OAP$ (equation (7) with $X=0$) shifts the supply of $FC$ and hence the total supply of components upwards.

The effects of removing the $OAP$ (with the tariff rate constant) are thus shown by moving from policy "$p$" to policy "$t$." With the $OAP$, the prices in Figure 1 of $DC$ and of $FC$ are $P_{dp}$, and the tariff revenue collected on imports of components is represented by the area $ADFC$. When the $OAP$ is eliminated, there is no longer any tariff revenue on components. The parts of former tariff revenue represented by rectangles $ADEB$ and $NEFM$ are transferred to other domestic uses (involving no change of welfare), while the part repre-

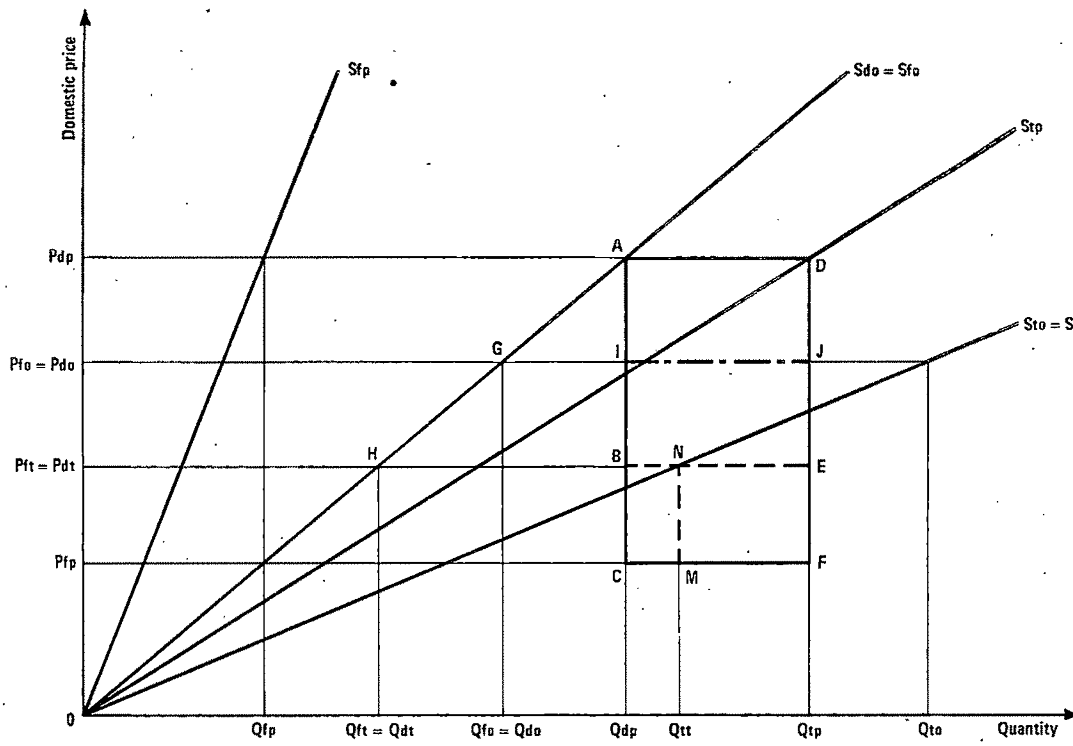

FIGURE 1. EFFECTS ON COMPONENTS

sented by *BNMC* is transferred from tariff revenue to payment for imports—a loss of domestic welfare.

The vertical dimension of the area *BNMC* is the change of the price of *FC* caused by eliminating the *OAP*, while the horizontal dimension is $Q_{tt}$ less $Q_{dp}$ which is equal to $Q_{ft}+Q_{dt}-Q_{dp}$. Changing the sign so that the change is defined as a gain rather than a loss, and converting to relative terms, we have

$$(24)\qquad \frac{Gain}{V_{fc}} = \frac{R_{dc}}{R_{fc}}\left(\frac{1}{1+T}\right)P^*_{fc}Q^*_{dc} - P^*_{fc}(1+Q^*_{fc})$$

In this expression $V_{fc}$ is the value in the $p$ instance, i.e., the instance for which we have observations.

Similarly, in Figure 2 the effects on *DA* of a tariff with and without an *OAP* have been sketched. As equation (8) shows, a tariff with an $OAP(X=0)$ shifts the supply of *FA* leftward, while a tariff without an $OAP(X=1)$ shifts it even further to the left. Tariff revenues in the $t$ and $p$ cases are represented by areas *ABCD* and *EFGH*. When the *OAP* is eliminated, area *IJKL* remains tariff revenue and hence does not involve a welfare change. Area *EILH* is transferred from tariff revenue to suppliers of *DA*, area *EIHL* is shifted from tariff revenue to suppliers of *DA*, area *ABJI* from domestic consumers to tariff revenue and area *JFGK* from tariff revenue to domestic consumers—involving in none of the three instances a change of the total wealth of the domestic

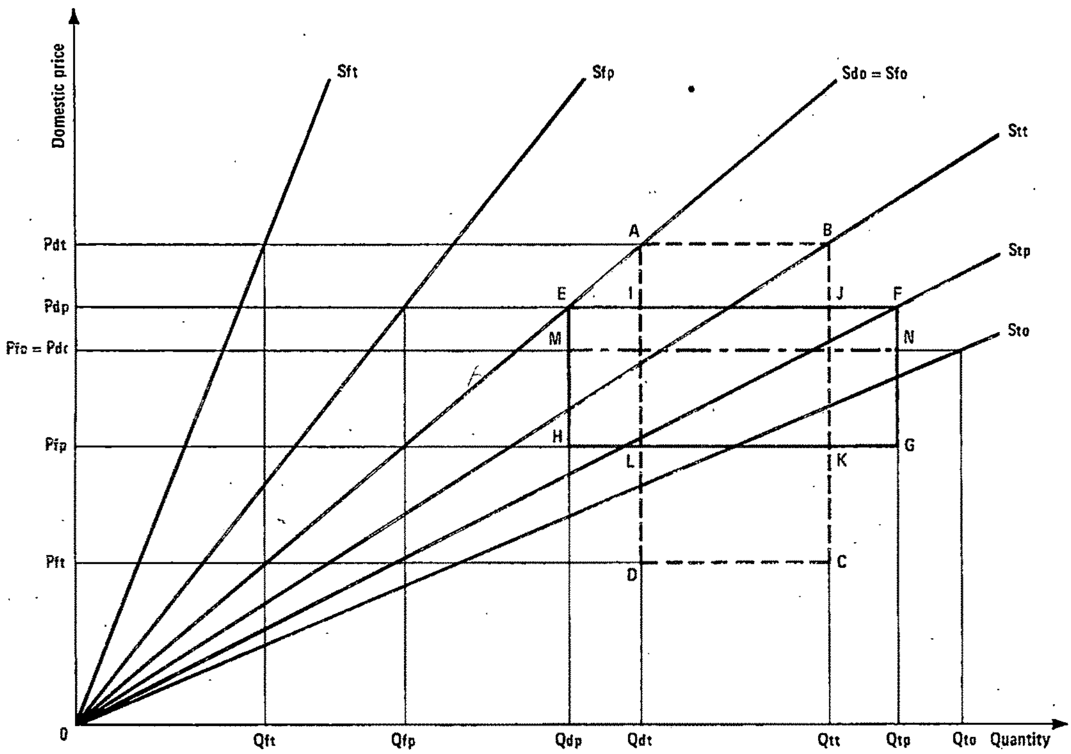

FIGURE 2. EFFECTS ON ASSEMBLY

economy.

Finally, *LKCD* is shifted from receipts of foreign assemblers in exchange for *FA* to tariff revenue—for which foreign assemblers receive no *quid pro quo.* Hence the area *LKCD* represents a welfare gain to the domestic economy. The horizontal and vertical dimensions of this area are $Q_{fa}$ in the *t* case, and the change of $P_{fa}$ caused by eliminating the *OAP*. Converted to relative terms, we have

$$\frac{Gain}{V_{fa}} = - P^*_{fa}(1 + Q^*_{fa}) \tag{25}$$

in which $V_{fa}$ is the value of *FA* in the *p* case.

## IV. Data Inputs and Parameters

### A. *Data*

The basic data used in the study were from the Census Bureau's report of the total and dutiable values of *OAP* imports. These data, plus data for "Directly Competitive Imports" (non-*OAP* imports in those 7-digit *TSUS* categories in which there were *OAP* imports)[10] provided the measures of imports of foreign assembly and of foreign components, and of *C*, the components' input-output coefficient.[11]

Components are identified in the data and therefore in the results only by the industry in which they are used, and not by the industry in which they are produced. It follows that labor-output coefficients could not be identified, and the

[10] I wish to thank the U.S. Tariff Commission and George N. Ecklund, Director of the Office of Economic Research at the Commission, for making these tabulations available.

[11] Tariff data were taken from a GATT tabulation, and import shares data (the parameters $R_{da}$ and $R_{fa}$) were based on data tabulated by the Trade Relations Council. Details of how the data were fitted together are available on request.

estimates of output displacement could not be translated into employment displacement estimates.

### B. *Parameters*

The selection of supply and demand elasticities began with estimates (from the literature) of the elasticity of import demand for finished goods ($\Gamma_m$). This elasticity was decomposed into consistent values for the elasticities of domestic demand ($\Gamma$) for and supply ($\Phi_s$) of finished goods, and the value of $\Phi_s$ was then decomposed into consistent values of $\Phi_{da}$ and $\Phi_{dc}$. Values for $\Phi_{fa}$ and $\Phi_{fc}$ were obtained by similar decomposition of the estimate of the foreign elasticity of export supply of finished goods used by Stephen Magee.[12]

The parameter values on which the results in Tables 1 and 2 are based are[13] $\Gamma=-0.75$, $\Phi_{da}=1$, $\Phi_{dc}=3$, $\Phi_{fa}=40$, and $\Phi_{fc}=10$. A sensitivity analysis indicated that the major conclusions reported below are quite robust with respect to assumed values for these parameters. The same values for these parameters were used for all industries, but the values for $T$, $C$, $R_{da}$, and $R_{dc}$ were specific to the industry.

## V. Results

The results shown in the tables are based on the assumption that $\Phi_{fa}$ and $\Phi_{fc}$ for textile products are restricted to zero by import quotas. Initial calculations using the same parameter values as for the other industries indicated that *OAP* removal would cause *U.S.* imports of foreign assembly of textile products to become negative—i.e., would cause the United States to become a reexporter of textile components produced abroad but assembled in the United States. This result seems to be inconsistent with the generally accepted pattern of *U.S.* comparative advantage and disadvantage, and might be the result of basing the estimates on a situation in which imports of assembly are less than they would be if all variables were at long-run equilibrium values, as the model assumes.

Comparison with the list of textile products subject to import quota[14] indicated an overlap with virtually every category of *OAP* imports, hence the assumption that $\Phi_{fa}$ and $\Phi_{fc}$ are zero for the textile industry. Because this assumption is somewhat tenuous, separate totals with and without textile products, which account for less than 3 percent of *OAP* imports, are given.

Because the ratio of duty-free value (i.e., domestic components) to total value, as given in the second column of Table 1, is very low for motor vehicles and household sewing machines, the tariff saving from the *OAP* is very low and hence the effects of the *OAP* on these industries is slight. In terms of gross value of trade involved, motor vehicles account for almost 40 percent of *OAP* imports. But in terms of the effects of the *OAP*, this industry is an almost insignificant part.

With motor vehicles and household sewing machines (on which the effects of the *OAP* are very slight) excluded, about half the value of imports affected by the *OAP* is assembly and half is foreign components. Thus the effects of the *OAP* on

[12] The reason for using indirect estimates is that more direct ones are not available. The relations involved are

$$\Phi_m = 1/M(\Gamma - \Phi_s) + \Phi_s$$

and

$$1/\Phi_s = ((1 - C)/\Phi_{da}) + C/\Phi_{dc}$$

The first of these is given by Magee and the derivation of the second is available from the author on request. The second expression, with the subscripts appropriately modified, relates $\Phi_{fa}$ and $\Phi_{fc}$ to the foreign elasticity of export supply of the finished good.

[13] This value for $\Gamma$ was used by Magee. The values for $\Phi_{fa}$ and $\Phi_{fc}$ are consistent (by the expression in fn. 12) with Magee's value of 1.5 for $\Phi_s$. The values of $\Phi_{fa}$ and $\Phi_{fc}$ imply a foreign export supply elasticity of the finished good equal to 16, which is slightly higher than the value of 14.4 used by Magee.

TABLE 1—VALUES OF IMPORTS AFFECTED BY THE OFFSHORE ASSEMBLY PROVISION, 1972, AND ESTIMATED EFFECTS ON THE TRADE BALANCE OF THE REMOVAL OF THE OFFSHORE ASSEMBLY PROVISION

(Values in millions of dollars)

| | *OAP* Imports | | | | Effects on imports of removing *OAP* | | |
|---|---|---|---|---|---|---|---|
| Industry | Total value | Duty free value as percent of total value | Tariff rate[a] | Directly competitive imports | Assembly | Components | Total |
| Textile products | 87 | 52 | 26 | 1202 | −60 | 82 | 23 |
| Lumber and paper products | 9 | 63 | 7 | 217 | −61 | 52 | −9 |
| Household sewing machines | 31 | 1 | 6 | 79 | −0.0 | 0.1 | 0.1 |
| Office machinery | 251 | 50 | 5 | 302 | −98 | 62 | −36 |
| Electronic products | 607 | 37 | 7 | 1093 | −122 | 157 | 35 |
| Motor vehicles | 1310 | 2 | 4 | 3488 | −24 | 19 | −5 |
| Aircraft | 109 | 34 | 5 | 365 | −86 | 50 | −35 |
| Other machinery | 557 | 28 | 6 | 5355 | −688 | 616 | −72 |
| Scientific instruments | 17 | 43 | 9 | 156 | −34 | 36 | 2 |
| Sporting goods | 45 | 38 | 14 | 207 | −38 | 52 | 14 |
| Miscellaneous manufactures | 69 | 43 | 13 | 2638 | −844 | 865 | 21 |
| Metal products (item 806.30) | 318 | 59 | 7 | 2247 | −715 | 617 | −98 |
| Total | 3409 | 25 | | 17,350 | −2768 | 2608 | −160 |
| Total excluding textiles | 3322 | 25 | | 16,148 | −2709 | 2526 | −183 |

*Note:* Parameter values are $\Gamma=-.75$, $\Phi_{da}=1$, $\Phi_{dc}=3$, $\Phi_{fa}=40$, $\Phi_{fc}=10$, for all except textile products. For these products, $\Phi_{fa}$ and $\Phi_{fc}$ were assumed restricted to zero by quotas.

[a] Shown in percent.

assembly and on components have a tendency to cancel each other.

### A. *Balance of Trade*

It appears that the balance-of-trade effect of the *OAP* is rather slight. With the parameter values used in Table 1, I estimate that repeal of the *OAP* would have reduced net-imports by less than $200 million in 1972. The estimated increase of imports from repeal of the *OAP* is less than 2 percent of total affected imports (dutiable value of *OAP* imports plus directly competitive imports)—this small net effect resulting from the offsetting changes of imports of assembly and components. By contrast, Magee estimated that removal of the tariff on imports directly competive with *U.S.* production would cause these imports to increase by 65 percent.

The conclusion that repealing the *OAP* would not significantly improve the trade balance was confirmed by the results of the sensitivity analysis. When other "reasonable" parameter values were used, it was often estimated that removal of the *OAP* would increase net imports.

### B. *Domestic Effects*

Estimates of the effects of removal of the *OAP* on domestic consumption and output, and on domestic economic welfare are given in Tables 2a and 2b. For perspective I have listed the value of domestic shipments and the implicit value of domestic output competitive with *OAP* imports,[15] calculated by dividing $V_{fa}$ and $V_{fc}$

[15] Because the $R_{fa}$ and $R_{fc}$ values used were matched as

TABLE 2A—VALUE OF DOMESTIC PRODUCTION DIRECTLY COMPETITIVE WITH *OAP* IMPORTS

(Values in millions of dollars)

| Industry | Value of domestic shipments 1971 (a) | Implicit value in 1972 of domestic output competitive with products imported under *OAP* Total (b) | Assembly (c) | Components (d) |
|---|---|---|---|---|
| Textile products | 27,973 | 4,707 | 2,037 | 2,670 |
| Lumber and paper products | 22,178 | 2,067 | 1,018 | 1,049 |
| Household sewing machines | 143 | 72 | 71 | 1 |
| Office machinery | 7,021 | 3,929 | 1,974 | 1,955 |
| Electronic products | 24,944 | 4,488 | 2,767 | 1,721 |
| Motor vehicles | 60,845 | 28,830 | 28,239 | 591 |
| Aircraft | 15,203 | 5,768 | 3,863 | 1,905 |
| Other machinery | 72,287 | 42,373 | 31,122 | 11,251 |
| Scientific and precision instruments | 12,311 | 967 | 576 | 391 |
| Sporting goods, toys, games | 2,786 | 829 | 534 | 295 |
| Miscellaneous manufactures | 21,470 | 19,363 | 11,729 | 7,634 |
| Metal products (item 806.30) | 42,026 | 20,970 | 8,887 | 12,083 |
| Total | 309,214 | 134,363 | 92,817 | 41,546 |
| Total, excluding textiles | 281,241 | 129,656 | 90,780 | 38,876 |

TABLE 2B—ESTIMATES OF THE EFFECTS ON THE DOMESTIC ECONOMY OF REMOVAL OF THE OFFSHORE ASSEMBLY PROVISION

| Industry | Quantity of $J$ consumed[a] (e) | Assembly Quantity[a] (f) | Assembly Value[b] (g) | Components Quantity[a] (h) | Components Value[b] (i) | Total Quantity[a] (j) | Total Value[b] (k) | Net Welfare Gain[b] (l) |

[b] Values in millions of dollars.

closely as possible with the product composition of imports affected by the *OAP*, they were usually larger than such figures for the entire industry. For this reason, and because imports affected by the *OAP* do not include all imports, the implicit values of affected domestic production are smaller than the values of domestic shipments of each industry.

by $R_{ja}$ and $R_{jc}$, respectively. The estimate for each industry of the effect on total domestic real output (col. (j)) is the average of the changes in real output of assembly and components, weighted by the input-

output coefficients (measured at domestic prices) for assembly and components. The other estimates, of course, were made by substitution of values into the appropriate expressions from Sections III and IV. For the estimates of changes of real output (cols. (f), (h), (j)) the "Total" lines are averages of the industry estimates weighted by the corresponding values from columns (b), (c), or (d).

The estimates indicate rather strongly that if the *OAP* were repealed the output of components would decline sufficiently to more than offset the increase of domestic assembly, so that the net impact would be a slight reduction of real domestic economic activity. Among product groups, the estimated net impact on domestic activity of removal of the *OAP* is positive only for aircraft, and in this case the figure is very small, only 0.05 percent.[16]

The estimated percentage effects on domestic output are relative to the implicit value of domestic output in column (b) rather than to value of total domestic shipments, as given in column (a). The 0.5 percent reduction thus is 0.5 percent of \$134 billion or about \$672 million (at 1972 prices). By comparison, the total value of manufacturers' shipments in 1971 was about \$671 billion.

Repeal of the *OAP* would reduce consumption of products affected by it by about 1 percent, and, as demand is assumed inelastic, would cause consumer expenditure on these products to increase by about \$200 million.

Finally, the welfare calculation in the last column of Table 2b indicates that the *OAP* generated in 1972 a net welfare benefit of about \$400 million. The net loss which would result from its repeal is made up of a \$1,424 million loss of consumers' surplus and a \$346 million transfer loss associated with tariff revenues, partly offset by a gain of producers' surplus of \$1,349 million. The sensitivity analysis again shows that the choice of parameters was not critical.

## VI. Offshore Assembly Provisions as Development Incentives

One is on solid ground to conclude that the United States benefits in a welfare sense from the existence of the *OAP*. I have pointed out elsewhere that in 1972 the value of *U.S.* imports from less developed countries (*LDC*) under the *OAP* was as large as exports of these countries to the European Economic Community (*EEC*) under the *EEC*'s system of tariff preferences, and I have estimated that the *U.S. OAP* generated in 1972 net foreign exchange earnings for *LDC* equal to those generated by the preference system of the *EEC*. And, while *U.S. OAP* imports from the *LDC* have been increasing very rapidly, it has been pointed out frequently that the potential for growth of *LDC* preferential exports to the *EEC* is severely restricted by the ceilings and quotas built into the scheme.[17] Hence it is probable that the *OAP* scheme of the United States at present is a more important contributor to the foreign exchange earnings of the *LDC* than is the *EEC*'s preference scheme, and that the difference is increasing rapidly year by year.

Why then do we observe these tight restrictions placed on preferential imports (indeed, the United States has only recently implemented a limited preference scheme), while *OAP* imports into the United States continue to increase rapidly? To the exporting country, preferences or *OAP* treatment are similar incentives.[18] Tariff preferences allow the *LDC* to compete more effectively with domestic producers in the industrial countries on those

[16] The conclusion that *OAP* removal will reduce domestic activity is reinforced by the sensitivity analysis.

[17] See Richard Cooper and Tracy Murray.

[18] As the *EEC* preference scheme allows generally for 50 percent preferences, and the dutiable value of *U.S. OAP* imports is about 50 percent of total value, the tariff reductions allowed by the two schemes are about equal.

products in which the *LDC* have comparative advantage—provided that these products are not excluded from the preference scheme and that the *LDC* are not required to use components produced domestically at high cost in order to satisfy the "country of origin" requirements of the preference scheme.

As for an *OAP*, it allows the labor rich *LDC* to do the assembly jobs in which they have comparative advantage without subjecting them to the higher effective rates of protection they would face if forced to bear the duty on the value of components which they do not produce.

Of course, this "out" provided by the *OAP* has a catch in it. The *LDC* must use *U.S.* components in order to qualify for the tariff reduction. But the estimates of the impact of the *OAP* on *LDC* exports referred to above indicate that this out with a catch is better than no out at all.

The other side of the *OAP*—its negative impact on production of foreign components—is probably not extremely burdensome to *LDC*. The displacement of foreign components by *U.S.* components in the *LDC* assembling country will often be the replacement by *U.S.* components of Japanese or German components rather than the displacement of components produced by *LDC*. Hence the shifting of the assembly process to the *LDC* will often be a net as well as a gross gain to these countries.

The fact that the *OAP* shifts demand toward domestic components generates domestic political support in the producing sector, which means that an *OAP* is more likely to attract sufficient political push for enactment and expansion than a tariff preference scheme, which has only widely diffused consumer interests and good will to back it.[19]

This suggests that efforts to liberalize *OAP* treatment of articles assembled in *LDC* could produce considerably greater benefits to the *LDC* than have resulted from attempts to negotiate tariff preferences.

[19] Additional support for an *OAP* comes from domestic firms who shift assembly operations to offshore affiliates, but these firms would also benefit from tariff reductions and hence would be expected to also support preferences.

Data are not available which would separate *OAP* imports among those assembled in offshore affiliates of *U.S.* firms, foreign assemblers who work under contract with *U.S.* importers, and foreign firms which buy *U.S.* components on their own account for assembly into product which will be marketed in the United States. The Tariff Commission's report, p. 94, does however state that two-fifths of *OAP* imports of apparel came from foreign establishments in which no financial interest was held by *U.S.* firms.

# Urban Renewal Policy and Economic Efficiency

*By* LAWRENCE D. SCHALL*

It has been argued that slums can arise because property owners seek to maximize their own profits and ignore the impact of their actions (for example, upkeep investment) on the values of surrounding properties; this disregard of "technological" externalities, or spillovers, by owners can produce a slum equilibrium at which maintenance outlays and *total* neighborhood profits are less than would prevail were such externalities internalized (taken into account).[1] Contrary to this view, the arguments of Ronald Coase imply that, with no transaction costs, owners will agree to upgrade their structures to a level maximizing total (joint) profits. With transaction costs, however, it is clear that this may not occur. A common prescription is renewal through a government initiated rehabilitation or redevelopment project.

Existing treatments of externalities and renewal center almost entirely around the competitive market's failure and the state's ability through renewal to internalize the spillover effects. These discussions have ignored three important issues, each of which will be explored in the present paper:

(i) The role of externality relationships in the neighborhood in determining the possible renewal states that can be achieved and maintained by alternative renewal approaches.

(ii) The conditions under which a renewed neighborhood will not revert to a slum even though postrenewal ownership and decision making remain fragmented. If prerenewal failure to internalize externalities produced the slum, the same behavior may imply redeterioration after renewal. It is shown below that the likelihood of postrenewal decay depends on the externality relationships and on the renewal strategy; the externalities will determine whether permanent controls will be needed to sustain renewal under fragmented ownership.

(iii) The method for evaluating both the relative economic efficiency of alternative renewal goals and the techniques for achieving those goals.

In Section I, it is shown that several equilibrium solutions other than the initial slum equilibrium exist for a neighborhood. Each solution is a potential renewal goal. The equilibria that are attainable depend on the nature of the land use spillover effects within the neighborhood. In Section II, and the related appendices, it is shown that the major conclusions of Section I hold under more general assumptions. In Section III, the results are used to develop a general method for evaluating renewal policies. The analysis determines those renewal approaches or strategies that are *effective* in permanently attaining each alternative renewal goal; from the effective approaches, a subset of *efficient*, i.e., cost minimizing, renewal strategies is identified. The renewal approach that is used

* Graduate School of Business, University of Washington. I wish to thank an unknown referee for valuable comments.

[1] See, for example, Otto Davis and Andrew Whinston (1961), Hugh Nourse, and Jerome Rothenberg; see Martin Bailey and the author (1971a) on land use choices and technological externalities. These externalities involve a change in a plot's production possibilities due to an altered neighborhood environment and not due to input price changes ("pecuniary" externalities); on technological externalities, see Buchanan and Stubblebine, E. J. Mishan, and the author (1971c).

should be efficient and the preferred renewal goal (which may be no renewal at all) is that which generates the greatest net benefits given the use of an efficient strategy in achieving that goal. An implication of the analysis is that permanent renewal can be efficiently achieved with fragmented ownership and with no post-renewal controls (private or government) if more than one competitive equilibrium exists for the neighborhood; if no higher competitive equilibrium exists, renewal with fragmented ownership will be inefficient unless long-run controls are imposed.

## I. Neighborhood Spillover Relationships

Four levels of improvement for a neighborhood will be compared: a slum competitive equilibrium ($c$), a higher competitive equilibrium ($c'$), a "cooperative" equilibrium ($o$), and a "state solution" ($s$). A competitive equilibrium involves fragmented ownership of the neighborhood with each owner seeking to maximize his own returns, disregarding the impact of his actions on surrounding property values. Assuming the neighborhood is initially at slum equilibrium $c$, it is shown that a higher competitive equilibrium $c'$ may also exist for the neighborhood. At the cooperative equilibrium $o$, all externalities are taken into account and net returns to property owners are maximized over the entire neighborhood, for example, as would occur with single ownership of the neighborhood or with permanent joint planning by property owners under fragmented ownership. A state solution is an objective that takes into account factors in addition to the net returns of neighborhood property owners (for example, government revenues and income distribution). The government would have to compel owners to maintain a state solution.

It is assumed in this section that all plots in the renewal area are identical, that there is a single land use variable "quality" designated $Q$, and that the neighborhood is small enough so that changes in land use do not affect the prices of land use services in the general metropolitan area. In Section II (and related appendices) it is shown that essentially the same conclusions hold with these assumptions relaxed.

### A. *Competitive Equilibrium*

Assume the competitive equilibrium of a neighborhood with $n$ separate plots. Define $Q_i$ as a quality measure of the structure and grounds of plot $i$. Any level of $Q_i$ implies a particular set of physical characteristics for $i$ with a higher $Q_i$ requiring a greater dollar investment. Define function $I_i(Q_i)$ as the present value of the investment in property $i$ necessary to *achieve and maintain* property $i$ at any quality level $Q_i$ *given the initial competitive equilibrium*, $c$. The net present value of returns from plot $i$ equals

$$(1) \qquad V_i = R_i(Q_i, \overline{Q}_i) - I_i(Q_i)$$

where $R_i(Q_i, \overline{Q}_i)$ is the present value of the revenues (after tax) from plot $i$ and $\overline{Q}_i$ equals the average $Q$ on all other parcels, that is

$$(2) \qquad \overline{Q}_i = [1/(n-1)] \sum_{j \neq i} Q_j$$

$R_i$ therefore depends on the average quality level of other neighborhood properties. Each owner $i$ maximizes $V_i$ with respect to $Q_i$ for any given $\overline{Q}_i$. Setting $\partial V_i/\partial Q_i = 0$ in (1):

$$(3) \qquad \partial R_i/\partial Q_i = \partial I_i/\partial Q_i$$

Equation (3) states that the incremental return to $i$ from $Q_i$ equals the marginal cost of $Q_i$. Schedule $Q_i(c)$ (identical for all $i$ with identical plots) in Figure 1 indicates the level of $Q_i$ satisfying (3) for each level of $\overline{Q}_i$. At $c$, which is on the 45° line, $Q_i = Q_j = Q^c$, all $i, j$ (for proof see Appendix 1).

Slum equilibrium $c$ is stable. Thus, for

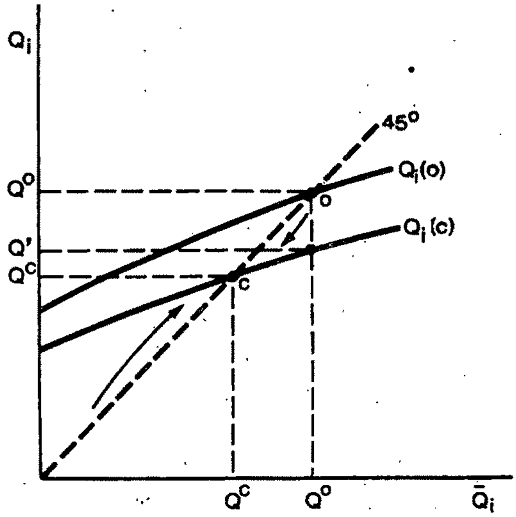

FIGURE 1

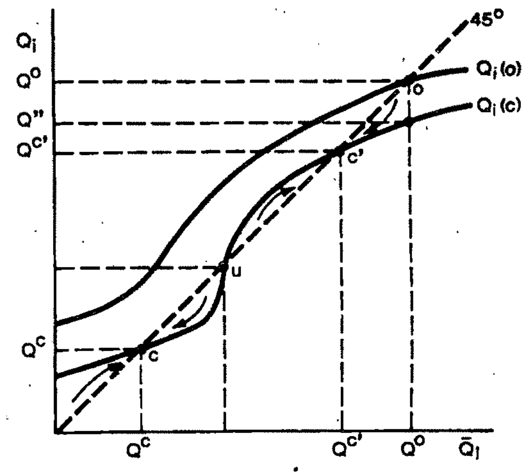

FIGURE 2

example, if $\bar{Q}_i$ were uplifted to $Q^o$, each owner $i$ would maximize his *own* profits by setting $Q_i = Q' < Q^o$. The result would be a deterioration of the neighborhood toward $Q'$. As $\bar{Q}_i$ declines, each owner would seek a $Q_i$ below $Q'$. Eventually the neighborhood would deteriorate to $c$.[2] This result holds for all $\bar{Q}_i > Q^c$ and the arrows in the figure indicate the direction of neighborhood quality change for each existing level of $\bar{Q}_i$. *Permanently uplifting the neighborhood above $Q^c$ must therefore provide for some means to compel competitive owners to maintain that higher $Q_i$.*[3]

Now assume the multiple competitive equilibria case of Figure 2. Equation (3) holds at locally stable competitive equilibria $c$ and $c'$, where $c$ still represents the slum equilibrium. Thus, if $\bar{Q}_i = Q^o$ in Figure 2, owners maximize their own profits by setting $Q_i = Q'' < Q^o$. Over time, the neighborhood declines to $c'$. Point $u$ in Figure 2 is an unstable competitive equilibrium.[4]

To clarify the multiple competitive equilibria concept, assume that all owners simultaneously upgrade their properties from slum level $Q^c$ to $Q^{c'}$. With the neighborhood renewed (rise in $\bar{Q}_i$), the marginal *private* product of investment by each owner has increased.[5] All owners conse-

[2] Only to simplify the discussion, the postrenewal slum is assumed to be the same as prerenewal slum $c$; in actuality, the two slums would differ.

[3] For $\bar{Q}_i < Q_i^c$, Figure 1 implies that owners will improve their properties above the existing $\bar{Q}_i$ until $Q_i^c$ is reached by all. This assumption is not necessary for the points to be made here; schedule $Q_i(c)$ might even lie along the 45° line for $\bar{Q}_i \leq Q_i^c$ in which case all $Q_i \leq Q_i^c$ would be equilibrium levels.

[4] A competitive equilibrium is stable if $0 \leq dQ_i(c)/d\bar{Q}_i < 1$, "system stable" (stable for all $\bar{Q}_i$) if $dQ_i(c)/d\bar{Q}_i = 1$, and unstable if $dQ_i(c)/d\bar{Q}_i > 1$; $c$ and $c'$ are locally stable and $u$ is unstable. To insure stability, it is assumed that all property owners maximize profits under the assumption that their neighbors will maintain their existing levels of $Q$; see Davis and Whinston (1962). It is assumed that $\partial^2 V_i/\partial Q_i^2 < 0$ at $c$ and $c'$, and, at all points, $\partial^2 V_i/\partial\bar{Q}_i\partial Q_i \geq 0$ and $\partial^2 V/\partial\bar{Q}_i\partial Q_i \geq 0$, where $V = \Sigma V_i$. Note that the multiple competitive equilibria case here differs from the Marshallian multiple equilibria for an industry with multiple intersections of a downward sloping demand and downward sloping supply. Prices here can be given even with multiple competitive equilibria, i.e., the area being renewed can be small enough not to alter the price structure for land use services.

[5] Differentiating competitive equilibrium condition $\partial V_i/\partial Q_i = 0$ (used for (3)), $dQ_i(c)/d\bar{Q}_i = -(\partial^2 V_i/\partial\bar{Q}_i\partial Q_i)/(\partial^2 V_i/\partial Q_i^2)$ on schedule $Q_i(c)$. For multiple competitive equilibria, $dQ_i(c)/d\bar{Q}_i > 1$ at some point between $c$ and $c'$;

quently find it profitable to maintain their structures at the new quality level ($Q^{c'}$) as long as their neighbors do likewise. With all owners behaving in this way, $c'$ is a self-sustaining locally stable competitive equilibrium. At $c'$, each owner is maximizing his own profits and is acting competitively, i.e., is *not* taking into account the externalities he is imposing on others. Also, although all $V_i$ are higher at $c'$ than at $c$ (see Section II), the value of the neighborhood is even higher at cooperative equilibrium $o$ ($o$ is discussed below) than at $c'$; at $o$, all marginal externalities are taken into account so as to maximize $V$ ($V=\Sigma V_i$). Nevertheless, as noted in Section III, $c'$ may be preferred to $o$ as a renewal goal because of lower upkeep enforcement costs.

Since all $V_i$ are higher at $c'$ than at $c$, an agreement among property owners (encouraged by the state) could be effected to raise the neighborhood from $c$ to $c'$. Or temporary state incentives (for example, an investment subsidy) could be instituted to produce $c'$. Only *temporary* measures are needed since $c'$ is a stable competitive equilibrium and once attained will be voluntarily sustained by property owners. Without state encouragement, joint property owner action may not arise, even though all would benefit, because of the transaction costs involved. No property owner may himself benefit sufficiently from renewal to initiate cooperative action.

A second competitive equilibrium above slum equilibrium $c$ is not implausible. A shift from $c$ to $c'$ is a transformation to a better neighborhood such as that which might exist (and be in competitive equilibrium) elsewhere in the metropolitan area. Just as most stable well-maintained neighborhoods are sustained without the imposition of upkeep restrictions, it is possible that the same situation is achievable through renewal in a currently deteriorated area. Indeed, there may be several higher competitive equilibria. Whether a $c'$ exists will depend upon such factors as the size of the renewal site, land uses surrounding the neighborhood, and the supply and demand for land use services throughout the metropolitan region.

### B. *Cooperative Equilibrium*

If owner $i$ were to take into account the effect of his investment on the value of the entire neighborhood, $V=\sum_{i=1}^{n} V_i$, then setting $\partial V/\partial Q_i=0$ to maximize $V$ with respect to $Q_i$ for any given level of $\overline{Q}_i$ implies that

$$(4)\qquad \partial R_i/\partial Q_i + \sum_{j\neq i} (\partial V_j/\partial Q_i) = \partial I_i/\partial Q_i$$

where, using (2),[6]

$$\begin{aligned}\partial V_j/\partial Q_i &= (\partial V_j/\partial \overline{Q}_j)(\partial \overline{Q}_j/\partial Q_i)\\ &= [1/(n-1)](\partial V_j/\partial \overline{Q}_j)\end{aligned}$$

Equation (4) states that the incremental return to the *entire neighborhood* from $Q_i$ equals the marginal cost of $Q_i$. Schedule $Q_i(o)$ is above $Q_i(c)$ in Figure 1 or Figure 2, is identical for all $i$, and indicates the level of $Q_i$ satisfying (4) for each level of $\overline{Q}_i$.[7] At cooperative equilibrium $o$ for the neighborhood, $V$ is maximized with respect to all $Q_i$ and (4) holds simultaneously for all

i.e., $\partial^2 V_i/\partial \overline{Q}_i \partial Q_i > -\partial^2 V_i/\partial Q_i^2$ where $\partial^2 V_i/\partial Q_i^2<0$ (by the strict concavity of $V_i$; see fn. 7); thus, the marginal profitability to $i$ of investment in $Q_i$, $\partial V_i/\partial Q_i$, must rise with $\overline{Q}_i$ and by more than the fall in $\partial V_i/\partial Q_i$ due to the increase in $Q_i$. This must hold for $i$ to be willing to increase $Q_i$ from $Q_i^c$ to $Q_i^{c'}$ and to maintain $Q_i^{c'}$.

[6] In this paper, it is assumed that $V=\Sigma V_i$, i.e., with uncertainty total value $V$ is independent of portfolio diversification effects from combining plot incomes; this is relevant with differing plots in Sections II to IV. By the principles of "risk independence" (Stewart Myers) and "value additivity" (the author, 1972a) $V=\Sigma V_i$ if capital markets (but not necessarily the neighborhood property market) are competitive and transaction costless. $V=\Sigma V_i$ may also hold with imperfections (see the author, 1971b).

[7] It is assumed in this section that an improved neighborhood environment raises a property's value, i.e., $\partial V_j/\partial \overline{Q}_j>0$; $V$ and $V_i$ are strictly concave functions of $Q_i$. Therefore, in Figures 1 and 2, schedule $Q_i(o)$ is above $Q_i(c)$ at all points and $Q^o>Q^c$ in Figure 1 and $Q^o>Q^{c'}$ in Figure 2.

plots. At $o$, $Q_i = Q_j = Q^o$, all $i$, $j$ (see Appendix 1).

Since total private (after tax) neighborhood returns are maximized at $o$, equilibrium $o$ will arise with permanent joint planning by property owners or with sole ownership of the neighborhood. Transaction costs of joint action or of effecting single ownership may prevent these outcomes, however. With retention of fragmented ownership, equilibrium $o$ will be permanently maintained only if *permanent* (and enforced) cooperative arrangements between property owners are effected or if the state imposes *permanent* controls to insure $o$. It follows from the earlier discussion that even if all owners uplift their properties to $Q^o$, unless compelled to remain there, each owner will permit his property to deteriorate to $Q'$ in Figure 1 (or to $Q''$ in Figure 2), resulting in an eventual regression to $c$ (or to $c'$ in Figure 2). Thus, with fragmented ownership, temporary owner cooperation or temporary state measures will not permanently maintain $o$.

### C. *State Solutions*

Any renewal objective for the neighborhood other than a competitive or cooperative equilibrium is referred to here as a "state solution" ($s$). A state solution may be preferred if it produces benefits not reflected in the returns to neighborhood property owners ($V$), for example, an improved income distribution, greater government revenues, or greater aesthetic returns to the city's inhabitants. A fundamental distinction between a state solution and the competitive and cooperative equilibria is that, in contrast with the latter outcomes, a state solution can be sustained over time only with *permanent government* intervention. This follows from the above discussion since, with fragmented ownership, $c$, $c'$, or $o$ will arise depending upon the degree of cooperation among owners; with sole ownership, $o$ arises. Therefore, the state must compel owners, for example, by permanent land use controls or fiscal measures (taxes or subsidies), to achieve and maintain any other position.[8]

## II. Generalization of the Model

Section I assumed identical plots, a single land use variable ($Q$), and no change due to renewal in the metropolitan area's price structure for land use services. Relaxing these assumptions does not nullify the general conclusions reached earlier although certain differences do apply. Both {1} and {2} below held in Section I, and, as shown in Appendix 2, {1} and {2} also hold with differing plots, multiple land use variables, and with a change in the price of land use services due to the renewal.[9] Specifically, if (a) for any given price structure for land use services, an increase in investment in property $j$ does not lower the value of property $i$, $i, j = 1, \ldots, n$, $i \neq j$, and if there are marginal externalities at $c$ and $c'$; and (b) the prices of land services in the neighborhood do not fall by too great an amount due to renewal (see Appendix 2C), it follows that:[10]

[8] There may be one or more unstable competitive equilibria for the neighborhood (designated as point $u$ in Figure 2; see fn. 4). Government controls would be necessary to stabilize the system at $u$ (although each property owner maintains his property at the $u$ level given that all other owners do the same). If a stable system is sought for the neighborhood by a renewal authority, $u$ can be viewed as a state solution since stability requires permanent government intervention; $u$ will be treated in Section III as a state solution. On property value relationships for $u$, see fn. 10.

[9] The price impact of renewal depends on the number of slum units removed and of new units created by renewal, the quality of the new units and the elasticities of demand (own and cross) and supply of all types of housing in the metropolitan region. This is analyzed by James Sweeney and the author (1975).

[10] {1} and {2} hold regardless of the number of competitive equilibria. For {1}, $c'$ and $c$ can be interpreted as any two competitive equilibria for which $I_i^{c'} > I_i^c$, all $i$; this includes an unstable competitive equilibrium such as $u$ in Figure 2 and therefore if $I_i^{c'} > I_i^u > I_i^c$, all $i$, then $V_i(c') > V_i(u) > V_i(c)$, all $i$ (to see this, in the Appendix 2 proof, first let $c = u$ and then let $c' = u$). By {2}, investment is greater for some or all $i$ (see condi-

{1} $V_i$ is greater at $c'$ than at $c$, *all i*, where "higher" competitive equilibrium $c'$ is defined to involve greater investment for all $i$.

{2} Investment is greater at $o$ than at $c'$ for *some* plots $i$, i.e., $I_i^o > I_i^{c'}$. Furthermore, if it is also assumed that, for any given price structure for land use services, at equilibrium $c'$ incremental investment on plot $j$ raises the marginal private product of investment on plot $i$, any $i \neq j$, then investment is greater at $o$ than at $c'$ for *all i*, i.e., $I_i^o > I_i^{c'}$, all $i$.[11]

In Appendices 2A, B, and C, {1} and {2} are established for the case in which plots may differ and land use service prices may change due to renewal; a single land use variable $Q$ is assumed. Appendix 2D extends the results of 2A, B, and C to the case of many land use variables.

The general arguments here are similar to those of Section I. {1} states that all property owners benefit from a shift from $c$ to $c'$. A movement from $c$ to $c'$ could be effected by private agreement between property owners or by government incentives, with no controls needed after $c'$ is achieved. In contrast, to maintain $o$ with fragmented ownership of the neighborhood, permanent controls are necessary since property owners benefit by undermaintaining their own structures. Single ownership of the neighborhood would also produce a cooperative equilibrium. To sustain a state solution, permanent government controls compelling owners to remain at that equilibrium are necessary regardless of the number of property owners in the neighborhood.

Even if condition (a) or (b) above is violated and {1} and/or {2} does not hold, there will be a cooperative solution $o$ and may be a higher stable competitive equilibrium $c'$ (or more than one higher competitive equilibrium) to which the state can uplift the neighborhood. If {1} is violated, $c'$ provides lower $V_i$ but involves greater investment than does $c$.[12] In this case, with $c$ and $c'$ stable competitive equilibria, each owner maximizes his own net returns by maintaining his property at equilibrium $c$ quality level if surrounding properties are also at $c$ quality level and by maintaining his property at $c'$ quality level if surrounding properties are also at $c'$ level; this is so even though owners earn more if all properties are at $c$ than at $c'$.[13] Stability of $c$ and $c'$ implies that only a temporary government incentive (for example, a short-term subsidy or tax) is needed to uplift the neighborhood to $c'$ and thereafter to maintain $c'$, since $c'$ will be automatically sustained once it is reached; permanent controls are unnecessary. If {2} does not hold, $o$ will involve an equal or lower level of renewal than solution $c'$. As given in {1} and {2}, $c'$ may be preferred by a renewal agency over $o$ in that permanent controls (private or state) or a change to sole ownership of the renewal area would be required to maintain $o$, but only temporary incentives are needed to permanently establish $c'$. The various factors that are relevant in choosing a re-

tions under {2}) at $o$ than at *any* competitive equilibrium (including the competitive equilibrium with the highest level of investment and including any unstable competitive equilibrium such as $u$); to see that {2} applies to unstable equilibrium $u$, simply let $c' = u$ in the Appendix 2 proof.

[11] Note that the result in the second sentence of {2} does not require that the price structure for land use services remain unchanged; it simply requires that $\partial^2 V_i / \partial I_j \partial I_i > 0$ for any given price structure (see Appendix 2C). Similarly, condition (a) above only requires that $\partial V_i / \partial I_j > 0$ for any given price structure.

[12] Strictly, if {1} is violated it is possible that $V_i$ is the same at $c'$ and $c$ in which case owners are indifferent between the two points.

[13] All $V_i$ can be lower at $c'$ than at $c$ if a fall in the price of land use services due to renewal more than compensates for the improved externalities from the upgraded neighborhood, i.e., if condition (b) and consequently {1} do not hold. If owners anticipate lower $V_i$ at $c'$, they will not seek $c'$ willingly and must be encouraged to do so by the state, e.g., with a temporary subsidy or tax. But once a locally stable $c'$ is achieved, each owner maximizes his own profits by remaining at $c'$ given that all or most of his neighbors do likewise.

newal goal are discussed in Section III.

### III. Implications for Urban Renewal

In this section, the results of Sections I and II are used to analyze the two common renewal techniques: *rehabilitation*, which provides for structure upgrading rather than replacement, with land use forms and ownership left relatively undisturbed; and *redevelopment*, which involves large scale clearance, new land uses, and changed ownership patterns. It is shown that the choices of a method and a level of rehabilitation or redevelopment depend on the externalities generated by the renewal project.

#### A. *Rehabilitation*

The renewal agency has two general means by which it can effect renewal of a neighborhood. First, it can change the private "decision framework" of the neighborhood, and second, it can institute government incentives to encourage owners to renew. The private decision framework of a neighborhood is categorized as $D_1$, fragmented ownership with competition; $D_2$, fragmented ownership with temporary cooperative planning by owners and competition thereafter; $D_3$, fragmented ownership with permanent cooperative planning; and $D_4$, sole ownership of the neighborhood. Decision framework therefore refers both to ownership and planning organization.

Category $D_1$ characterizes the initial slum equilibrium. The state could effect $D_2$ by encouraging an agreement between owners to upgrade their structures to a particular level but with no provision for future maintenance. As explained earlier, assuming no permanent state maintenance controls, this fails to provide lasting improvement with a unique competitive equilibrium since the neighborhood will regress to a slum at $c$; but, it follows from Sections I and II that with multiple competitive equilibria, $D_2$ would lead to a *permanent* shift of the neighborhood to a higher competitive equilibrium at $c'$. Both $D_3$ and $D_4$ result in cooperative equilibrium $o$ (assuming no government controls preventing this outcome) since under either scheme the long-run objective is to maximize total neighborhood returns. Category $D_3$ involves permanently enforced private agreements between owners to maintain $o$. Such agreements are necessary since each owner maximizes his own returns by maintaining his property below the cooperative level as long as other owners remain at the cooperative level.

Government incentives to encourage owners to improve and maintain their properties are categorized as $G_1$, no incentives; $G_2$, temporary incentives; and $G_3$, permanent incentives. The incentive might involve a maintenance subsidy to owners, or a maintenance code with a penalty if violated. An incentive is temporary ($G_2$) if it requires owners to initially upgrade from above $Q^c$ in Figure 1 or 2, with no permanent obligation to maintain that higher level; for example, an upkeep code with a duration of one year is temporary.[14]

The renewal approaches ($(D, G)$ combinations) will now be evaluated in terms of *effectiveness* and *efficiency* in achieving each alternative renewal goal. The renewal goals considered are $c$ (no renewal), $o$, $s$, and with multiple equilibria, $c'$. A given $(D, G)$ is *effective* for a goal only if it *permanently* achieves that goal. Thus, $(D_4, G_2)$ would not be effective in producing $s$ since once the temporary government incentives under $G_2$ expire, the neighborhood's sole owner under $D_4$ would shift to $o$ (to maximum $V$). A given $(D, G)$ is *efficient* in achieving a given goal if it is effective *and* if there is no other effective $(D, G)$ that can always (in all situations) achieve that goal at a lower cost. Note that

[14] Permanent renewal generally means a renewal period of at least twenty or thirty years. A permanent renewal measure remains in effect for the entire renewal period whereas a temporary measure does not.

TABLE 1—EFFECTIVE REHABILITATION OR REDEVELOPMENT STRATEGIES WITH A UNIQUE COMPETITIVE EQUILIBRIUM

| | $G_1$ | $G_2$ | $G_3$ |
|---|---|---|---|
| $D_1$ | $c$ | $c$ | $c, o, s$ |
| $D_2$ | $c$ | $c$ | $c, o, s$ |
| $D_3$ | $o$ | $o$ | $c, o, s$ |
| $D_4$ | $o$ | $o$ | $c, o, s$ |

TABLE 2—EFFECTIVE REHABILITATION OR REDEVELOPMENT STRATEGIES WITH MULTIPLE COMPETITIVE EQUILIBRIA

| | $G_1$ | $G_2$ | $G_3$ |
|---|---|---|---|
| $D_1$ | $c$ | $c, c'$ | $c, c', o, s$ |
| $D_2$ | $c'$ | $c'$ | $c, c', o, s$ |
| $D_3$ | $o$ | $o$ | $c, c', o, s$ |
| $D_4$ | $o$ | $o$ | $c, c', o, s$ |

the $D$ need not be simultaneous with the $G$ in a $(D, G)$ policy; for example, to achieve $o$, $(D_4, G_2)$ may initially involve a temporary government incentive program to encourage owners to upgrade their properties $(G_2)$ followed by a transfer of the neighborhood to a sole owner who maintains the neighborhood at level $o$ $(D_4)$. It is assumed below that renewal does not cause a major decline in the price of land use services throughout the metropolitan region and that therefore $\{1\}$ and $\{2\}$ of Section II hold; relaxing this assumption would cause only a minor change in the results.[15]

1. *Effective Renewal Strategies*

Assuming first a unique competitive equilibrium, it follows from the above discussion that *temporary* measures alone (i.e., $(D_1, G_2)$, $(D_2, G_1)$, or $(D_2, G_2)$) uplifting the neighborhood above $c$ in Figure 1 will result in reversion to $c$. Therefore, only permanent controls—whether private ($D_3$ or $D_4$) or state ($G_3$)—can be effective in producing $o$. To produce $s$, only $G_3$ is effective since owners will never seek $s$ unless encouraged to do so by the state. In Table 1, the entries for any $(D, G)$ indicate the renewal goals ($c$, $o$, or $s$) that the $(D, G)$ can be *effective* in achieving. For each goal, several alternative $(D, G)$ are effective; for example, $s$ can be achieved regardless of $D$ as long as the appropriate incentive under $G_3$ is instituted. Similarly, under $D_3$ or $D_4$ equilibrium $o$ can be produced with $G_1$, $G_2$, or $G_3$. All renewal goals appear in each element of the $G_3$ column since the government can permanently compel (through taxes, subsidies, etc.) owners to achieve any level regardless of $D$.

Consider next the case of multiple competitive equilibria. Since the neighborhood will remain at high equilibrium $c'$ once it is achieved, its permanent attainment does not require permanent state or private measures. Only short-run government incentives or a short-run cooperative effort by property owners (who, as noted earlier, all gain from a movement from $c$ to $c'$) is necessary to achieve $c'$. Table 2 indicates the $(D, G)$ that will achieve each renewal goal assuming the presence of multiple competitive equilibria. Notice that temporary cooperative action by owners under $(D_2, G_1)$ or $(D_2, G_2)$ will result in $c'$ (rather than in $c$ as with a unique competitive equilibrium) because of the gain by all owners from such a shift. Also, as indicated in element $(D_1, G_2)$ in Table 2, short-run government incentives under $G_2$ can result in either $c$ or $c'$. With owners acting competitively $(D_1)$, the incentives must be sufficiently strong if the neighborhood is to rise to $c'$. Weak measures will produce $c$ in the long run.[16]

[15] If prices fall radically then the only change in results is that, as noted in Section II, temporary government incentives may be necessary to achieve $c'$. In this case, $c'$ is to be deleted from the $(D_2, G_1)$ cell in Tables 2 and 3.

[16] The temporary state incentive must be strong enough to elicit investment given the assumption by each owner under $D_1$ that his neighbors will retain their properties in their existing condition. Even if it were

TABLE 3—EFFICIENT REHABILITATION OR REDEVELOPMENT STRATEGIES

| | $G_1$ | $G_2$ | $G_3$ |
|---|---|---|---|
| $D_1$ | $c$ | $c'$ | $o, s$ |
| $D_2$ | $c'$ | $c'$ | $o, s$ |
| $D_3$ | $o$ | $o$ | $s$ |
| $D_4$ | $o$ | $o$ | $s$ |

2. *Efficient Renewal Strategies*

An effective $(D, G)$ is efficient for a particular goal if no other effective $(D, G)$ exists which in all cases is less costly in achieving that goal. There may be more than one efficient $(D, G)$ for a given goal, with one of those efficient $(D, G)$ being the least costly under some circumstances and another of those $(D, G)$ the least costly under different circumstances.

To determine the *efficient* $(D, G)$, the "program costs" (designated $C$) of implementing the $(D, G)$ include $C_d$, the costs of organizing and enforcing private cooperative land use agreements under $D_2$ and $D_3$ and of transferring property rights to a single owner under $D_4$; and $C_g$, the costs of implementing government incentives and insuring that owners achieve and maintain the structure standards set by the state. Thus, $C=C_d+C_g$. Program costs do not include the physical investment in structure improvements (included in $I_i$ in Sections I and II) since these costs are the same for any given structure quality (renewal goal) regardless of the $(D, G)$ employed. It is the program costs $C$ that distinguish the various $(D, G)$ in terms of renewal costs. Program costs as defined here exclude any "social costs" of increased state control or increased private wealth concentration; however, the inclusion of these costs reinforces the results presented here.[17]

For each goal, an effective $(D, G)$ from Tables 1 and 2 is inefficient if it *necessarily* involves greater costs than do one or more of the other $(D, G)$ in achieving that goal. The effective $(D, G)$ that are not inefficient are the efficient $(D, G)$ in Table 3. It is assumed below that the same $(D, G)$ is used and the same equilibrium ($c$, $c'$, $o$, or $s$) is sought for all land use variables and all plots; the effect of relaxing this assumption is discussed at the end of Section IIIA.3. The efficient $(D, G)$ are determined as follows:

$c$: The least cost method for maintaining $c$ is to do nothing: $(D_1, G_1)$. Entry $c$ appears in the $(D_1, G_1)$ cell in Table 3.

$c'$: With multiple competitive equilibria, any approach (for $c'$) in the $D_3$ row or $G_3$ column of Table 2 is inefficient since it involves the short-run task of uplifting the neighborhood to $c'$ as do the temporary measures, but in addition, it involves more costly *permanent* (and unnecessary) private ($D_3$) or government ($G_3$) measures. Only $(D_1, G_1)$, $(D_2, G_1)$, and $(D_2, G_2)$ are efficient. The choice of $(D_2, G_2)$ might minimize costs by providing an initial application of temporary government structure improvement incentives ($G_2$) followed by temporary cooperative action by property owners ($D_2$) once the program has gained momentum.

$o$: With permanent cooperative private planning ($D_3$) or sole ownership ($D_4$), equilibrium $o$ will arise and consequently permanent government measures ($G_3$) are not needed; $(D_3, G_3)$ and $(D_4, G_3)$ are therefore inefficient. Note that $(D_3, G_2)$ and $(D_4, G_2)$ cannot be classified as inefficient since costs might be minimized through short-run government effort to lift the

assumed that each owner anticipates that his neighbor will renew due to the government incentive; the incentive would have to be sufficient to raise investment to a "self-sustaining" level (a $\overline{Q}_i$ greater than that at point $u$ in Figure 2, if the Section I model applies).

[17] Government control increases with higher numbered columns ($G_1$ to $G_2$ to $G_3$) and private wealth concentration increases with higher numbered rows (higher $D$). Including these social costs in $C$ does not alter the Table 3 results since it accentuates the rise in $C$ as column or row numbers increase.

neighborhood to $o$ followed by private enforcement of $o$ over the long term; and $(D_2, G_3)$ might be cost minimizing by providing for a temporary cooperative effort by owners to shift to $o$ with the government enforcing $o$ thereafter. Of the effective strategies for $o$, only $(D_3, G_3)$ and $(D_4, G_3)$ are inefficient.

$s$: None of the $(D, G)$ effective in producing $s$ is inefficient. Even $(D_2, G_3)$ could be cost minimizing by providing some renewal through short-run cooperative action $(D_2)$ followed by implementation and enforcement of an even higher renewal level using permanent government incentives. Therefore, all cells in the $G_3$ column are efficient for $s$.

The $(D, G)$ which minimizes costs for any goal will be one of those indicated in Table 3. For example, to achieve $c'$, $(D_1, G_2)$, $(D_2, G_1)$, or $(D_2, G_2)$ will minimize $C$. Which efficient $(D, G)$ minimizes $C$ will depend upon circumstances; for example, upon the number and cooperativeness of property owners, the dollar costs of private and government enforcement measures, etc. Notice that a particular $(D, G)$ and goal does not imply a unique policy; for example, to reach $o$ under $(D_1, G_3)$, the permanent government controls might involve tax penalties, subsidies, various enforcement and inspection schemes, etc. Consequently, in order to determine the efficient $(D, G)$ which minimizes $C$ *for a particular goal* (signified $(D, G)^*$), two steps are necessary: (i) for each efficient $(D, G)$ (in Table 3), determine the specific policy that achieves the goal with minimum cost; (ii) determine the efficient $(D, G)$ (and its cost minimizing policy determined under (i)) that minimizes $C$ for that goal. For example, if the goal is $o$, under (i) the least cost method for $(D_1, G_3)$ might be a particular subsidy program; the least cost method for reaching $o$ would also be determined for each of efficient strategies $(D_2, G_3)$, $(D_3, G_1)$, $(D_3, G_2)$, $(D_4, G_1)$, and $(D_4, G_2)$. Under step (ii), these six costs would be compared and the least cost efficient $(D, G)$, $(D, G)^*$, would be identified. Thus, $(D, G)^*$ for goal $o$ would be $(D_1, G_3)$ if the subsidy program mentioned above were the least costly of all methods for producing $o$.[18]

### 3. *The Choice of a Renewal Goal*

The selection of a renewal plan will depend upon what is included in benefits and costs and how those benefits and costs are weighted. However, whether Paretian efficiency alone or a social welfare function is the criterion used, program costs $C$ will likely be viewed as outlays to be deducted (along with other costs) from the benefits of a given plan. It follows that only the least cost efficient $(D, G)$, the $(D, G)^*$, are relevant in appraising alternatives. To determine the preferred goal and method of renewal, the net benefits of each possible state solution and of the competitive and cooperative equilibria are estimated by deducting all costs (including $C$) from the related benefits, *assuming the use of the relevant* $(D, G)^*$ *for each goal.*[19] Since all (private and state) revenues and costs must enter the analysis, net benefits must take into account the impact on government receipts and expenses.[20] Furthermore, the costs of renewal include any negative effects on other areas if the slum

[18] The cost comparison of the Table 3 strategies may proceed quickly in some cases. For example, if there are very large setup costs for private $(D)$ or government $(G)$ renewal strategies, it may be clearly uneconomical to use both $D$ and $G$ renewal measures (rather than just one). For rehabilitation in this case, the efficient $(D, G)$ in Table 3 would be: $(D_1, G_1)$ for $c$; $(D_1, G_2)$ and $(D_2, G_1)$ for $c'$; $(D_1, G_3)$, $(D_3, G_1)$, and $(D_4, G_1)$ for $o$; and $(D_1, G_3)$ for $s$.

[19] The number of state solutions is infinite; however, in most actual situations a manageably few state solutions can be identified which are clearly most acceptable (are feasible and yield the greatest net benefits) and these are then analyzed more carefully to determine the best state solution.

[20] On government revenues and renewal, see Groberg, Rothenberg and Slayton. See Jack Hirshleifer (1965, 1966) and Kenneth Arrow and Robert Lind on the appropriate private and public sector discount rates.

relocates to other parts of the city. That goal (which may be no renewal, $c$) with the highest net benefits is chosen:[21]

Solution $o$ which maximizes $V$ would be Pareto optimal assuming the nonexistence of government, zero renewal program costs ($C$), a competitive market for land use services in the metropolitan area, no inefficiencies in other sectors, and no neighborhood "social externalities" (for example, disease, crime, aesthetic costs, or wealth maldistribution due to the slum) at $o$ at nonoptimal levels.[22] However, all of these conditions do not hold in actuality and, therefore, even with Pareto efficiency the standard, cooperative equilibrium $o$ may not be preferred.

It was assumed in the above discussion that the same type of equilibrium ($c$, $c'$, $o$, or $s$) and the same ($D$, $G$) would be applied to all plots and to all land use variables (for example, we would not place structure quality and landscaping at $s$ and refuse control at $c'$). The analysis is more complex if equilibria or ($D$, $G$) differ between plots or variables, but the results in Tables 1, 2, and 3 still hold for each plot and variable. Furthermore, the advantage of using the suggested method (comparing only efficient ($D$, $G$)) is significantly greater in this complex case since many more policy combinations are involved.[23]

### B. *Redevelopment*

The above analysis (including Tables 1, 2, and 3) also applies to redevelopment, which ordinarily involves new land uses and multiple land use variables (see Appendix 2D on multiple variables). Redevelopment may raise the neighborhood to a higher competitive equilibrium or to a cooperative or state solution. In contrast with rehabilitation, however, under redevelopment a higher competitive equilibrium or cooperative equilibrium for all land use variables may fail to adequately approximate the renewal agency's plan for the neighborhood. A state solution will generally be sought by permanently requiring (a $G_3$ strategy) a particular general plan for the neighborhood. It may be that the state plan under $G_3$ covers certain aspects of the neighborhood, for example,

[21] The timing of renewal may affect the choice of a renewal goal since $c$, $c'$, and $o$ may shift over time with changes in the demand and supply for land use services. Also, neighborhood quality may not be static over time even if a given type of equilibrium ($c$, $c'$, $o$, or $s$) is maintained; e.g., maintaining $o$ (maximum $V$) over time may require slow neighborhood deterioration for some period, say sixty years, rejuvenation at time 60, etc. However, as long as the assumptions of the present paper hold at a point in time, {1} and {2} of Section II also hold at that point in time. If neighborhood changes over a renewal period (for example, 50 years) for any given type of equilibrium are small or at least not dominant in relation to the differences between equilibria (e.g., in terms of quality) at any moment in time, equilibrium estimates at the time of renewal can be useful for long range planning. If shifts are rapid, however, the time path of each equilibrium will be required.

[22] Three points are relevant here. First, if there is government, then $V$ (net value of property owner returns) will generally not equal the net value of all (private *and government* (*taxpayers*)) returns and costs from the neighborhood. Second, if the renewal area is large enough that renewal can affect the price structure for land use services, then maximizing $V$ introduces the inefficiencies arising when marginal cost is set equal to a marginal revenue that is less than price. Third, maximizing $V$ may not Pareto optimally deal with "*social externalities*"; Pareto optimality requires that any parties (e.g., taxpayers) desirous of paying for the removal of the externalities do so (e.g., through renewal) if consequently no one else is worse off; on such Pareto optimal wealth transfers, see Kenneth Boulding and the author (1972b).

[23] With differing types of goals ($c$, $c'$, $o$, or $s$) or ($D$, $G$) among land use variables, the following interdependencies are important: (a) the benefits, program costs, and renewal construction costs of any solution ($c$, $c'$, $o$, or $s$) and ($D$, $G$) for a particular variable depends on the solution achieved by all other variables; (b) program costs associated with a given solution and given ($D$, $G$) for a particular variable also depend on the ($D$, $G$) applied to all other variables; and (c) the level achieved by a particular land use variable at $c'$ or $o$ (or at $c$ with redevelopment, which is discussed in Section IIIB) depends on the solution achieved by all other variables. These interdependencies necessitate the comparison of the benefits and costs of all combinations of goals ($c$, $c'$, $o$, and $s$), efficient ($D$, $G$) (from Table 3), and land use variables. The combination with the highest net benefits should be adopted. The number of alternative combinations would be even further expanded if the solution ($c$, $c'$, $o$, or $s$) or ($D$, $G$) for any particular land use variable can differ between plots, e.g., $c'$ on plot $i$ and $o$ on plot $j$ for land use variable $h$.

type of structures, landscaping, parking facilities, but allows nonstate solutions for other land use variables, for example, upkeep, type of lessee tenants, work hours of employees (affecting traffic congestion), etc. The problem for renewal planners is whether a nonstate solution for these latter variables is better than a state solution, and, if so, which solution and policy should be pursued.

To analyze this problem, assume $n$ plots in the neighborhood *after* renewal and $m$ land use variables for each plot, for example, type of structure, quality of structure, and landscaping; define these variables for plot $i$ as $(Q_{i1}, Q_{i2}, \ldots, Q_{im})$. Based on the costs and benefits of various alternatives, the renewal authority establishes a plan under which $(Q_{i1}, \ldots, Q_{if}) \equiv {}_fQ_i$ are fixed at levels $(Q_{i1}^s, \ldots, Q_{if}^s) \equiv {}_fQ_i^s$, each $i$. Vector ${}_fQ_i$ might include type of structure, structure height limit, or quantities of parking and landscaped areas; ${}_fQ_i^s$ may differ between plots. Assume that variables $(Q_{ig}, \ldots, Q_{im})$ are *not* necessarily fixed in the plan, where $(Q_{ig}, \ldots, Q_{im}) \equiv {}_mQ_i$. Vector ${}_mQ_i$ could include structure and landscape upkeep, refuse control, or noise and traffic congestion associated with the use of plot $i$. Points $c$, $c'$, $o$, and $s$ are solutions for the ${}_mQ_i$ *given that* ${}_fQ_i = {}_fQ_i^s$, $i = 1, \ldots, n$. Assume for the moment that the same type of solution ($c$, $c'$, $o$, or $s$) and same $(D, G)$ apply to all $i$ for all land use variables $g$ to $m$.

Competitive equilibria $c$ and $c'$, cooperative equilibrium $o$, and any state solution $s$ are points that the ${}_mQ_i$ (for all plots $i$) can achieve given that ${}_fQ_i = {}_fQ_i^s$, $i = 1, \ldots, n$. The results of Section II fully apply here. As with rehabilitation, $c$, $c'$, or $o$ for the ${}_mQ_i$ may not provide conditions sought by the renewal agency. For example, at $c$ or even at higher competitive equilibrium $c'$, landscaping might be neglected, refuse unremoved, and traffic highly congested due to a failure by competitive property owners to control these factors; similar conditions might prevail at $o$. On the other hand, at one or more of these points ($c$, $c'$, and $o$), conditions might be highly acceptable, i.e., involve well-maintained landscaping, good traffic control, etc. The situations prevailing at $c$, $c'$, and $o$ will depend on the particular circumstances.

The renewal agency has the same $(D, G)$ alternatives for ${}_fQ_i^s$ and ${}_mQ_i$ as exist for rehabilitation. Many property owners (developers) may compete $(D_1)$ or cooperatively plan on a temporary $(D_2)$ or permanent $(D_3)$ basis; or the neighborhood may be transferred to a sole owner $(D_4)$. Government upkeep incentives may not be instituted $(G_1)$ or instituted temporarily $(G_2)$ or permanently $(G_3)$. Tables 1, 2, and 3 still fully apply. Note that the mode of ownership (fragmented under $D_1$, $D_2$, or $D_3$; or single under $D_4$) must be the same for ${}_fQ_i^s$ and ${}_mQ_i$ although, with fragmented ownership, it is possible in general to have different $D$ (of the first three) for different variables in ${}_mQ_i$ ($Q_{ig}$ to $Q_{im}$), for example, temporary cooperative planning $(D_2)$ for trash removal but permanent cooperative planning $(D_3)$ for structure upkeep; Tables 1 to 3 still apply to each land use variable.

As an example, to achieve $c'$ using $(D_1, G_2)$ the renewal authority could require that owners provide for trash removal during the first year after the development's completion. If each property owner maximizes profit by providing his own trash removal *given* that his neighbors do likewise, the state requirement can expire after the year and all property owners will maintain their sanitation facilities (i.e., remain at $c'$). With no such temporary government stipulation, all owners might initially fail to provide cleanup on the assumption that their neighbors planned to do the same, producing a competitive equilibrium $c$ at which all fail to provide for refuse removal.

As with rehabilitation, the benefits and costs (including $C$) of each potential goal ($c$, $c'$, $o$, or $s$) for ${}_mQ_i$ and its least cost

$(D, G)$ must be evaluated, but with only the efficient methods of Table 3 being considered. A cooperative or competitive equilibrium may approximately achieve the goals of the renewal authority and with lower $C$ than under a state solution, for example, if pollution or traffic congestion were limited at either equilibrium.

The analysis and Tables 1, 2, and 3 apply even if the type of equilibrium or the $(D, G)$ differ between plots or between land use variables; the conclusions at the end of Section IIIA concerning this issue also hold here.

## IV. Summary and Conclusions

In addition to their analytical interest, the present results should be helpful in planning actual renewal programs. In determining a plan, only efficient methods need be evaluated. This can greatly reduce the cost of analysis since the efficient set for any goal is appreciably smaller than the total set of possible strategies. Further, because any method that is efficient is also effective, adoption of an approach that will likely result in redeterioration of the neighborhood is avoided. Indeed, as was pointed out earlier, unless multiple competitive equilibria exist for a neighborhood, a renewal program with fragmented property ownership that does not include permanent private or state controls will lead to postrenewal deterioration, i.e., it will be inefficient and ineffective.

As a closing point, although the above analysis was specifically directed to the problem of urban renewal, many of the concepts outlined here are also applicable to the general issue of externalities and public policy. The policy measures utilizing private arrangements between parties and sole owner planning or employing state controls are applicable to most, if not all, cases involving technological externalities. In addition, the selection of policy actions on the basis of effectiveness and efficiency as described here should be appropriate for a wide range of situations in addition to those concerned with urban renewal. The assumptions used in deriving the effective strategies of Tables 1 and 2 and in determining the efficient strategies shown in Table 3 apply regardless of the source of externalities. The approaches in Table 3 are therefore efficient for a variety of situations. These results should be useful since the principle that only efficient strategies need be considered in evaluating alternatives would seem to hold in most cases.

## Appendix

### 1. *Identical Plot Competitive and Cooperative Solutions*

The Section I assumption of identical functions for all plots is not sufficient to insure that $Q_i = Q_j$, all $i, j$, at $c$, $c'$, or $o$. However, with the additional assumptions noted below it is so that $Q_i = Q_j$, all $i, j$, at $c$, $c'$, and $o$. To see this, note from equation (2), $\partial V_i/\partial Q_i = 0$ at $c$ or $c'$ and, from equation (3), $\partial V/\partial Q_i = 0$ at $o$. Differentiating these terms respectively:

$$\text{(A1)} \qquad \frac{dQ_i^c}{d\overline{Q}_i} = -\frac{(\partial^2 V_i/\partial \overline{Q}_i \partial Q_i)}{(\partial^2 V_i/\partial Q_i^2)}$$

$$\text{(A2)} \qquad \frac{dQ_i^0}{d\overline{Q}_i} = -\frac{(\partial^2 V/\partial \overline{Q}_i \partial Q_i)}{(\partial^2 V/\partial Q_i^2)}$$

The denominators of (A1) and (A2) are negative by the strict concavity of $V_i$ and $V$ (see fn. 7). The numerators are nonnegative by assumption (see fn. 4) and therefore (A1) and (A2) are nonnegative, i.e., $dQ_i/d\overline{Q}_i \geq 0$, all $i$, in both (A1) and (A2).

To see that $Q_i = Q_j$, all $i, j$, if $dQ_i/d\overline{Q}_i \geq 0$, all $i$, assume an equilibrium $E_1$ where $Q_g = Q^-$, $Q_k = Q^+ > Q^-$, any $g$, $k = 1, \ldots, n$ and $Q_i = Q_i^1$, all $i \neq g, k$. Since all $V_i$ functions and $I_i$ functions are identical, a second equilibrium $E_2$ must exist at which $Q_g = Q^+$, $Q_k = Q^-$ (same $g$, $k$ as for $E_1$) and $Q_i = Q_i^1$. Therefore, from $E_1$ to $E_2$, $\Delta Q_g = Q^+ - Q^-$, $\Delta Q_k = Q^- - Q^+$, and $\Delta Q_i = 0$, $i \neq g, k$. But this implies:

$$\text{(A3)} \quad (\Delta Q_g/\Delta \overline{Q}_g)$$

$$= \Delta Q_g \Big/ \left(\Delta Q_k + \sum_{i \neq g,k} \Delta Q_i\right)$$
$$= (Q^+ - Q^-)/(Q^- - Q^+) < 0$$

Equation (A3) implies that $dQ_g/d\overline{Q}_g < 0$ for some levels of $Q_g$ and $\overline{Q}_g$ which is inconsistent with the above result that $dQ_g/d\overline{Q}_g \geq 0$. Identical arguments hold for $Q_k$. Therefore, no equilibrium with $Q_g \neq Q_k$, any $g$, $k$, can occur. Hence, $Q_i = Q_j$, all $i$, $j$.

### 2. *Solutions for the General Case*

In Sections A, B, and C below it is assumed that (A4) and (A5) will hold where specifically indicated; land use service price changes are introduced in Section C and multiple land use variables are introduced in Section D.

$$\text{(A4)} \qquad \frac{\partial V_i}{\partial Q_j} \geq 0, \qquad \text{all } i, j, i \neq j$$

with the inequality near $c$ and $c'$

$$\text{(A5)} \qquad \frac{\partial}{\partial Q_j}\left(\frac{\partial V_i}{\partial Q_i}\right) \geq 0, \qquad \text{all } i, j, i \neq j$$

with the inequality near $c$ and $c'$

Let $\hat{Q}_i$ equal $Q$ on all plots other than $i$; $\hat{Q}_i = (Q_1, Q_2, \ldots, Q_{i-1}, Q_{i+1}, \ldots, Q_n)$. Define the net returns to $i$ given that $Q_i = Q_i^x$ and $\hat{Q}_i = \hat{Q}_i^t$ as $V_i(Q_i^x, \hat{Q}_i^t)$ where

$$\text{(A6)} \quad V_i(Q_i^x, \hat{Q}_i^t) = \int_0^{Q_i^x} \left(\frac{\partial R_i}{\partial Q_i}\right)_{\hat{Q}_i^t} dQ_i - I_i^x$$

where

$$(\partial R_i/\partial Q_i)\Big|_{\hat{Q}_i^t}$$

is the change in $R_i$ with respect to $Q_i$ given that $\hat{Q}_i = \hat{Q}_i^t$, $I_i^x$ is $I_i$ given that $Q_i = Q_i^x$, and $V_i = R_i(Q_i, \hat{Q}_i) - I_i(Q_i)$, with $R_i$ and $I_i$ defined in the text; assume that $(\partial I_i/\partial Q_i) > 0$ and $(\partial^2 R_i/\partial Q_i^2) < 0$.

A. *Net returns are greater at $c'$ than at $c$ for all plots, i.e., $V_i(Q_i^{c'}, \hat{Q}_i^{c'}) > V_i(Q_i^c, \hat{Q}_i^c)$, all $i$.* Proof: $V_i(Q_i^{c'}, \hat{Q}_i^{c'}) > V_i(Q_i^c, \hat{Q}_i^{c'})$, all $i$ since $Q_i^{c'}$ maximizes $V_i$ if $\hat{Q}_i = \hat{Q}_i^{c'}$; $V_i(Q_i^c, \hat{Q}_i^{c'}) > V_i(Q_i^c, \hat{Q}_i^c)$ using (A4) since $\hat{Q}_j^{c'} > \hat{Q}_j^c$ ($c'$ is the higher equilibrium). Combining these relations, $V_i(Q_i^{c'}, \hat{Q}_i^{c'}) > V_i(Q_i^c, \hat{Q}_i^{c'}) > V_i(Q_i^c, \hat{Q}_i^c)$; thus, $V_i(Q_i^{c'}, \hat{Q}_i^{c'}) > V_i(Q_i^c, \hat{Q}_i^c)$.

B. *With* (A4), *$I_i$ at $o$ exceeds $I_i$ at $c'$ for some plots $i$, i.e., $I_i^o > I_i^{c'}$, some $i$. With* (A5) *as well as* (A4), *$I_i^o > I_i^{c'}$, all $i$.*

To prove the above, we will prove Propositions (i), (ii), and (iii):

(i) At any point $e$ at which $Q_j^e = Q_j^{c'}$ and $Q_k^e < Q_k^{c'}$, $j$, $k = 1, \ldots, n$, $j \neq k$, $V_i^e < V_i^{c'}$, all $i = 1, \ldots, n$, i.e., all values are less at $e$ than at $c'$. Therefore, point $e$ cannot be cooperative equilibrium $o$ ($V$ is maximized at $o$).

(ii) At any point $w$ at which $Q_j^w \geq Q_j^{c'}$, with the inequality for one to $(n-1)$ of the $j$, and $Q_k^w < Q_k^{c'}$, $j$, $k = 1, \ldots, n$, $j \neq k$, $V_i^w < V_i^z$, all $i$, for point $z$ at which $Q_j^z = Q_j^w$ and $Q_k^z = Q_k^{c'}$. Therefore, point $w$ cannot be point $o$.

(iii) At $c'$, a small increase in all $Q_i$ above $Q_i^{c'}$, $i = 1, \ldots, n$, raises $V$, where the increase in $V$ is greater the larger the number of $Q_i$ increased above $Q_i^{c'}$.

Proposition (i) alone implies that at $o$, $Q_i^o > Q_i^{c'}$, one or more $i$; (i) holds assuming (A4). With (A4) and (A5), (i), (ii), and (iii) hold, implying that $Q_i^o > Q_i^{c'}$, all $i$. This implies that $I_i^o > I_i^{c'}$, all $i$, since $(\partial I_i/\partial Q_i) > 0$.

PROOFS:

(i) At $e$, $Q_j^e = Q_j^{c'}$, $j = 1, \ldots, f$, $Q_k^e < Q_k^{c'}$, $k = f+1, \ldots, n$; therefore $\hat{Q}_j^e < \hat{Q}_j^{c'}$ and $\hat{Q}_k^e \leq \hat{Q}_k^{c'}$, where the inequality holds if there is more than one $k$ plot. For $j = 1, \ldots, f$, $V_j^e \equiv V_j(Q_j^e, \hat{Q}_j^e) = V_j(Q_j^{c'}, \hat{Q}_j^e) < V_j(Q_j^{c'}, \hat{Q}_j^{c'}) \equiv V_j^{c'}$, all $j$, where $Q_j^e = Q_j^{c'}$; the inequality holds applying (1′) since $\hat{Q}_j^e < \hat{Q}_j^{c'}$.

For $k = f+1, \ldots, n$, $V_k^e \equiv V_k(Q_k^e, \hat{Q}_k^e) \leq V_k(Q_k^e, \hat{Q}_k^{c'}) < V_k(Q_k^{c'}, \hat{Q}_k^{c'}) \equiv V_k^{c'}$, all $k$. The first inequality for $k$ holds using (A4) and the fact that $\hat{Q}_k^e \leq \hat{Q}_k^{c'}$; the second inequality holds since $Q_k^{c'}$ maximizes $V_k$ given that $\hat{Q}_k = \hat{Q}_k^{c'}$. Therefore $V_i^e < V_i^{c'}$, all $i = 1, \ldots, n$, and point $e$ cannot be $V$ maximizing point $o$.

(ii) Define: point $w$ at which $Q_j^w \geq Q_j^{c'}$, $j = 1, \ldots, f$, with the inequality for one to $(n-1)$ of the $j$, and $Q_k^w < Q_k^{c'}$, $k = f+1, \ldots, n$; point $z$ at which $Q_j^z = Q_j^w$, $j = 1, \ldots, f$, and $Q_k^z = Q_k^{c'}$, $k = f+1, \ldots, n$, where the $j$ and $k$ relate to the same plots for $w$ and $z$. It fol-

lows that $\hat{Q}_j^w < \hat{Q}_j^z$; and $\hat{Q}_k^w \leq \hat{Q}_k^z$, the inequality holding if there is more than one $k$ plot. It will be shown next that $V_i^z > V_i^w$, all $i$, and therefore $w$ cannot be $V$ maximizing point $o$.

For $j=1, \ldots, f$, it follows from (A4) that $V_j^z \equiv V_j(Q_j^z, \hat{Q}_j^z) > V_j(Q_j^w, \hat{Q}_j^w) \equiv V_j^w$, all $j$, since $Q_j^z = Q_j^w$ and $\hat{Q}_j^z > \hat{Q}_j^w$. For $k=f+1, \ldots, n$, note that $V_k$ is maximized at $Q_k = Q_k^{c'}$ if $\hat{Q}_k = \hat{Q}_k^{c'}$ and therefore for $Q_j^z = Q_j^{c'}$, $V_k(Q_k^z, \hat{Q}_k^{c'}) = V_k(Q_k^{c'}, \hat{Q}_k^{c'}) > V_k(Q_k^w, \hat{Q}_k^{c'})$, i.e., $V_k(Q_k^z, Q_k^{c'}) - V_k(Q_k^w, Q_k^{c'}) \equiv D_1 > 0$. But, using (A5), we know in (A6) that

$$(\partial R_k/\partial Q_k)\Big|_{\hat{Q}_k^z} > (\partial R_k/\partial Q_k)\Big|_{\hat{Q}_k^{c'}}$$

since $\hat{Q}_k^z > \hat{Q}_k^{c'}$; thus, using (A6) $V(Q_k^z, \hat{Q}_k^z) > V(Q_k^z, Q_k^{c'})$. It follows that $V_k(Q_k^z, \hat{Q}_k^z) - V_k(Q_k^w, \hat{Q}_k^z) > D_1 > 0$; that is $V_k(Q_k^z, \hat{Q}_k^z) > V_k(Q_k^w, \hat{Q}_k^z)$. Also, using (A4), since $\hat{Q}_k^z \geq \hat{Q}_k^w$, $V_k(Q_k^w, \hat{Q}_k^z) \geq V_k(Q_k^w, \hat{Q}_k^w)$. Thus, $V_k^z \equiv V_k(Q_k^z, \hat{Q}_k^z) > V_k(Q_k^w, \hat{Q}_k^z) \geq V_k(Q_k^w, \hat{Q}_k^w) \equiv V_k^w$, $k = f+1, \ldots, n$. Therefore $V_j^z > V_j^w$, $j=1, \ldots, f$, $V_k^z > V_k^w$, $k=f+1, \ldots, n$; that is, $V_i^z > V_i^w$, all $i=1, \ldots, n$, and, therefore, point $w$ cannot be $V$ maximizing point $o$.

(iii) Assume initially that $Q_i = Q_i^{c'}$, all $i$ and therefore, $(\partial V_i/\partial Q_i) = 0$, all $i$. Raise $Q_j$ to $Q_j^x$, $Q_j^x > Q_j^{c'}$, any $j=1, \ldots, n$. By (A4), this raises $V$, $V = \Sigma V_i$. For all $Q_k$, $k \neq j$, $\hat{Q}_k > \hat{Q}_k^{c'}$ with $Q_j = Q_j^x > Q_j^{c'}$ and by (A5), $\partial V_k/\partial Q_k > 0$; also, for all rises in any $Q_{k'}$, $k'$ = a particular $k$, there is no decline by (A4) in $V_i$, $i \neq k'$, and there is no decline by (A5) in any $\partial V_i/\partial Q_i$, any $i \neq k'$. Therefore, for some rise in all $Q_k$, $k \neq j$, $\partial V_k/\partial Q_k > 0$, and $\partial V/\partial Q_k > 0$. A rise in all $Q_i$ above $Q_i^{c'}$, all $i=1, \ldots, n$, therefore raises $V$.

C. The proofs above required only (A4) and (A5) and did not require the constancy of the price of land use services. To relate (A4) and (A5) to price changes due to renewal, note that the value of plot $i$ equals $V_i = V_i(Q_i, \hat{Q}_i, P_i)$ where $P_i$ is the price of land use services provided by property $i$. Thus, in (A4),

$$\text{(A7)} \qquad \frac{\partial V_i}{\partial Q_j} = \left(\frac{\partial V_i}{\partial Q_j}\right)_{P_i} + \left(\frac{\partial V_i}{\partial P_i}\right)\left(\frac{\partial P_i}{\partial Q_j}\right)$$

where $(\partial V_i/\partial Q_j)_{P_i}$ is the change in $V_i$ with respect to a change in $Q_j$ given $P_i$. With no price change, $\partial P_i/\partial Q_j = 0$ and, using (A7), (A4) is satisfied if $(\partial V_i/\partial Q_j) = (\partial V_i/\partial Q_j)_{P_i} \geq 0$. Near $c$ and $c'$, $\partial V_i/\partial Q_j > 0$ by (A4). With price changes, to satisfy (A4) (A7) must be positive; that is

$$\text{(A8)} \qquad \left(\frac{\partial P_i}{\partial Q_j}\right) \geq -\frac{(\partial V_i/\partial Q_j)_{P_i}}{(\partial V_i/\partial P_i)}$$

At $c$ and $c'$, $(\partial V_i/Q_j)_{P_i} > 0$ by the assumption that (A4) holds for a fixed $P$; $(\partial V_i/\partial P_i)$ is necessarily positive. Therefore, by (A8), if the change in $P_i$ is not too large a negative magnitude, (A4) is satisfied. To examine (A5),

$$\text{(A9)} \qquad \frac{\partial}{\partial Q_j}\left(\frac{\partial V_i}{\partial Q_i}\right) = \frac{\partial}{\partial Q_j}\left(\frac{\partial V_i}{\partial Q_i}\right)_{P_i} + \left\{\frac{\partial}{\partial P_i}\left(\frac{\partial V_i}{\partial Q_i}\right)\right\}\left(\frac{\partial P_i}{\partial Q_j}\right)$$

With no price changes, $(\partial P_i/\partial Q_j) = 0$ and (A9) is simply (A5) given $P_i$. Earlier, we assumed (A5) to hold for a given $P_i$. If prices do change, then rearranging (A9), (A5) is satisfied if

$$\text{(A10)} \qquad \left(\frac{\partial P_i}{\partial Q_j}\right) \geq -\frac{\dfrac{\partial}{\partial Q_j}\left(\dfrac{\partial V_i}{\partial Q_i}\right)_{P_i}}{\dfrac{\partial}{\partial P_i}\left(\dfrac{\partial V_i}{\partial Q_i}\right)}$$

where the numerator of the right-hand term of (A10) is (A5) for a given $P_i$; this term was assumed positive at $c$ and $c'$ for a fixed $P_i$. The denominator of (A10) is necessarily positive. Thus (A9) and therefore (A5) are positive if $(\partial P_i/\partial Q_j)$ is not too large a negative quantity.

D. The above results also hold with $m$ land use variables. Let vector $Q_i = (Q_{i1}, \ldots, Q_{im})$ where $Q_{ih}$ is land use characteristic $h$, for example, plot size, structure quality, etc. Let $I_i$ be investment on plot $i$ where vector $\hat{I}_i = (I_1, I_2, \ldots, I_{i-1}, I_{i+1}, \ldots, I_n)$. Thus, $\hat{I}_i^{c'} > \hat{I}_i^c$ if $I_j^{c'} > I_j^c$, all $j \neq i$. As before, $V_i = R_i(Q_i, \hat{Q}_i) - I_i$. Analogous to (A4) we assume that

$$\text{(A11)}\quad \frac{\partial V_i}{\partial I_j} = \sum_{h=1}^{m}\left(\frac{\partial V_i}{\partial Q_{jh}}\right)\left(\frac{\partial Q_{jh}}{\partial I_j}\right) \geq 0$$
$$\text{all } i, j, j \neq i; \quad h = 1, \ldots, m$$

and, analogous to (A4), to establish (ii) and (iii) below, we assume that

$$\text{(A12)}\quad \frac{\partial}{\partial I_j}\left(\frac{\partial V_i}{\partial I_i}\right) \geq 0, \qquad \text{for all } i, j, j \neq i$$

where the inequalities hold for changes in $Q_j$ near $Q_j^c$ and $Q_j^{c'}$. At a competitive equilibrium, $\partial V_i/\partial Q_{ih}=0$ and, at $o$, $\partial V/\partial Q_{ih}=0$, all $i=1,\ldots,n$, all $h=1,\ldots,m$, where $V=\Sigma V_i$. The results of Appendix 2A follow as before since $V_i(Q_i^{c'}, \hat{Q}_i^{c'}) = V_i(I_i^{c'}, \hat{I}_i^{c'}) > V_i(I_i^c, \hat{I}_i^{c'}) > V_i(I_i^c, \hat{I}_i^c) = V_i(Q_i^c, \hat{Q}_i^c)$, where, as earlier, the first inequality holds since $I_i^{c'}$ maximizes $V_i$ given that $\hat{I}_i = \hat{I}_i^{c'}$ and the second inequality holds using (A11) and the fact that $\hat{I}_i^{c'} > \hat{I}_i^c$.

The proof in Appendix 2B that $I_i^o > I_i^{c'}$, all $i$, is virtually the same here as before except that investment $I_i$ rather than $Q_i$ is used in the arguments. Only proof of (i) is shown here to illustrate the approach. To show (i), define point $e$ at which $I_j^e = I_j^{c'}$, $j=1,\ldots,f$, and $I_k^e < I_k^{c'}$, $k=f+1,\ldots,n$; therefore, $\hat{I}_j^e < \hat{I}_j^{c'}$ and $\hat{I}_k^e \leq \hat{I}_k^{c'}$, the inequality holding if there is more than one $k$ plot. Thus, for $j=1,\ldots,f$, $V_j^e \equiv V_j(I_j^e, \hat{I}_j^e) = V_j(I_j^{c'}, \hat{I}_j^e) < V_j(I_j^{c'}, \hat{I}_j^{c'}) \equiv V_j^{c'}$, $j=1,\ldots,f$, using (A11) and the fact that $\hat{I}_j^e < \hat{I}_j^{c'}$. For plots $k=f+1,\ldots,n$, $V_k^{c'} \equiv V_k(I_k^{c'}, \hat{I}_k^{c'}) > V_k(I_k^e, \hat{I}_k^{c'}) \geq V(I_k^e, \hat{I}_k^e)$, $k=f+1,\ldots,n$. Thus, $V_j^e < V_j^{c'}$, $j=1,\ldots,f$, and $V_k^e < V_k^{c'}$, $k=f+1,\ldots,n$; that is, $V_i^e < V_i^{c'}$, all $i=1,\ldots,n$.

Propositions (ii) and (iii) are established in an analogous manner, and it follows that assuming (A11) and (A12) investment at $o$ exceeds investment at any competitive equilibrium.

The discussion and conclusions regarding price changes are as in Appendix 2C above except that $I$ instead of $Q$ is used in the equations.

# Regional and Distributional Effects of a Negative Income Tax

By FREDRICK GOLLADAY AND ROBERT HAVEMAN*

Although income transfer policies have economic consequences similar to those of resource-using public expenditures, analyses of their impacts have been narrower in scope. Evaluation of the equity effects of such programs has been limited to an accounting of the primary incidence of transfers and corresponding tax liabilities.[1] Research on their impacts on resource allocation has concentrated on labor supply,[2] headship and family structure,[3] fertility,[4] and migration.[5] It is clear, however, that such programs will provoke a wide variety of other economic adjustments whose net effect on the structure of output and the distribution of income is not readily apparent. Understanding these ultimate effects is essential for designing efficient and equitable income transfer policy.

## I

This paper presents numerical estimates of the micro-economic effects of redistributing purchasing power through a uniform, national program of income supplementation for the poor. The model developed here is rich in descriptive detail; however, because of its complexity, it is not amenable to solution by analytic methods. Moreover the model does not presume rapid, costless readjustment to a new equilibrium. Instead, it explores the sequence of economic decisions which are likely to be made in response to a redistribution of income. It focuses primarily on demand phenomena; it is argued that because of the nature and size of the policy change, neither significant supply responses nor price changes are induced.

The model provides a framework for evaluating income transfer policies which encompasses a wide range of economic impacts not previously considered. The effect of such programs on patterns of consumption expenditure is analyzed, and, by simulating a sequence of responses to these changes, the implications for regional output (by industry), employment (by industry and by occupation), and earnings (by earnings class) are estimated. By focusing on the impact of policy on goods and factor markets, the extent to which behavioral responses and market adjustments induced by the policy tend to reinforce or offset the initial or first-round allocation and distributional effects is determined.

The paper begins with a heuristic statement of the model and a discussion of the differences between its structure and the more familiar Leontief formulation of impact analysis. Then the model is presented formally and its empirical implementation

* Economist, World Bank, and professor of economics and Fellow, Institute for Research on Poverty, University of Wisconsin-Madison, respectively. Kevin Hollenbeck, Economist, Mathematica-Washington, provided extensive assistance. The research was conducted under the sponsorship of the Institute for Research on Poverty, and was supported in part by funds granted to the Institute by the Department of Health, Education, and Welfare pursuant to the Economic Opportunity Act of 1964. We wish to acknowledge the helpful comments on an earlier version of the manuscript of John Bishop, Sheldon Danziger, Irwin Garfinkel, Robert Lampman, Stanley Masters, Eugene Smolensky, and Harold Watts. The opinions expressed are our own.

is described. Finally, some empirical results of the model applied to a negative income tax proposal are reported and analyzed. The relationship of the first-round incidence to the indirect distributional effects of the policy is emphasized, and the impacts of the policy on various regions, industries, and occupations are described.

## II

Public policy measures can be interpreted as exogenous shocks to the economy which induce complex adjustments both in individual and firm behavior, and in markets. Such economic consequences of public sector decisions have been recognized in both regional impact studies[6] and recent analyses of the impact of aggregate economic performance on the size distribution of income.[7] The analytic structure for the former type of study derives from the modified, open Leontief system. The latter type of analysis seeks to translate policy-induced changes in macro-economic variables into changes in the income distribution through reduced form models relating the responses of occupational or demographic groups to aggregate changes. Inherent in both formulations are strong and often unacknowledged assumptions regarding the adjustments required to achieve a new equilibrium. Typically, it is presumed that adjustment will occur rapidly, and that the question of interest is the nature of the new equilibrium.

While the present model employs elements of the Leontief framework, it highlights the short-term adjustment process generated by the policy measure. This is accomplished by characterizing the response to the policy initiative as a sequence of private economic decisions occurring in the short run. Through this emphasis on the sequential nature of induced decisions, the adjustments themselves can be evaluated and the interequilibrium states can be observed.

In a general equilibrium analysis, any disturbance to an initial position would be traced through the series of induced behavioral adjustments, market responses, and income impacts until a new equilibrium position is attained. The framework employed here focuses on adjustments occurring in the initial period only. First, the disbursement of benefits and the incidence of taxes associated with an assumed income redistribution program is traced to individual households classified by income, region, and other socioeconomic characteristics. Then, the induced changes in item expenditures are evaluated for families grouped by region. Such shifts in final demands will call forth increases in the outputs of some industries in some regions and decreases in the outputs of others. These production responses are portrayed by an open interregional input-output system; this presumes that production equilibrium will be achieved within the period of analysis. The demand for labor—sectorally and spatially distinguished—will change in response to induced changes in gross output (by industry and region). Here again a Leontief technology is postulated and it is assumed that markets fully adjust within the period of analysis. As a result of shifts in the demand for labor, earnings flows by earnings class and region of recipient will change and the distribution of earned income will be altered.[8]

## III

The model is composed of five submodels (referred to here as "modules") which portray economic processes from the incidence of the initial transfer to the ultimate impact on the distribution of earnings. These processes are: 1) the direct

[6] See for example, Wassily W. Leontief et al. and William H. Miernyk et al.

[7] See Charles Metcalf and Thad Mirer.

[8] The model could be operated dynamically by introducing a module which would update demographic and economic variables at the end of each period. The system could then be solved recursively.

tax and transfer allocation process; 2) the consumption expenditure process; 3) the sectoral gross output process; 4) the factor demand process; and 5) the regional earnings distribution process.

The *tax-transfer module* simulates the incidence of changes in tax and transfer policies. The eligibility rules and benefit (tax) schedules implied by the policy are applied to a national sample of households, containing detailed information on demographic characteristics, earnings, and nonearned income.[9] From this simulation, estimates of the first-round benefits and tax liabilities generated by the policy are obtained for households classified by race, region, family size, education of the head, and preprogram income level. These estimates presume no work effort,[10] migration, or family structure responses to the program.

Assume $y_s$ is a vector, each element of which is the 1973 income level of a household included in the 1971 Current Population Survey (*CPS*).[11] Each household is indexed by family size, place of residence, marital status, and all other sociodemographic characteristics which enter the eligibility and benefit rules of the transfer and taxation programs to be simulated. Assume $\Phi$ is a diagonal matrix portraying the eligibility rules and benefit (tax) schedules of the program in the form of taxation and/or benefit rates corresponding to each element of $y_s$; $\Phi_{ii}$ (the $i$th element along the diagonal) is the taxation (and/or benefit) rate corresponding to the $i$th element of $y_s$. By premultiplying $y_s$ by $\Phi$, an estimate of the program-induced change in income is obtained for each family in the sample. Call this vector $t_s$.

$$t_s = \Phi \cdot y_s \tag{1}$$

Let $\Omega$ be a diagonal matrix of weights, which when applied to $t_s$ yields national estimates of program induced income changes.

$$t_n = \Omega \cdot t_s \tag{2}$$

The summation of all the elements of $t_n$ yields the total national transfer cost (or tax yield), $t_n^0$, of the program. For the combined transfer and taxation programs analyzed in the study, $t_n^0 = 0$ by assumption.

These estimates of policy-induced changes in family disposable income imply alterations in the level and composition of family consumption expenditures. Such expenditure responses are estimated in the *consumption expenditure module* through the application of savings propensities and marginal budget shares defined on current income to the estimated changes in family income.[12]

In estimating the change in total household expenditures resulting from the policy, all households in the *CPS* file are ag-

[9] Data from the Current Population Survey (*CPS*) were employed in this module. The March 1971 Survey (containing 1970 information on 50,000 family units) was aged to allow for demographic changes, economic growth, and inflation through 1973. In addition, the 6.0 percent unemployment rate of 1970 was adjusted to 4.9 percent by randomly assigning unemployment and duration of unemployment experiences to groups identified by age, sex, occupation, and unemployment experience using the RIM model developed by the Urban Institute. See Nelson McClung, John Moeller, and Eduardo Siquel.

[10] Recent studies indicate negligible reductions in labor supply for male family heads and moderate work effort reductions by spouses in response to income transfers. See Watts et al.

[11] Uppercase Greek letters represent matrices and lowercase Roman letters represent column vectors.

[12] By employing estimates of changes in current income, this approach implicitly assumes that changes in current rather than normal or permanent income motivate consumption behavior. However, if the policy change represents a permanent alteration in the income generation process, the evaluation of normal income will be affected. As a result, families not eligible for benefits in any given year may well experience increments in their normal income because of the policy and, in response, alter their consumption behavior. Moreover, because of transitory shifts in income, the change in normal income may well be quite different than the change in current income for families eligible for benefits in any given year. Simulation estimates of consumption responses to changes in normal income have been developed and, while not presented here, are available from the authors on request. The primary empirical results from this normal income approach are not, in substance, different from those presented here.

gregated into six preprogram income classes, and marginal expenditure propensities specific to each class are applied to the policy-induced change in household disposable income.[13] The resulting change in household expenditure is allocated among individual commodity categories by multiplying the expenditure change by a vector of marginal budget shares specific to the income class of the household.[14] From this calculation, induced changes in expenditures by detailed commodity categories are obtained for each household. By aggregating these vectors over all the family units in a region, a vector of policy-induced changes in expenditures within a region for each of 79 commodities is obtained.

More formally, let $M$ be a diagonal matrix in which the $i$th element along the diagonal is the estimated marginal propensity to consume from current income for the $i$th household. The elements of $M$ can assume one of six values depending on the pretransfer income class to which the corresponding household belongs. By premultiplying $t_n$ from the transfer module by $M$, the household consumption expenditure induced by the tax-transfer program is estimated for each weighted observation. This vector is represented by $c$.

$$c = M \cdot t_n \tag{3}$$

Summing the elements of $c$ yields $c^0$, an estimate of total national personal consumption expenditure induced by the program.

The estimated changes in aggregate household expenditure by region are allocated among individual commodity categories by multiplying the estimated change in total expenditure for each of the income groups in any region by a vector of estimated marginal budget shares for the 79 commodity categories for that income class. First, the vector $c$, which is indexed by region and income, is aggregated over households to form a new vector $\hat{c}$ of aggregate expenditures by region and income class. This is accomplished by premultiplying $c$ by an operator matrix $\Sigma$.

$$\hat{c} = \Sigma \cdot c \tag{4}$$

The marginal budget shares estimated from empirical data are used to construct a block diagonal matrix $\beta$. Each block along the diagonal is a submatrix of marginal budget shares for a region. The $i$th row of a submatrix is the vector of budget shares for the $i$th income class for that region. By premultiplying $\hat{c}$ by $\beta$ we obtain $e$, the vector of commodity specific expenditures of each region.

$$e = \beta \cdot \hat{c} \tag{5}$$

where

$$\beta = \begin{bmatrix} \beta_1 & & & & O \\ & \beta_2 & & & \\ & & \beta_3 & & \\ & & & \ddots & \\ O & & & & \beta_r \end{bmatrix}$$

[13] The marginal propensities are based on analysis of the 1960–61 Survey of Consumer Expenditures reported by Irwin Friend and Ronald Jones. They represent current expenditure out of current income. In the lowest income class where approximately a third of the households have higher permanent incomes, the marginal propensities are in excess of unity. The marginal propensities were adjusted for price level changes between 1960–61 and 1973. For the six preprogram income classes (in 1960–61 dollars), the marginal propensities are; less than \$2,500, 1.09; \$2,500–\$3,500, 1.01; \$3,500–\$4,500, .89; \$4,500–\$6,250, .84; \$6,250–\$8,750, .70; \$8,750 or more, .57.

[14] The marginal budget share vectors are obtained from a piecewise loglinear regression analysis in which household expenditures on each of 56 commodities were regressed against family income, family size, education of head, home ownership, region, age of head, and urban-rural location. The regression model was chosen to accommodate nonlinearities observed in previous studies and was patterned after that developed in John Moeller. The analysis employed household data from the 1960–61 Survey of Consumer Expenditure file containing commodity expenditure estimates for 343 categories and 14,000 consumer units.

$$(6) \qquad \beta_i = \begin{bmatrix} \overset{a}{b_1} & \overset{b}{b_1} \dots & \overset{n}{b_1} \\ \overset{a}{b_2} & & \\ \vdots & & \\ \overset{a}{b_6} & \dots\dots & \overset{n}{b_6} \end{bmatrix}$$

and in which $\overset{h}{b_g}$ is the marginal budget share for commodity $h$ and income class $g$. The marginal budget shares are obtained from marginal propensities to spend by commodities and hence sum to unity. It is assumed that $\beta_1=\beta_2= \dots =\beta_r$.

Policy-induced changes in the commodity and regional composition of consumption expenditures affect the demand for outputs of individual firms and result in a revised pattern of production throughout the economy. The ultimate impact of these changes on the structure of production is obscured by the complexity of interindustry and interregional dependencies. In the *regional gross output module*, the indirect regional and industrial production responses to changes in commodity expenditures are estimated.

The empirical module is adaptated from the Multi-Regional Input-Output Model (*MRIO*).[15] This model relies on a Leontief production technology—implying linearity, additivity, and nonsubstitutability—for each of 79 sectors in each of 44 regions.[16] The input-output requirements for the several sectors of this model were estimated individually for each region.[17] Trading patterns were estimated by dividing shipments from each region to each region by total uses in the receiving region; the column sum of the coefficients is therefore unity.[18]

The product of a block diagonal matrix of input-output coefficients with a matrix of trade coefficients estimates the input by commodity and origin per unit of output by sector. Solution of the Leontief equation then reveals the gross output by region and sector required to satisfy the increment to final demand.

In the previous module, policy-induced consumption demands were estimated for each of 79 production sectors in each of 23 regions and summarized in an 1817 element vector $e$ (equation (5)). Let $\Gamma$ be a square matrix of dimension 1817 x 1817 composed of 79 x 79 diagonal submatrices. Each element $(\Gamma_i^{gh})$ describes the fraction of total uses of commodity $i$ in region $h$ that is imported from region $g$. Further define $\hat{A}$ to be a block diagonal matrix (1817 x 1817) with 23 square submatrices (79 x 79) of input-output coefficients along the diagonal describing the structure of production in each region.

$$(7) \qquad \underset{1817 \times 1817}{\hat{A}} = \begin{bmatrix} A^1 & & & \bigcirc \\ & A^2 & & \\ & & \ddots & \\ \bigcirc & & & A^{23} \end{bmatrix}$$

$$\underset{79 \times 79}{A^r} = \begin{bmatrix} \overset{r}{a}_{1,1} & \dots & \overset{r}{a}_{1,79} \\ \vdots & & \vdots \\ \overset{r}{a}_{79,1} & \dots & \overset{r}{a}_{79,79} \end{bmatrix}$$

$$\underset{1817 \times 1817}{\Gamma} = \begin{bmatrix} \hat{\Gamma}^{1,1} & \hat{\Gamma}^{1,2} & \dots & \hat{\Gamma}^{1,23} \\ \hat{\Gamma}^{2,1} & \hat{\Gamma}^{2,2} & \dots & \hat{\Gamma}^{2,23} \\ \vdots & \vdots & & \vdots \\ \hat{\Gamma}^{22,1} & \hat{\Gamma}^{21,2} & \dots & \hat{\Gamma}^{22,23} \\ I & I & \dots & I \end{bmatrix}$$

$$(8) \qquad \underset{79 \times 79}{\Gamma^{xy}} = \begin{bmatrix} \Gamma_1^{xy} & & & \bigcirc \\ & \Gamma_2^{xy} & & \\ & & \ddots & \\ \bigcirc & & & \Gamma_{79}^{xy} \end{bmatrix}$$

[15] This model is described in Karen Polenske (1975).

[16] In order to ensure conformability between the regional breakdown in the prior modules and this module, it was necessary to reduce the dimensionality of the regionalization from 44 to 23. Aggregation was in transactions and shipments form.

[17] The regional technical coefficients are based upon the 1963 input-output study for the United States and upon sector studies for agriculture, mining, and construction. See Polenske (1974).

[18] The interregional trade flows are from a study conducted by John Rodgers of Jack Fawcett Associates and are based upon sources for the standard public modes of transportation. See John M. Rodgers (1973).

Multiplying $e$ by the matrix of trade coefficients [$\Gamma$], the allocation of final demands by industry among the regions is obtained. The resulting vector is multiplied by the inverse of an identity matrix minus the block diagonal matrix of input-output coefficients, which has been premultiplied by [$\Gamma$]. This calculation yields an 1817 element vector of gross output [$x$].

$$x = (I - \Gamma\hat{A})^{-1}\Gamma e \tag{9}$$

Equation (9) yields an estimate of the change in gross output in each of 79 industries in each of 23 regions resulting from the policy change. (In the empirical calculation, power series expansion was employed in estimating indirect requirements rather than general solution by inversion.)

The final two modules trace policy-induced demands back to the household sector—first by developing estimates of the pattern of induced labor demands by occupation and then by deriving the implications of this pattern for the distribution of earned income. The *occupational employment module* provides estimates of the occupational distribution of new job opportunities and, hence, of the effect of the program on the employment prospects of workers of various skill levels. As suggested above, these indirect effects may either reinforce or offset the primary antipoverty objective of the program.

Employment effects are estimated in two steps. First, the total change in regional and sectoral employment is obtained by multiplying unit labor requirements[19] by the detailed incremental gross outputs from the previous module. Second, the estimates of total sectoral employment are distributed over 114 occupational categories by applying a matrix of the percentage distribution of employment by occupation for each industry[20] to the sectoral employment estimates.[21]

Following the above notation, total employment requirements by industry and region [$n$] are obtained by multiplying the 1817 element gross output vector [$x$] by the matrix of employment-output coefficients [$\Lambda$] (composed of 23 block diagonal 79 x 79 matrices).

$$n = \Lambda \cdot x \tag{10}$$

The occupational composition of the employment is determined by multiplying the vector of incremental employment by sector and region $n$ by the matrix of occupational composition ratios [$\Theta$]. The matrix [$\Theta$] is block diagonal with submatrices [$\Theta^r$] of dimension 114 x 79, giving the occupational composition of employment by sector and region. In this study, it is assumed that [$\Theta^1$] = [$\Theta^2$] = ... = [$\Theta^{23}$]. The increment to the demand for labor in each of the 114 occupations in each of the 23 regions is given by the vector $w$.

$$w = \Theta \cdot n \tag{11}$$

Finally, the implications of this induced pattern of occupational demands on the marginal size distribution of labor income is ascertained in the *regional earnings distribution module*. It is assumed that any earned income attributable to incremental employment in an occupation and region is distributed by earnings class as existing earned income is distributed over those

[19] The employment-output coefficients are based upon employment by sector and region reported in the *MRIO* project. See Rodgers (1972). Annual compound productivity growth rates computed for each sector for the 1947–63 period are employed in aging the 1963 coefficients to 1973.

[20] The estimates of occupational composition by sector are from a *BLS* study based on the 1970 Census of Population. For a description of the methodology employed, see U.S. Bureau of Labor Statistics. It is assumed that the occupational employment patterns in any sector are constant across regions.

[21] While this is obviously a highly simplified model of the labor market, its use in a short-run, intraequilibrium framework is justified. Adjustments to relative wages are likely to be modest within a one-year period, and the nonlinearities in the derived demands for managerial and professional workers are in part offset by their lower supply elasticity.

currently employed in an occupation and region.[22] The incremental labor demand in each occupation and region (estimated in the previous module) is multiplied by the relative frequency distribution of all employed members of the labor force by earnings class in the corresponding region and occupation.[23] By aggregating these distributions over occupations within a region (or the nation), the induced employment by earnings class for the region (or the nation) is obtained. The structure of these marginal distributions may then be compared to the preexisting earnings distributions to determine the effect of the policy on high skill-high wage relative to low skill-low wage workers. Through such comparisons the impact of the indirect demands of the policy change in reinforcing or offsetting the primary incidence of the program can be ascertained.

This final module can be stated formally as

$$f = \Psi \cdot w \tag{12}$$

where $\Psi$ is a block diagonal matrix constructed from the 23 regional relative frequency distributions[24] and $f$ is a vector of the distribution of jobs induced by the transfer policy by earnings class.

## IV

This sequential simulation model is applied to a well-known income transfer proposal—a Negative Income Tax (*NIT*).[25] The *NIT* guarantees a minimum income of $800 per adult and $400 per child; all families with children are eligible for benefits. Beyond an earnings level of $720, the ratio of marginal benefits to marginal earnings is −.67; a benefit reduction rate of .60 is applied to unearned income. The transfer proposal is assumed to be financed by a surtax on the federal personal income tax. In the simulation, the sum of benefit and tax flows is set at zero, implying no net effect on the public sector budget.

Of the many detailed estimates obtained from implementation of the model, two are presented here.[26] In this section, the initial effect of the policy on the distribution of income will be compared with its ultimate impact on the earnings distribution. In Section V, the initial and ultimate regional effects will be compared.

The aggregate 1973 benefit payments from the *NIT* are estimated to be $3,421 million. The aggregate tax cost for the program is set equal to aggregate benefit payments, implying a federal personal income surtax of 3.67 percent. For any family or group of families, the *net benefit* (cost) from the program is equal to the benefit payment received (referred to as *gross benefit*) less the additional tax liability incurred.

In Table 1, simulation results of the distribution of the net benefits (transfers less taxes) of the proposal are shown. While net transfers accrue to all income classes below $6,000, all income classes above $6,000 incur net costs. The extent of the initial income redistribution accomplished by the plan is indicated by the disparities between the lowest and highest income classes. Families with incomes in excess of $15,000 are estimated to incur income losses of $2.3 billion while households with incomes below $2,000 stand to gain approximately $1.8 billion. When the gains and losses from the program are spread

[22] This implicitly assumes that the preexisting distribution of earned income reflects the distribution of skill, ability, and work effort of the pool of workers available in an occupation in a region.

[23] The regional relative frequency distributions are from a special tabulation using 1-in-100 tapes of the 1970 U.S. Census of Population. A total of 114 occupational categories and 23 regions are employed. Fifteen earnings classes are distinguished.

[24] Each block of $\Psi$ is a 15 x 114 matrix representing a regional distribution.

[25] In the full study, variants of this *NIT* were analyzed as well as the Family Assistance Plan of the Nixon Administration.

[26] A more complete presentation of the results is included in a forthcoming monograph, a draft of which is available from the authors on request.

TABLE 1—DISTRIBUTION OF NET TRANSFERS OF A NEGATIVE INCOME TAX BY INCOME CLASS, 1973

| Income Class | Net Benefits ($ millions) | Net Benefits Per Family |
|---|---|---|
| less than $1,000 | $991.8 | $511.69 |
| $1,000–$2,000 | 824.0 | 225.08 |
| $2,000–$3,000 | 808.5 | 193.74 |
| $3,000–$4,000 | 514.7 | 145.58 |
| $4,000–$5,000 | 186.8 | 57.13 |

| $20,000 or more | −1615.4 | −179.89 |

over all families within an income group, the average net benefit for the lowest income groups is nearly $500 and the average net loss to the highest income groups is over $250.

This first-round redistribution from higher to lower income groups is reflected in a narrowing of the income distribution from before to after implementation of the program. Prior to implementation, the Gini coefficient for the distribution of current family income was estimated to be .435.[27] If it assumed that *NIT* and its surtax financing arrangement is put into effect, the Gini coefficient would fall to .426, a reduction of nearly .01.

Whether this first-round redistribution is a valid measure of the ultimate equity impact of the program depends upon the distributional implications of the induced, indirect effects. By tracing the induced demands generated by the policy through the several simulation modules, the distributional pattern of the induced earnings can be estimated. If incremental employment is concentrated at the bottom of the earnings distribution, the demand for low skill-low wage workers will be stimulated (relative to the preprogram pattern of labor demand) and the indirect effects of the program may be said to reinforce the primary distributional impact.[28]

For all regions and for the United States, it is estimated that the *NIT* will result in an increase in aggregate labor demand. This is due to the lower marginal propensity to consume of higher income groups (who are net cost bearers) relative to lower income groups (who are net beneficiaries). The aggregate increase in labor demand is estimated to be about 120,000 positions. As a result, the high wage-low wage comparisons to be described focus on relative incremental labor demands by earnings class. The benchmark used is the composition of labor demands by earnings class *prior to* the program.

The induced effect of the program on any skill or earnings class is measured by an impact indicator.[29] This indicator compares the incremental labor demand in a regional earnings class with the preexisting employment in that class. Within a region, those earnings classes with an indicator in excess of (less than) that of the region as a whole will experience an increase (decrease) in their share of regional employment. Similar comparisons can be made for any regional earnings class relative to the induced national labor demand effect.

In Table 2, the induced earnings distribution impact of the *NIT* is presented for 23 detailed regions, 4 Census regions, and for the entire United States. One pattern dominates. The lowest skill/earnings

[27] The procedure for estimating the Gini coefficient is from N.C. Kakwani and N. Podder. For the preprogram Gini coefficient, the standard error was .03; it was .017 for the post-*NIT* Gini coefficient.

[28] Data on induced employment refer to individual jobs, and are not readily matched with family units—the basis of the size distribution of incomes.

[29] The earnings class indicator is the ratio of induced labor demand in a regional earnings class to 1970 employment in that earnings class times .001. Symbolically,

$$S_i = \frac{Mi}{.001\ (E_i)}$$

where $S_i$ is the impact indicator for a regional earnings class, $M_i$ is the program induced change in employment in that earnings class, and $E_i$ is the total 1970 employment in that earnings class.

[a] The lowest impact indicator in a region.
[b] The highest impact indicator in a region.

class (less than $4,000) has the lowest impact indicator in 21 of the 23 regions. In the remaining 2 regions, the impact indicator of the lowest earnings class lies below that of the region, even though it is not the lowest among the earnings classes. The opposite result is observed for higher skill classes. For the $10,000–$20,000 earnings class, the impact indicator is the highest among the earnings classes in 9 of the 23 regions, and in *no* region is the impact indicator for this class below that for the region as a whole. The results for the highest skill level (more than $20,000) show a similar pattern: for 14 of the 23 regions the impact indicator for this earnings class exceeds that of any other earnings class. Indeed, if the two highest earnings classes are aggregated, the lowest earnings class would have the lowest impact indicator and the highest class would have the highest in all of the regions. A similar pattern is present when the impacts are simulated for the nation as a whole: the lowest impact is on the $4,000–$10,000 class and the highest relative impact is recorded for the above $20,000 earnings class.

The underlying economic adjustments

which account for the program's adverse effect on the employment of low skill-low wage workers can be identified by examining the policy-induced demands placed on detailed industrial and occupational categories. In a number of prominent low wage occupations incremental labor demands are very small or negative, while some recognized high wage occupations are relatively heavily impacted. The low skill-low wage occupations with very low or negative demand effects (together with their impact indicators)[30] include: Textile Operatives (−.18), Health Service Workers (.98), Other Service Workers (.78), Protective Service Workers (.55), and Farmers and Farm Workers (.95).[31]

These comparisons suggest the following: the final distributional effect of explicitly redistributional policies is likely to be weaker than that indicated by the target efficiency of the *net* transfers. While the induced consumption and production decisions would be expected to be less propoor than the initial redistribution, these induced effects, in fact, tend to undo in part the initial redistribution. The earnings increments are somewhat more heavily concentrated among high earnings classes than even the *preprogram distribution of earned income*. Low income families tend to spend their income increments on goods and services produced by relatively high earnings groups, while higher income families tend to concentrate their spending reductions on sectors employing workers with relatively low earnings. While the program will achieve some reduction in inequality, the indirect effects tend to shift the structure of employment away from low skill/low earnings classes and toward high skill/low earnings classes.

## V

When the indirect effects are analyzed from a regional perspective, much the same sort of moderating effect is observed. While net transfers are heavily concentrated on certain regions, the induced industrial output and employment impacts tend to fall heavily on other regions.

Table 3 presents the distribution of *net* transfers by region for the *NIT*. On balance the South receives substantial net transfers—over $650 million. Each of the other three Census regions incur net costs. The average Mississippi family experiences an increase in disposable income of $203 while the average family in New York incurs a liability of $37. In terms of this first-round flow-of-funds effect, then, there is a substantial redistribution of disposable income from the richer to the poorer states in general, and from the North to the South, in particular.

In response to these changes in disposable income, consumption demand increases in some regions while expenditures in other regions decrease. Some of these expenditure changes increase demand for goods produced by local or regional industries, but other increments to demand affect businesses far from the site of the increased expenditure. This is especially notable after the second, third, and *n*th order interindustry demands are accounted for.

Table 3 also presents measures of the distribution of induced gross output. For the nation, gross output increases by about $3 billion. About 53 percent of this increase accrues to the South, while the North Central region receives almost a third. The Northeast and West each account for 5 and 11 percent, respectively. Impact indicators are also shown in the table.[32] While these results indicate a sub-

[30] These indicators are to be compared to the national indicator of 1.3 (Table 2).

[31] The reverse story could be told by observing the detailed occupations with simulated demand increases yielding high impact indicators. These occupations tend to be relatively high skill-high wage occupations. They include Managers, Officials, Administrators, and Skilled Workers.

[32] This indicator is analogous to that described in fn. 29.

TABLE 3—DISTRIBUTION OF NET TRANSFERS OF A NEGATIVE INCOME TAX AND INDUCED PRODUCTION BY REGION, 1973

| Region | Total Net Transfers ($ millions) | Per Family Net Transfer ($) | Ratio of Gross Transfers to Taxes | Gross Output (million $) |

stantial impact on the South, its share of total gross output is significantly smaller than its share of either net transfers or consumption expenditures. There is a substantial leakage of generated demands out of the region. The extent of this leakage is indicated in Table 4 which shows 1) the ratio of gross output to consumption expenditures induced by the program for each of the major regions and the nation, and 2) the difference between per capita net transfers and per capita gross output induced by the program. While the ratio of gross output to consumption expenditures is 1.9 for the nation, it is between 1.4 and 1.5 for both the South and the West. For the North Central region, the ratio is 3.6. Similarly, while the North Central region experiences *negative* net transfers from the *NIT*, the difference between per capita gross output and per capita net transfers for that region is about 130 percent of that in the South and about 165 percent of that in the West. As a result of the structure of interregional and interindustry relationships, then, a substantial share of second, third, and *n*th order demands falls on sectors whose productive capacity is concentrated in the North Central region. The high concentration of net

TABLE 4—INDICATORS OF OUTPUT LEAKAGE FOR THE *NIT* SIMULATION

| Region | Ratio of Gross Output to Consumption Expenditures | Per Capita Gross Output less Per Capita Net Transfer ($) |
|---|---|---|
| **Northeast** | a | $13.57 |
| **North Central** | 3.6 | 19.01 |
| **South** | 1.4 | 14.60 |
| **West** | 1.5 | 11.69 |
| **United States** | 1.9 | 14.64 |

[a] This ratio cannot be calculated as estimated consumption expenditures are negative for this region.

transfers in low-income regions is eroded in the exchange and production process so that the stimulation of economic activity in these regions is substantially smaller than the pattern of net transfers would imply.

## VI

This study has extended the framework for evaluating the economic impacts of tax-transfer policy by the construction and implementation of a short-run, multiregional multisectoral model. The model permits analysis of both policy-stimulated resource reallocations and redistributional impacts; here the redistributional effects—by income class and region—were emphasized.

The analysis has demonstrated that the indirect output and employment effects of the *NIT* tend to offset its primary distributional impact. Although the proposal has as its primary objective poverty reduction, relatively more high skill-high wage jobs are created than low skill-low wage jobs. Moreover, although the bulk of net transfer benefits are targeted at low income (primarily southern) states, most of the indirect employment and output gains are recorded in the relatively prosperous North Central and Northeast regions.

While results such as these expand the basis for evaluating proposed transfer policies, they neither comprehend the full range of economic impacts nor are they immune from criticism. To facilitate empirical development of the model, several likely behavioral responses had to be suppressed; hence, induced changes in labor supply, migration, and household structure were not investigated. Consumption expenditure responses were based on changes in current disposable income; current account Leontief production functions implying homogeneity, linearity, and nonsubstitutability were employed; and constant market prices were presumed. No estimates were made of the distributional impacts of induced income streams other than earnings. It is expected (a priori) that the net impact of these omitted effects—especially those related to wage rate inflexibility,[33] restricted labor supply, absence of household labor and investment demands, and the distributional impact of nonlabor income—would tend to reinforce the indirect distributional impacts presented above. Moreover, the model is designed to evaluate short-term effects and does not illuminate long-run or comparitive equilibrium effects of policy changes.

For policy purposes, these results suggest that the regional and income redistributional impacts of direct tax-transfer policies may not be as powerful as evaluations based on only primary incidence effects indicate. Given the pattern of induced effects, such policies may lose some of their edge when compared to, say, public employment programs or other policies with high employment impacts on low-skill workers. Moreover, if the induced shift in the skill composition of labor demand is combined with some presumed policy-induced reduction in the supply of low-skill labor, the future budgetary costs of the program are likely to be in excess of the first-year estimates presented here.

[33] With imperfect occupational mobility, relatively full employment, or segmented labor markets, a shift in the structure of labor demands toward high skill occupations may lead to relative wage rate—and, hence, earnings—increases in these occupations. This result would magnify the adverse indirect distributional effects described above.

# Illiquidity, Consumer Durable Expenditure, and Monetary Policy

*By* FREDERIC S. MISHKIN*

In the literature on consumer durable expenditure,[1] monetary policy has a major impact either through interest rate[2] or liquid asset (real balance) effects. The theoretical justification for the inclusion of liquid assets as an important determinant of consumer durable expenditures is not particularly strong,[3] and results with this variable have been mixed.[4] Yet, even though there is a solid theoretical basis for monetary policy effects through interest rates, empirical econometric work has rarely found these effects to be substantial.[5]

One possible conclusion from research in this area is that monetary policy has only a marginal effect on consumer durable expenditures. Another possibility, however, is that channels of monetary policy as yet unexplored might be a crucial determinant of this type of expenditure.

This paper studies the neglected illiquid aspect of the consumer durable asset. It finds that increased consumer liabilities are a major deterrent to consumer durable purchases and increased financial asset holdings a powerful encouragement. The results show that monetary policy has a strong impact on consumer durable expenditure through two additional channels of monetary influence: 1) Monetary policy affects the price of assets in the economy. Consumer financial asset holdings, thereby affected, influence expenditure on durables. 2) Past monetary policy will have affected the cost and availability of credit, thus influencing the size of consumers' debt holdings and hence consumer durable expenditure.

The paper proceeds in the following way: the next section develops a model which determines the effects of consumer durable illiquidity on the desirability of this asset; the second section contains aggregate time-series tests of this model; and the final section discusses the implications for monetary policy and contains concluding remarks.

## I. Illiquidity of the Consumer Durable Asset

One aspect of the consumer durable asset that distinguishes it from financial assets is its illiquidity. Well-developed capital markets exist for most financial assets,

* Teaching assistant, department of economics, Massachusetts Institute of Technology. I want to thank Stanley Fischer, Paul Joskow, Franco Modigliani, William Poole, and the participants in the Money Workshop at M.I.T. for their helpful comments. I would also like to thank Roger Hankin for computational assistance. This research was conducted while I was the recipient of a NSF Graduate Fellowship. Further research support has been provided by the Federal Reserve Bank of Boston. The evidence and conclusions set forth here are solely my own, and do not indicate concurrence by the Federal Reserve System.

[1] See Franco Modigliani; Michael Hamburger; F. Thomas Juster and Paul Wachtel (1972a); Michael McCarthy; Albert Hirsch, Maurice Liebenberg, and George Green; Ta-Chung Liu and Erh-Cheng Hwa; and Otto Eckstein, Edward Green, and Allen Sinai.

[2] Classified with interest rate effects are the effects of installment credit terms.

[3] One justification for the inclusion of liquid assets in consumer expenditure equations is found in Arnold Zellner, David Huang, and L. C. Chau.

[4] In none of the models mentioned in fn. 1 does the liquid asset variable enter significantly and with the right sign—indeed it often enters with the wrong sign—in both equations for the autos and parts and nonauto components of consumer durable expenditure.

[5] Hamburger's study seems to be the only piece of empirical work where these effects are substantial. Yet, he only finds these powerful effects when interest rates enter his equations with very long lags.

and cash can be generated with a minimum of cost in time, money, and effort by selling them in their near perfect markets. Capital markets for used consumer durables are, on the other hand, highly imperfect. Durable goods are very heterogeneous, and much information which is costly to obtain is needed to determine their value.[6] Also the bulk and difficulty in handling of durables leads to high transaction costs in their purchase or sale. These transaction and information problems lead to a wide spread between the price the consumer receives from selling his used consumer durable and its value in use.[7,8]

A simple two-period model of the effects of consumer durable illiquidity on the desirability of this asset is developed below. It is shown that the nature of markets for consumer durables forces the consumer to take account of his balance sheet status, i.e., his debt and financial asset position, as well as the riskiness of his income stream, in determining the desired level of his consumer durables stock.

Assume that a consumer buys a unit of durables with price equal to unity at the beginning of period one. The durable's in-use value at the end of the period would be $1-d$, where $d$ is the depreciation rate.[9] Yet, if the consumer suffers a shortfall in income so that the durable good has to be sold in a distress manner, its full value cannot be realized. Its illiquidity stems from the imperfect nature of the used consumer durable capital market. The degree of this illiquidity will be described by the variable $q$ ($q<1$), which is the fraction of in-use value that can be realized from a distress sale. This formulation is quite general: it is not dependent on any specific type of illiquidity loss; it includes the loss from a low sales price as well as from transaction costs. If, as a result of an income shortfall, a distress sale of the durable at the end of the period is required to raise cash, then the realized value of the durable at the end of the period will be $q(1-d)$, where $q$ is less than one.

If there is no distress sale, the one-period opportunity cost $C_0$ of holding a durable rather than a financial asset will be:

$$(1) \qquad C_0 = 1 - (1 - d) + r = r + d$$

But if there is a distress sale as a result of an income shortfall, then:

$$(2) \qquad C_0 = 1 - q(1 - d) + r = r + d + (1 - q)(1 - d)$$

where[10] $C_0$= one-period opportunity cost

[6] For example, how well has the owner treated his durable, has it been damaged, how frequently has it been used, was it a lemon to start with, etc.

[7] The value-in-use is the present discounted value of the durable's flow of services.

[8] To see why costly information would lead to a spread between selling price and in-use value, see George Akerlof. In an extreme case no organized market might exist as a result of information problems. The absence of organized markets for many types of used consumer durable goods is quite common.

[9] In the case of a durable where there is a planned trade-in, the expected costs incurred in the trade-in—transactions and otherwise—are included in depreciation. The value of the durable at the end of the period reflects these costs.

[10] The opportunity cost in equation (2) assumes that a consumer cannot borrow to cover his income shortfall or that the cost of borrowing over and above the yield on financial assets is more than $(1-q)(1-d)$. It is well known that financial intermediaries are more than happy to make loans to consumers when they least need it and are extremely reluctant to make loans to consumers when they are in financial trouble. If the financial intermediary does make a loan at all to a consumer with an income shortfall, it charges a very substantial premium to compensate for the increased risk. Thus the assumption inherent in equation (2) is quite reasonable. If the difference between the borrowing cost and the yield on financial assets is less than $(1-q)(1-d)$, the consumer will borrow instead of selling his consumer durables. This can be incorporated into the above model by replacing $(1-q)(1-d)$ with the spread between the distress borrowing rate and the yield on financial assets. This leads to the same results as found in the text.

The reluctance of financial intermediaries to lend to consumers in financial trouble explains why most consumers hold debt and financial assets at the same time, even if borrowing costs for the consumer not suffering financial distress are somewhat higher than the yield on

of holding a durable, and $r$ = one-period return on financial assets (which is assumed certain).

We can now view the opportunity cost of holding durable goods in an uncertain world with a Tobin-Markowitz mean-variance framework. If the probability of making a distress sale is $p$ and not making a distress sale is $1-p$, then

$$(3)\qquad E(C_0) = p[r + d + (1 - q)(1 - d)] + (1 - p)(r + d) = r + d + p(1 - q)(1 - d)$$

$$(4)\qquad Var\,(C_0) = p(1 - p)[(1 - q)(1 - d)]^2$$

where $E$ and $Var$ are the expectation and variance operators, respectively.

A distress sale occurs whenever consumption[11] plus debt service (interest plus amortization) is larger than income, plus readily available financial assets; i.e., when

$$(5)\qquad DS + CON - Y - FIN > 0$$

where $DS$ = debt service
$CON$ = consumption
$Y$ = disposable income
$FIN$ = holdings of financial assets

The permanent income hypothesis implies that

$$(6)\qquad CON = k\overline{Y}$$

where $k$ = the propensity to consume out of permanent income, and $\overline{Y}$ = expected average (permanent) income. If income is a normally distributed random variable, then using the standard normal distribution formula we may write:

$$(7)\qquad p = f[(DS - FIN - (1 - k)\overline{Y})/\sigma_Y]$$

where $\sigma_Y$ = the square root of the income variance, with

$$\frac{\partial p}{\partial DS} > 0, \qquad \frac{\partial p}{\partial FIN} < 0$$

$$\frac{\partial p}{\partial \sigma_Y} > 0, \quad \text{and} \quad \frac{\partial p}{\partial \overline{Y}} < 0$$

since $k$ is usually assumed to be less than one.

Debt service is a positive function of the consumer's liabilities at the beginning of the period, hence

$$(8)\qquad \frac{\partial DS}{\partial DEBT} > 0$$

where $DEBT$ = liabilities at the beginning of the period. Now:

$$(9)\qquad \frac{\partial E(C_0)}{\partial DEBT} = (1-q)(1-d) \cdot \left[\frac{\partial p}{\partial DS}\,\frac{\partial DS}{\partial DEBT}\right] > 0$$

$$(10)\qquad \frac{\partial E(C_0)}{\partial FIN} = (1-q)(1-d)\left[\frac{\partial p}{\partial FIN}\right] < 0$$

$$(11)\qquad \frac{\partial E(C_0)}{\partial \sigma_Y} = (1-q)(1-d)\left[\frac{\partial p}{\partial \sigma_Y}\right] > 0$$

$$(12)\qquad \frac{\partial E(C_0)}{\partial \overline{Y}} = (1-q)(1-d)\left[\frac{\partial p}{\partial \overline{Y}}\right] < 0$$

and

$$(13)\qquad \frac{\partial\, Var\,(C_0)}{\partial DEBT} = [(1 - q)(1 - d)]^2 \cdot [1 - 2p]\left[\frac{\partial p}{\partial DS}\,\frac{\partial DS}{\partial DEBT}\right]$$

$$(14)\qquad \frac{\partial\, Var\,(C_0)}{\partial FIN} = [(1 - q)(1 - d)]^2 \cdot [1 - 2p]\left[\frac{\partial p}{\partial FIN}\right]$$

financial assets. When a consumer suffers a drop in income, financial assets are a buffer that help prevent the consumer from taking losses either by selling his durables or borrowing at inflated rates to raise cash; thus the consumer will not try to minimize his borrowings by holding no financial assets as he would in a world of absolute certainty and perfect capital markets.

[11] Since a distress sale can be avoided at a relatively low cost by a reduction in consumer durable expenditure, consumption, not consumer expenditure, is the relevant variable for the necessity of a distress sale.

$$(15)\quad \frac{\partial\, Var\,(C_0)}{\partial \sigma_Y} = [(1-q)(1-d)]^2 \cdot [1-2p]\left[\frac{\partial p}{\partial \sigma_Y}\right]$$

$$(16)\quad \frac{\partial\, Var\,(C_0)}{\partial \overline{Y}} = [(1-q)(1-d)]^2 \cdot [1-2p]\left[\frac{\partial p}{\partial \overline{Y}}\right]$$

If the probability of a distress sale is less than one-half ($p<1/2$) for consumer durables, which would certainly seem to be the case for most individuals in our economy, then[12]

$$(17)\quad \frac{\partial\, Var\,(C_0)}{\partial DEBT} > 0, \qquad \frac{\partial\, Var\,(C_0)}{\partial FIN} < 0,$$
$$\frac{\partial\, Var\,(C_0)}{\partial \sigma_Y} > 0, \qquad \frac{\partial\, Var\,(C_0)}{\partial \overline{Y}} < 0$$

In a Tobin-Markowitz mean-variance model, both a lower expected opportunity cost and a lower variance are preferred.[13] Therefore, a consumer durable is a more desirable asset: the lower the debt holdings, the higher the financial asset holdings, the lower the variance of income, and the higher is expected income in this period.[14]

## II. Time-Series Tests of the Liquidity Model

A stock adjustment model incorporating the results of the "liquidity" model of the previous section is developed here. It is tested on quarterly aggregate time-series data for consumer durables expenditure and its two component parts: autos and parts expenditure, and nonauto consumer durables expenditure. The models are estimated over the period 1954-I through 1972–IV, with the exclusion of quarters in which there were auto strikes, i.e., 1964-IV to 1965-II and 1970-IV to 1971-II.[15] All quantities are in real per capita terms (thousands of 1958 dollars per capita) with flows as seasonally adjusted annual rates.[16]

### A. *The Model*

The literature views a consumer durable as an asset in the portfolio which yields a return of consumption services; the consumer derives benefits from the services of the stock, not from the flow of durable purchases.[17] The consumer thus desires a

[12] As can be seen in an appendix available from the author, the assumption that $p$ is less than one-half is certainly not needed for the debt and financial asset results obtained here.

[13] If the consumer has a diversified portfolio, then the capital asset pricing model applies; he prefers a lower mean opportunity cost and a lower covariance with the market return. If the correlation of the opportunity cost of holding a durable and the market return is positive and reasonably constant, then a lower variance of the opportunity cost is preferred as in the simple mean-variance model used above. Richard Bower and Donald Lessard indicate that for most situations the simple mean-variance model usually leads to the same decisions as the capital asset pricing model.

[14] The model above is quite simple and gives a nice neat result, yet it does make the unrealistic assumption that consumption cannot be lowered below its desired level to meet the problem of an income shortfall, or that it would be more costly to do so than to incur a loss from distress selling a consumer durable. Furthermore, the mean-variance model used here requires special assumptions which have been objected to in the literature. A more general model, found in an appendix available from the author, has been developed which does not rely on the special assumptions of the mean-variance model and allows the consumer to meet an income shortfall by lowering his consumption below its desired level. The results for the effects of debt and financial asset holdings on the desirability of the consumer durable asset are the same in this model as in the mean-variance model presented above. The more general model is not used here because its exposition is not as simple, and because the role of income stream riskiness is not as clear.

[15] Strong strike effects are felt in both the quarter of the strike and the quarter following. Use of first-order serial correlation corrections necessitates excluding the second quarter following the strike from the sample period as well as the two previous quarters in the consumer durables and autos and parts estimations. These quarters were also excluded for the nonauto consumer durables estimations because aberrations in the auto sector might have an impact on nonauto durable purchases. In fact, model estimates for the nonauto consumer durable sector were not appreciably affected when the excluded quarters were included in estimating the models.

[16] The sources of these data are described in another appendix available from the author.

[17] See Arnold Harberger, Gregory Chow, Modigliani, Richard Stone and D. A. Rowe, and Juster and Wachtel (1972a).

certain stock of durables which is a function of permanent income and the user rental cost of capital. The liquidity model developed in the previous section indicates that, in addition, the desired durables stock is a function of the value of the consumer's debt and financial asset holdings at the beginning of the period. Therefore:

$$K^* = f(Y_P, CAPC, DEBT, FIN) + E_A \tag{18}$$

where $K^*$ = real per capita desired stock of durables,

$Y_p$ = real per capita expected average (permanent) income,

$CAPC$ = user rental cost of consumer durable capital[18] $(RCB+D)(PCD/PCON)$,

$RCB$ = Moody's AAA corporate bond rate,

$D$ = annual depreciation rate,[19]

$PCD$ = consumer durables implicit price deflator,

$PCON$ = consumption implicit price deflator,

$DEBT$ = real per capita debt holdings of households—beginning of quarter,

$FIN$ = real per capita gross financial asset holdings of households (includes demand deposits plus currency, time and savings deposits, bonds, corporate equity, life insurance and pension funds, and other miscellaneous assets)—beginning of quarter,

$E_A$ = additive error term.

When expected income is high, and the desired durables stock is high, a change in the user capital cost should cause a larger dollar change in the desired stock of durables. Thus, equation (18) is linearized with the coefficient of permanent income a linear function of the user rental capital cost,[20] i.e.,

$$K^* = a + (b + c\,CAPC)\,Y_P + d\,DEBT + e\,FIN + E_A \tag{19}$$

Consumer durable expenditure is modeled with the stock-adjustment or so-called flexible-accelerator model which views consumers as adjusting only slowly to their desired stock of durables. The change in the stock, i.e., net investment, is only a fraction, $\lambda$, of the gap between the desired and actual stock at the beginning of the period. Net investment is also viewed as a function of transitory income because: 1) some portion of transitory income and hence saving should be reflected in consumer durable purchases; and 2) transitory income is a proxy to some extent for perceptions of income variance[21,22] which

[18] The user rental cost of consumer durable capital used here is completely analogous to the user rental cost of capital in the investment studies of Robert Hall and Dale Jorgenson and of Charles Bischoff. The interest rate in the formula above is a nominal interest rate, not a real interest rate as would be appropriate in the Hall-Jorgenson formulation; thus the effect of inflation on consumer durable expenditure is not incorporated into this model. Attempts were made to estimate the effect of inflation on consumer durable expenditure and include it in the model, yet experiments with varied distributed lags of past inflation rates proved fruitless; no significant effects could be obtained. This is not surprising for the effect of inflation is by no means clear. On one hand, with constant nominal interest rates inflation lowers the user rental cost of capital and encourages durable expenditures. Yet evidence from consumer surveys indicates that inflation increases consumers' perceptions of uncertainty (see Juster and Wachtel, 1972b), and this has a depressing effect on consumer durable expenditures.

[19] The assumed depreciation rate used in calculating the capital cost measure for all consumer durables is .20, while it is .25 for autos and parts, and .15 for nonauto consumer durables.

[20] This assumption is not critical to our argument. If $K^*$ is alternatively assumed to be a linear function of the right-hand side variables in (18), i.e.,

$$K^* = a + bY_P + c\,CAPC + d\,DEBT + e\,FIN + E_A \tag{19a}$$

the fit of the estimated model and the asymptotic $t$-statistics of the coefficients (except for the constant term) change hardly at all, and the important empirical results of this paper still hold.

[21] Transitory income is a cyclical variable which is related to the probability of a worker losing his job and suffering an interruption of his normal income stream.

the liquidity model indicates affects the desired stock of durables and hence net investment.[23] Therefore:

$$(20)\quad (K - K_{-1}) = \lambda(K^* - K_{-1}) + fY_T + E_B$$

where

$K$ = real per capita stock of durables at the end of quarter,
$\lambda$ = the quarterly adjustment rate,
$Y_T$ = real transitory income per capita,
$E_B$ = additive error term,

and subscripts refer to the time period of the $K$ variable.

Consumer durable expenditures, or equivalently, gross investment in consumer durable goods, equals the sum of net investment and replacement. Assuming a quarterly replacement rate of $\delta$:

$$(21)\quad EXP/4 = \delta K_{-1} + (K - K_{-1})$$

where $EXP$ = real per capita consumer durable expenditures at an annual rate. Combining equations (18) through (21) we derive the model to be estimated:

$$(22)\quad EXP = 4\lambda a + [4\lambda b + 4\lambda c\, CAPC]Y_P + 4\lambda d\, DEBT + 4\lambda e\, FIN + 4fY_T + 4[\delta - \lambda]K_{-1} + u$$

where $u$ = additive error term $= 4(\lambda E_A + E_B)$.

The signs of all the coefficients of equation (22) are easily determined. The coefficients on permanent and transitory income should both be positive because increased permanent or transitory income encourages consumer durable purchases.[24] Increased user capital costs should discourage purchase of consumer durables; this implies that $4\lambda c$ is less than zero. The lagged stock coefficient will be negative if the speed of adjustment is higher than the replacement rate—the usual case.

The results of the previous section indicate that illiquidity of the consumer durable asset should lead to a positive $FIN$ coefficient and a negative $DEBT$ coefficient in the above model. Changes in the value of financial assets for the wealthy, for whom liquidity is not a problem, might have a smaller impact on consumer durable expenditure than for the middle or lower income groups. For this reason, the

When transitory income is low, workers have a high probabilty of being laid off and have a larger income variance, and when it is high, workers have a low probability of being laid off and have a correspondingly lower income variance.

[22] The unemployment rate is also a cyclical variable that reflects the probability of losing one's job and is related to income stream variance. If transitory income is excluded from the expenditure model and the unemployment rate is used as a proxy for income variance in its place, it enters with the appropriate negative sign (indicating that higher income variance depresses consumer durable demand). It is statistically significant at the 5 percent level or higher in regression models for all consumer durables and its two component parts: nonauto consumer durables and autos and parts. The debt and financial asset variables results are not qualitatively different when unemployment is used in the expenditure models instead of transitory income.

[23] Attempts to find further measures of perceived income variance were unsuccessful. The unemployment rate, the Survey Research Center (*SRC*) consumer sentiment index, a filtered version of this index (see Juster and Wachtel, 1972b), a crude measure of perceived risk in the financial markets using yield spreads between low grade corporate bonds and comparable government securities, and calculated income variance from past data, were all tested in the equation (22) model shown here. Only the unemployment rate and the filtered *SRC* index proved to be statistically significant in any regression equation. Both of these variables were significant in the autos and parts regressions, yet the transitory income and adjustment speed coefficient took on unreasonable values. Furthermore, both variables had the wrong sign in the nonautos regression. The failure to find further measures of consumers' perceptions of income variance is not a severe problem. The estimated effect of financial asset holdings on the desired consumer durables stock should in any case reflect perceived income variance effects because of high correlation of the perceived variance and asset measures. When perceived income variance increases, a higher risk premium would probably be used in discounting the earning streams of equity. This causes a lower valuation of equity; thus the value of financial assets falls. A strong negative correlation between the gross financial assets measure and perceived income variance is thus expected.

[24] The transitory income coefficient should be positive not only because transitory income might be saved in the form of consumer durables, but also because a rise in transitory income indicates that consumers' income variance may have declined, thus increasing the desired stock of durables and durable purchases.

unequal and highly skewed distribution of financial asset holdings in this country would tend to sharply lower the aggregate financial assets coefficient in a model estimated on aggregate time-series data. On the other hand, consumer liabilities are distributed far more equally than financial assets; thus the coefficient on consumer liabilities should still retain a high value in time-series estimations. Even though the liquidity model does not imply that for an individual the debt coefficient should be markedly larger in absolute value than the financial assets coefficient, this result might be expected in time-series estimates of these coefficients which reflect the distribution effects described above.

### B. *Empirical Estimates*

Equation (22)—whether it be estimated for expenditures on all consumer durables, or for autos and parts and nonauto consumer durables expenditures—is just one equation in a simultaneous system; thus simultaneous equation bias will result from ordinary least squares estimation. In the above model this bias would be especially severe for the debt coefficient.[25] To avoid least squares bias, an instrumental variable technique has been used.[26] Strong serial correlation is evident in all the regression equations, and to achieve efficient estimates a first-order serial correlation correction has been made using Ray Fair's method and the appropriate additional instruments.[27,28] The results for each sector are denoted by superscripts: $D$ for all consumer durables; $A$ for autos and parts; and $NA$ for nonauto consumer durables.

The estimates for consumer durables are as follows, with asymptotic $t$-statistics in parentheses. The coefficient on $u_{-1}$ is the first-order serial correlation coefficient.

$$(23)\quad \underset{}{EXP^D} = \underset{(-2.45)}{-.3378} + \underset{(3.89)}{.2693}\, Y_T + (\underset{(2.40)}{.4295} - \underset{(-2.41)}{.4527}\, CAPC^D) Y_P - \underset{(-.01)}{.0014}\, \overset{D}{K_{-1}} - \underset{(-4.63)}{.2167}\, DEBT + \underset{(4.08)}{.0453}\, FIN + .5527\, u_{-1}$$

$R^2 = .9932$; Durbin-Watson $= 1.90$; Standard Error $= .007529$.

The results are good. The coefficients of the debt and financial asset variables have the signs hypothesized by the liquidity model and are highly significant; the coefficients are over four times their respective asymptotic standard errors. The depressing effect of debt holdings on consumer durable purchases is quite substantial; for every \$1 of debt held at the beginning of the quarter, durable purchases at an annual rate will be decreased by 22¢. The value of financial asset holdings has a

[25] Ordinary least squares estimates of the debt coefficient would be severely biased upward if the error term is positively serially correlated—the usual case. A positive error last period would imply a positive error in the current period, while increased durable purchases last period—a result of the positive error term—would lead to increased debt holdings at the beginning of the current period. The debt variable and the error term would thus be positively correlated, and this would lead to an upwardly biased ordinary least squares coefficient estimate. A comparison of the ordinary least squares and instrumental variables estimates of equation (22) indicates that the bias in ordinary least squares estimates is of the predicted direction and is quite strong.

[26] The list of instruments includes unborrowed reserves at member banks plus currency outside of banks, the discount rate, exports, federal government expenditures, the effective rate of personal income tax, these five variables lagged one period, the constant term, and population.

[27] Except for the lagged stock coefficients, regression estimates where there was no correction for serial correlation were not appreciably different from the corrected regression estimates. The serial correlation corrected regressions exhibited a higher adjustment speed of desired to actual stocks.

[28] Ordinary least squares estimates using a Cochrane-Orcutt technique for autocorrelation correction are provided in an appendix available from the author. Qualitatively the results are similar to those in the text (i.e., signs and $t$-statistics), though coefficient estimates sometimes differ by as much as 30 percent.

significant positive effect on the demand for durables, though, as might be expected, it is not as strong as the depressing effect of debt; an extra dollar of financial assets held at the beginning of the quarter leads to $4\frac{1}{2}$¢ of increased durables purchases.

In addition, the $Y_T$, $Y_P$, and $CAPC^D$ coefficients are all significant and of the expected sign in the estimated equation above. The magnitudes of these coefficients are also quite reasonable; 27¢ of a $1 increase in transitory income is spent on consumer durables, while a $1 increase in permanent income leads to somewhere in the neighborhood of 34¢ of increased durables expenditures. At the means of the sample data the interest rate elasticity of consumer durables expenditure is $-.14$, while the price elasticity is $-.71$. The lagged stock coefficient implies that approximately 6 percent[29] of the discrepancy between desired and actual stocks of durables is made up within the quarter; this is an annual adjustment rate of 22 percent.

The consumer durables demand model presented so far only allows for lags in the adjustment of actual to desired consumer durable stocks; i.e., no decision lags are allowed in the consumer's determination of his desired stock. This assumption seems rather naive. The consumer may acquire information on his user rental cost of durables slowly, and thus his decision on his desired stock of durables may be influenced by past as well as present user rental costs. Capital gains or losses may not be considered fully part of financial assets until they are realized. Movements in common stock prices, which lead to unrealized capital gains or losses in the short run, should not have their full impact immediately; instead, the valuation of common stock would affect the desired consumer durables stock with a distributed lag.

To test for the possibility of the lags described above, experimentation with polynomial distributed lags of the user rental cost variable and stock market financial assets have been pursued. There is no improvement in the standard error of the regression or asymptotic $t$-statistics from a lag on the capital cost variable. It seems that the consumer does not take long to acquire information on his cost of capital. On the other hand, a substantial improvement in fit is obtained when the value of stock market assets affects the desired stock of durables with a distributed lag. The liquidity model implies that there should be no differences in the effect of stock market and non-stock market assets on consumer durable desirability; thus the sum of the lagged stock market asset coefficients should be equal to the coefficient of unlagged non-stock market financial assets. Applying this a priori equality as a constraint,[30] experiments with polynomial distributed lags constrained to be zero at the tail resulted in an endpoint constrained, second degree polynomial with a four-quarter lag having the best fit (lowest standard error of the regression). The result using instrumental variables and Fair's method is:

$$
\begin{aligned}
(24)\quad EXP^D = &\underset{(-3.30)}{-\,.5239} + \underset{(2.94)}{.2167}\, Y_T \\
&+ (\underset{(3.39)}{.7026} - \underset{(-3.25)}{.6409}\, CAPC^D) Y_P \\
&- \underset{(-1.18)}{.2630}\, K^D_{-1} - \underset{(-4.43)}{.3118}\, DEBT \\
&+ .0632\, NSFIN \\
&+ \underset{(3.50)}{.0231}\, STK + \underset{(4.61)}{.0173}\, STK_{-1}
\end{aligned}
$$

[29] This assumes a quarterly replacement rate of .05625, which is the depreciation rate used in computing the consumer durables stock.

[30] The null hypothesis that this constraint is valid cannot be rejected at the 5 percent level. This hypothesis was tested with a two-tailed asymptotic $t$-test. The asymptotic $t$-statistic equals .3276 while the critical $t$ at the 5 percent level is approximately two.

$$+ \underset{(2.75)}{.0121}\, STK_{-2}$$

$$+ \underset{(1.58)}{.0074}\, STK_{-3}$$

$$+ \underset{(1.03)}{.0034}\, STK_{-4} + .6383\, u_{-1}$$

$$\sum_{L=0}^{4} \text{coefficients of } STK_{-L} = \underset{(4.10)}{.0632}$$

$R^2 = .9940$; Durbin-Watson $= 2.01$; Standard Error $= .007104$.

$STK$ = real per capita value of households' stock market asset holdings—beginning of quarter.

$NSFIN$ = real per capita non-stock market financial asset holdings of households—beginning of quarter $= FIN - STK$.

The lag pattern of equation (24) has a desirable shape, with a stronger impact on durables expenditure from more recent movements of stock market asset holdings. Furthermore, the overall impact of gross financial consumer assets on durables expenditures is larger in the lagged equation (24), than in the unlagged version (23): the overall financial assets coefficient is .0632 in (24) vs .0453 in (23). The debt coefficient also increases in absolute value in (24); \$1 of increased debt holdings now leads to a 31¢ decrease in durables purchases. The $Y_T$ and $Y_P$ coefficients still have reasonable magnitudes in this regression and are significant at the 1 percent level, while the lagged stock coefficient now implies that over 12 percent of the discrepancy between desired and actual stocks is made up within the quarter—an annual adjustment rate of approximately 40 percent. This speed of adjustment is quite plausible and is in the middle of the range of estimated adjustment speeds in other consumer durable studies.[31]

[31] See Harberger.

A striking result of allowing a distributed lag on stock market financial assets is the increase in absolute value of the capital cost coefficient and the rise of its asymptotic $t$-statistic to a value over three. In this model, the user rental cost of capital, and hence interest rates, has a strong and significant effect on consumer durable purchases. At the sample means the interest rate elasticity of consumer durable purchases is $-.20$.

To put the regression results of (23) and (24) in perspective, it would be worthwhile to compare them to results from a regression which does not include the debt and financial asset terms which are implications of the liquidity model. Instrumental variable estimates using Fair's method for this "standard" stock-adjustment consumer durables model are as follows:

$$(25)\quad EXP^D = \underset{(-1.52)}{-.2205} + \underset{(2.01)}{.1954}\, Y_T$$

$$+ (\underset{(2.39)}{.4611} - \underset{(-3.10)}{.7982}\, CAPC^D) Y_P$$

$$- \underset{(-.23)}{.0535}\, K^D_{-1} + .7846\, u_{-1}$$

$R^2 = .9919$; Durbin-Watson $= 1.75$; Standard Error $= .008111$.

The regression results of equation (23) and especially (24), which incorporate the liquidity model, are much superior to the results of the standard regression (25). The fit is better and the autocorrelation coefficient—an indicator of specification error—is far lower. The $Y_T$ and $Y_P$ coefficients are not as statistically significant in the standard regression, and the speed of adjustment—a quarterly rate of 7 percent—is somewhat low.

The model of equation (22) has also been estimated for the autos and parts, and the nonauto consumer durables sectors separately. Regression estimates using instrumental variables and Fair's method

appear in Tables 1 and 2. Experiments with endpoint constrained, polynomial distributed lags were also carried out for these sectors, and, as in the case for all consumer durable expenditures, the best fits were obtained with a four-quarter endpoint constrained, polynomial distributed lag on stock market assets. The constraint that the sum of the $STK$ coefficients should equal the coefficient on $NSFIN$ was imposed.[32] The estimates incorporating lags on stock market asset holdings also appear in Tables 1 and 2.

The results for both the autos and parts and nonauto consumer durable sectors are excellent. The debt and financial asset variables are of the right sign and are significant in all cases. The lag pattern of stock market assets in the lagged versions of the model is very similar in both sectors and has a sensible shape; more recent movements in the value of stock

[32] The null hypothesis that this constraint is valid cannot be rejected at the 5 percent level for either sector. The asymptotic $t$-statistic for the auto and parts and nonauto consumer durables regressions were .4294 and 1.1728, respectively. The critical $t$ at the 5 percent level is approximately two.

market asset holdings have greater impact on purchases, as in the estimates for all consumer durables. The $Y_T$, $Y_P$, capital cost, and lagged stock terms are all of the expected sign and are usually significant. The magnitudes of these coefficients are also reasonable. The lagged versions of the estimated model for the two sectors, equations (27) and (30), do have a superior fit to the unlagged models, (26) and (29); and the quarterly speed of adjustment implied by these lagged models is over 12 percent for autos and parts, and over 13 percent[33] for nonauto consumer durables; at annual rates these are both over 40 percent.

It is interesting to note that the estimated debt and financial assets coefficients are so much larger in the autos and parts regressions than in the nonauto regressions, in spite of the fact that autos and parts make up not quite half of total consumer durable purchases. The consumer's financial position seems to have more impact on his decision to purchase an automobile than it does on his decision to purchase a household consumer durable.[34] This is a worthwhile subject for further research.

Standard regression equations for both sectors where the debt and financial assets variables have been excluded have been estimated and appear as equations (28) and (31) in Tables 1 and 2. For both sectors, regression equations which incorporate the results of the liquidity model are superior to the standard regressions. They have a better fit, a lower standard error, and a smaller autocorrelation coefficient. Furthermore, in the nonauto consumer durables case the standard regression has an impossibly low speed of adjustment; only .5 percent of the discrepancy between desired and actual stocks is made up within the quarter—an annual rate of 2 percent.

Disaggregation of the consumer durable sector into its autos and parts and nonauto consumer durables components has resulted in further tests of the liquidity model. The results are still strongly supportive of this hypothesis.

## III. Implications for Monetary Policy and Concluding Remarks

The consumer durable expenditure model which incorporates the results of the liquidity model developed in this paper leaves monetary policy with a strong role to play in the demand for one of the most volatile components of gross national product. Three routes for monetary policy effects on consumer durable expenditures can now be envisioned.

1) Monetary policy affects interest rates and hence the user rental cost of capital. Tight monetary policy which raises interest rates will be a strong deterrent to consumer durable purchases because of the high interest elasticity of consumer durable demand indicated by empirical results in this paper.

2) In a Tobin, Foley-Sidrauski theoretical framework, monetary policy has a strong influence on asset prices in the economy. Tight monetary policy will lead to a fall in stock and bond prices and will thus result in a smaller valuation of the gross financial assets in the community. This will lead to decreased purchases of durables because consumers' financial positions have deteriorated; they are now left with a high probability of income shortfalls that would have to be met by the distress sale of consumer durables or a drop in consumption.

3) Past monetary policy will have affected the cost and availability of credit

[33] These adjustment rates assume a quarterly replacement rate of .07 for autos and parts and .045 for nonauto consumer durables.

[34] As a result of indivisibilities in the consumer's portfolio, the absolute size of the loss from selling a durable, and not just the loss per unit of the durable, could be important to consumer behavior. High priced durables such as automobiles would have a greater potential absolute loss from a forced sale than low priced durables, and this might explain the result found above.

to the consumer and will have thus affected the size of consumers' liabilities. Easy past monetary policy which has encouraged the buildup of consumer debt holdings will eventually prove a deterrent to future consumer durable purchases. The increased debt holdings force the consumer to desire more liquid assets.[35]

Viewing the consumer durable as an illiquid asset which must be traded in imperfect capital markets has led to a consumer durables demand model where perceived risk, and consumer liabilities and gross financial asset holdings influence consumer durables expenditure. In contrast to other work on macro-economic financial asset effects where net wealth influences consumer behavior,[36] this approach finds that the composition of the consumer balance sheet is critical to spending decisions.[37] The empirical estimates of this model have proved very encouraging, and several new and apparently potent channels of monetary policy that affect aggregate demand have been proposed. Furthermore, a traditional path for monetary policy effects on consumer durable expenditure has proved to be quite powerful in the model estimated here.

The liquidity model developed in this paper should also have applications in such areas as residential housing demand, and this will be the subject of further research. Many producer's goods, such as inventories and producer's durables are also illiquid assets; incorporating this feature into investment models might throw light on other possible channels of monetary policy effects in our economy. This avenue of monetary research should prove very fruitful.

[35] Simulations with a macro-econometric model (see the author) indicate that the two liquidity channels discussed in (2) and (3) far outweigh the interest rate effects discussed in (1), and are indeed extremely important in the determination of aggregate demand.

[36] For example, see Modigliani.

[37] An important implication of the analysis of this paper is that changes in the composition of the household balance sheet which leave net wealth unchanged can affect the expenditure behavior of households. An increase in indebtedness matched by an increase in holdings of nonfinancial assets which leaves net wealth constant would still lead to a future decline in consumer durable expenditure; a decrease in the value of financial asset holdings matched by an increase in nonfinancial asset holdings that left net wealth constant would also lead to a decline in consumer durable demand.

# Monopoly and the Rate of Extraction of Exhaustible Resources

By JOSEPH E. STIGLITZ*

In some recent discussions of the "energy crisis," the suggestion has been put forward that the oil producing countries or the oil companies have been acting collusively and have forced the price of oil to a level far higher than it would have been in competitive equilibrium. The object of this paper is to compare the rate of exploitation of an exhaustible natural resource in competitive markets with that of a profit maximizing monopolist. The basic result of my analysis is that there is a very limited scope for the monopolist to exercise his monopoly power; indeed, under the natural "first approximation" of constant elasticity demand schedules, with zero extraction costs, monopoly prices and competitive equilibrium prices will in fact be identical. In other cases there is some tendency for a monopolist to be more "conservation minded" than a competitive market would be.[1]

## I. A Two-Period Model

The basic intuition behind my result may easily be seen. First, consider a two-period problem. Assume that there are zero extraction costs. We have a fixed stock of oil to

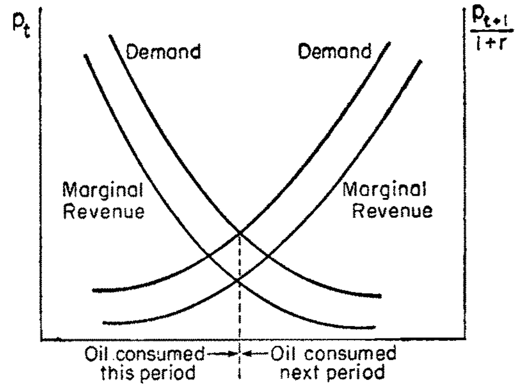

FIGURE 1

divide between two periods. That part of the stock which we do not consume the first period will be consumed the second. In Figure 1, I have plotted the demand curve this period, from the left, and the demand curve for next period, deflated by $1+r$, where $r$ is the rate of interest, from the right. In competitive equilibrium, an individual must be indifferent between selling a unit of oil today or tomorrow, so $p_t = p_{t+1}/(1+r)$. Thus, market equilibrium is the point of intersection of the two demand curves.

A monopolist, on the other hand, compares the marginal revenue he obtains this period with the marginal revenue, discounted by $1+r$, he would obtain next period by transferring a unit of sales from this period to next. In Figure 1, I have drawn the corresponding marginal revenue schedules, and the monopoly equilibrium is the intersection of the two. As I have drawn the curves, they intersect at exactly the same value of sales this period as did the price schedules, i.e., the monopoly equilibrium and the competitive equilibrium are identical. Clearly, if we have constant elasticity demand schedules, then price will be

* This work is an extension of research originally financed by the Energy Policy Project of the Ford Foundation. This work is supported in part by National Science Foundation Grant SOC74-22182 at the Institute for Mathematical Studies in the Social Sciences, Stanford University. This paper was originally written while I was a visiting fellow at St. Catherine's College, Oxford, 1973–74. Research support of the National Science Foundation and Ford Foundation is gratefully acknowledged. I am indebted to Partha Dasgupta, R. Zeckhauser, Geoffrey Heal, and an anonymous referee for discussions on the questions raised here. J. Sweeney has independently provided a similar analysis.

[1] This result is referred to in Robert Solow without a precise statement of the conditions under which it obtains. Milton Weinstein and Richard Zeckhauser establish the optimality of the competitive market's depletion of natural resources.

proportional to marginal revenue, and the two equilibria will be the same. If the elasticity of demand next period is higher than this period, the ratio of marginal revenue to price will be higher next period than this period which means that at the competitive price, discounted marginal revenue next period exceeds marginal revenue this period, so it pays to sell more next period: the monopolist is more conservationist than the competitive market. Conversely if the elasticity next period is lower than this period.

With extraction costs, the condition for competitive equilibrium is that rents, i.e., price minus extraction costs, $c$, rise at the rate of interest, i.e.,

$$p_t - c = \frac{p_{t+1} - c}{1 + r}$$

while the corresponding monopoly condition is that net marginal revenues rise at the rate of interest,

$$MR_t - c = \frac{MR_{t+1} - c}{1 + r}$$

Clearly, with constant elasticity demand schedules, since marginal revenues are a fraction of price, net discounted marginal revenue next period is greater than that for this period, when discounted rents (price minus extraction costs) next period equal that of this period. Again it pays to contract sales this period and expand them next period; with positive extraction costs and constant elasticity demand schedules, a monopolist is more conservation minded than is socially optimal.

As I shall show below, these basic results admit of considerable generalization. The basic argument is a simple one: the monopolist, like the competitor, eventually will exhaust all of the natural resource. It is not like a conventional commodity, where the total amount that will eventually be sold is smaller for a monopolist than for a competitor. Here, the only question is whether a monopolist can rearrange the patterns of sales over time to increase the present discounted value of his profits. My analysis suggests that his power to do this may be severely limited.

In a multiperiod model with zero extraction costs, competitive equilibrium will entail price rising at the rate of interest, while monopoly will require the marginal revenue to rise at the rate of interest. But if there is a constant elasticity of demand, price is proportional to marginal revenue, so price also is rising at the rate of interest. Since equilibrium entails exhaustion of the stock of resources as time approaches infinity, the competitive market equilibrium and the monopoly are described by exactly the same set of equations: the two equilibria are identical. This will be shown more formally in the next section.

## II. The Basic Model: Zero Extraction Costs, Infinite Time Horizon

Let the demand function for a quantity, $q$, of the natural resource, be of the form,[2]

$$p = f(t)q^{\alpha-1}, \qquad 1 > \alpha > 0 \tag{1}$$

where $1/(1-\alpha)$ is the elasticity of demand. The monopolist wishes to

$$\max \int_0^\infty p(t)q(t)e^{-rt}dt \tag{2}$$

subject, of course, to the constraint on the total stock of the resource, $S_0$,

$$\int_0^\infty q(t)dt \leq S_0 \tag{3}$$

Substituting (1) into (2), and introducing $\lambda$ as the Lagrange multiplier on the constraint (3), our maximization problem may be reformulated as

$$\max \int_0^\infty [f(t)q^\alpha e^{-rt} - \lambda q]dt \tag{4}$$

implying that we set $q(t)$ so that

$$\alpha e^{-rt}fq^{\alpha-1} - \lambda = 0 \tag{5}$$

which, upon substituting (1) and differentiating logarithmically, yields

[2] Obviously, if $\alpha<0$, one can obtain larger profits by reducing $q$. Some have suggested that the demand for oil in the very short run has less than unitary elasticity, but whether it is optimal for the monopolist to raise its price in these circumstances depends on the long-run demand elasticity as well. See Edmund Phelps and Sidney Winter.

$$\frac{\dot{p}}{p} = r \tag{6}$$

which is identical to the familiar condition for the time path of the price of a natural resource in a competitive market: the price must rise at the rate of interest. Again using (1), this is equivalent to

$$\frac{\dot{q}}{q} = \frac{r - \dfrac{f'}{f}}{\alpha - 1} \tag{7}$$

Thus, both the competitive market and the monopolist will satisfy the differential equation (7) and the condition (3).[3] This implies that prices at each moment of time in the competitive and monopolistic markets are identical, and hence so must be the rate of utilization of the natural resource. Because of our assumption of constant elasticity, so long as $f(t)>0$, $q>0$. Hence, if $f(t)>0$ for all time, the resource is used up only asymptotically. On the other hand, if $f(t)=0$ for $t\geq T$, then the resource is used up—in both the competitive and monopolistic markets—at exactly date T.

### III. Increasing Elasticity of Demand

There were two assumptions which were crucial to my result of the previous section—a constant elasticity which did not change over time, and zero extraction costs. In this and the next section, these two restrictions are removed.

If the elasticity of demand increases over time—as we might expect—as a result of the discovery of good substitutes for the given resource,[4] we obtain exactly the same equation for the optimal value of $p(t)$ as before (equation (5)). Differentiating (5) with respect to time, we obtain

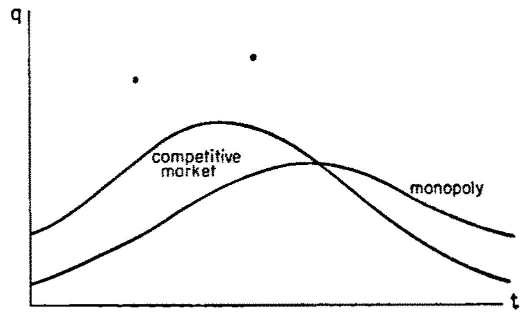

FIGURE 2. INCREASING ELASTICITY OF DEMAND

$$\frac{\dot{p}}{p} = r - \frac{\alpha'}{\alpha} \tag{8}$$

where, by assumption, $\alpha'>0$. The rate of increase of the price will be slower for the monopolist than that in the competitive market.[5] This in turn implies that if (3) is to be satisfied, the rate of utilization of the natural resource initially will be lower for the monopolist—the monopolist takes a more conservationist policy. Figure 2 compares a possible time profile of the utilization of the resource in the two markets.[6]

### IV. Extraction Costs

A similar bias for a monopolist to follow an excessively conservationist policy emerges when extraction costs are taken into account. Let the extraction cost be constant per unit of extraction but be declining with time.

[3] Equation (3) is essentially a boundary value condition.

[4] In the limiting case, where the new substitute is available with an infinite elasticity of supply the moment after discovery, if the date of discovery is known, the competitive and monopoly equilibria are identical. The case we have in mind here is where, say, a substitute is either not a perfect substitute, or does not have a perfectly elastic supply.

[5] Clearly, a more interesting case is that where the change in the elasticity of demand is an endogenous variable, say, a function of the price charged in the market. This turns out to be a far more complicated question, a special case of which is examined by Dasgupta and the author.

[6] Obviously, our formulation still is not as general as it might be, that is, within every period we assume constant elasticity demand curves. More generally, if the revenue function is of the form $R(q, t)$, then while in the monopoly market

$$\frac{\dot{q}}{q} = \frac{\left(r - \dfrac{R_{qt}}{R_q}\right)}{\dfrac{R_{qq}q}{R_q}}$$

in the competitive market

$$\frac{\dot{q}}{q} = \frac{\left(r - \dfrac{R_t}{R}\right)}{\dfrac{qR_q}{R} - 1}$$

Thus we let $g(t)$ = unit extraction cost at time t, $g' \leq 0$. The monopolist's profits are now just:[7]

$$(9) \qquad \int_0^\infty (fq^\alpha - gq)e^{-rt}dt$$

Profit maximization entails

$$(10) \qquad e^{-rt}(\alpha f q^{\alpha-1} - g) - \lambda = 0$$

which, upon differentiation and rearrangement, becomes

$$(11) \qquad \frac{\dot{p}}{p} = r(1 - \gamma_m) + \frac{\dot{g}}{g}\gamma_m$$

where

$$(12) \qquad \gamma_m = \frac{g}{\alpha p}$$

$\gamma_m$ is extraction costs divided by marginal revenue. It is clear that $\gamma_m$ must be less than unity; if extraction costs are falling rapidly, or $\gamma_m$ is large, then the market price may actually fall.

In contrast, the competitive solution requires that the individual be indifferent between extracting the oil today, receiving a net revenue (per barrel, say) of

$$p(t) - g(t)$$

or holding the oil one more period and extracting it next period, receiving a net amount of

$$\frac{p(t+1) - g(t+1)}{1+r}$$

i.e.,

$$\frac{p(t+1) - p(t)}{p(t)} = \frac{g(t+1) - g(t)}{g(t)} \cdot \frac{g(t)}{p(t)} + \frac{r(p(t) - g(t))}{p(t)}$$

or, in continuous time

$$(13) \qquad \frac{\dot{p}}{p} = r(1 - \gamma_c) + \frac{\dot{g}}{g}\gamma_c$$

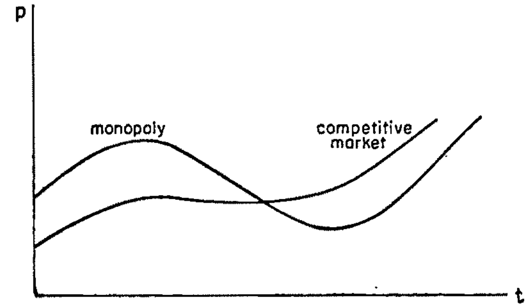

FIGURE 3. DECLINING EXTRACTION COSTS

where

$$(14) \qquad \gamma_c = \frac{g}{p}$$

Thus if at any t, $p(t)$ were the same for the competitive and monopoly markets, $\gamma_c(t) < \gamma_m(t)$ so $\dot{p}/p$ for the competitive market is greater than for the monopoly market. Thus, the "price curves" can only cross once, and the monopolist takes a more conservationist policy.[8,9] See Figure 3.

Note that if the monopolist has a lower

[7] We revert for simplicity to our assumption that $\alpha$ is constant.

[8] It is possible to show that asymptotically both the monopolist and competitor will use up the entire stock.

[9] The above formulation can be made somewhat more general by letting the extraction costs depend on the stock remaining, i.e., the costs of obtaining a flow $q$ from a field with stock $S$ at time t is $g(t)h(S, q)$. Assume we had a large number ($N$) of identical oil fields. If each owner acted competitively he would

$$\text{(a)} \qquad \text{maximize} \int_0^\infty [p(t)q(t) - g(t)h(S, q)]e^{-rt}dt$$

so, forming the Hamiltonian

$$\text{(b)} \qquad He^{rt} \equiv pq - gh(S, q) - vq$$

we obtain the result that $q$ must satisfy

$$\text{(c)} \qquad p - gh_q = v$$

while

$$\text{(d)} \qquad \dot{v} = rv + gh_S$$

The corresponding problem for the monopolist is to

$$\text{(e)} \qquad \text{maximize} \int_0^\infty [fq^\alpha N^{\alpha-1} - gh(S, q)]e^{-rt}dt$$

rate of output initially than a competitive industry, the monopolist's price must eventually be lower, if total supply is to be used up. Thus although the present generation pays higher prices for oil, subsequent generations will benefit. The monopoly equilibrium, however, is dynamically inefficient. If the monopoly were eliminated, the present generation could compensate the future generation for the higher prices, and still be better off.

## V. Speculators and Mixed Markets

In some of the cases depicted above, for example, where the elasticity of demand was falling, the price of the natural resource was rising faster than the rate of interest. This would provide an incentive for a speculator to purchase the natural resource and store it, provided storage costs were not too large. In the limit, if storage costs were zero, price would have to rise at the rate of interest, and even though the monopolist would like to be profligate with society's resources, consuming them too quickly, speculators will prevent him from doing so. Thus the monopoly and competitive equilibria are identical.

A converse argument does not hold if price is rising more slowly than the rate of interest. But if there is a mixed market, with one large holder of oil stocks and a large number of small holders, then in equilibrium the small holders will extract their oil first, with the price rising at the rate of interest; subsequently when all of their stocks are exhausted the large producer will extract, with the price rising more slowly than the rate of interest.[10]

## VI. Other Biases in the Rate of Extraction

There may, of course, be other differences between a monopoly and a competitive market. In particular, the required rate of return may be different; the monopolist for instance may have easier access to the capital market, and because of his larger size, be better able to pool risks. These suggest that the monopolist might have a lower required rate of return on capital (i.e., $r$ is smaller), which again implies a more conservationist policy for the monopolist than for the competitive market.

In any of the cases where a monopolist is conservation minded, if an industry which was previously competitive becomes cartelized, the effect will be a discontinuous jump in the price.

Whether the recent jump in the price in oil can be attributed to the factors discussed in this paper remains a moot question. It might be argued that in this case, the governments involved have less access to the capital market than do the large oil companies, so that the relevant rate of interest after cartelization was higher; on the other hand, if the oil companies had thought that there was a significant probability of nationalization, they would have pursued a policy of excessively fast extraction.

Similarly, if the rate of interest facing different firms (countries) is different, then the rate at which they would like to extract the natural resource will be different. It is clear that market equilibrium will entail the firm with the highest rate of interest extracting first (with price rising at his interest rate while he is the producer); then the next

---

so

(f) $$\alpha p - gh_q = v$$

where

(g) $$\dot{v} = rv + gh_S$$

To see clearly the difference between the two solutions, let $h = \phi(S)q$. Then for the competitive market,

$$\frac{\dot{p}}{p} = r(1-\hat{\gamma}_c) + \hat{\gamma}_c \frac{\dot{g}}{g}$$

where now $$\hat{\gamma}_c = \frac{g\phi(S)}{p}$$

while for the monopoly (letting $\hat{\gamma}_M = g\phi(S)/\alpha p$)

$$\frac{\dot{p}}{p} = r(1-\hat{\gamma}_M) + \hat{\gamma}_M \frac{\dot{g}}{g}$$

i.e., with the modification in the definition of $\gamma$, we have the same equations as before. Again, it can be shown that the monopolist pursues a more conservationist policy.

[10] This can be viewed as a Stackleberg equilibrium in which the large firm is the leader, and knows that the small firm will behave competitively; for an analysis of the Nash-Cournot equilibrium of this market, see Steve Salant.

highest, etc. If different firms face different extraction costs, the firm with the lowest extraction cost will extract first, then the next, etc. (i.e., it always pays to postpone postponable costs into the future). The competitive market equilibrium ensures that this will happen; the monopolist would behave in an identical way.

The fact that different firms with different extraction costs and apparently different rates of discount are producing simultaneously can then be attributed to: (a) marginal extraction costs are the same, even though average extraction costs are not; (b) offsetting effects of extraction costs and rates of time preference, with low extraction costs being associated with low rates of interest; (c) firms (countries) do not face a constant interest rate at which they can borrow and lend (invest); (d) risk; more particularly, differences in attitudes towards and judgments of the risks involved in postponing extraction.

Tax policy has provided further biases in the rate of extraction between the market solution and the optimal rate of extraction, but the most important provisions—the special treatment of capital gains and the depletion allowances—may not affect the relative rates of extraction of monopoly and competition. If extraction costs were zero, a constant depletion allowance would have no effect on intertemporal allocation (since price is rising at the rate of interest, the value of the depletion allowance, in present discounted terms, is independent of when the oil is depleted); hence, with constant elasticity of demand, the intertemporal resource allocation of monopoly and competition with and without the depletion allowance are all identical. With positive extraction costs, the depletion allowance encourages excessively fast depletion (since rents are rising at the rate of interest, prices are rising more slowly than the rate of interest, and hence the present discounted value of the depletion allowance is declining. Since prices with monopoly are rising more slowly than with competition, there is some presumption that the effect of the depletion allowance in accelerating extraction will be more marked in the former than in the latter. In any case, to the extent that the depletion allowance serves to offset the excessively conservative bias of monopoly, the depletion allowance may actually serve to increase social welfare. Since the return to holding a stock of a natural resource is a capital gain, and capital gains are taxed at a preferential rate, the equilibrium rate of increase of prices[11] is $r(1-t_p)/(1-t_{cg})$ where $t_p$ and $t_{cg}$ are the personal and capital gains tax rate; hence the preferential treatment of capital gains leads to excessive conservation.

A further potential source of bias is related to uncertainty, which we have ignored in this paper. An explicit treatment of the effect of monopoly when there is uncertainty is contained in Partha Dasgupta and the author.

Finally, we note that any analysis of the oil markets in the real world should probably entail an analysis of the behavior of oligopolistic markets. This would clearly take us beyond the scope of this paper; it is my hope, however, that the insights gained from comparing the polar cases of monopoly and competition will be of value in the study of these more realistic market situations.

[11] Assuming the rights for the oil under the land were acquired at essentially zero cost; otherwise, we have to take account of the tax reduction from the write-off of the value of oil rights upon exhaustion of the oil.

# Specification Error in Macro-Econometric Models: The Influence of Policy Goals—Comment

By STEPHEN M. GOLDFELD*

In recent years, there has been a rapidly growing literature on various technical aspects of macro-economic policy. This has included both theoretical work on the optimal settings for policy instruments and empirical work which, by the estimation of "reaction functions," is aimed at uncovering whether actual historical policies have been systematically related to posited macro-economic targets or goals.[1] In a related strand of this literature, a number of writers have examined the consequences of systematic policy for the estimation of macro-econometric models. An article in this vein by James Crotty, which recently appeared in this *Review*, suggests that "the purposeful nature of economic policy," will typically lead model builders astray. More specifically, Crotty purports to demonstrate that systematic policy making will generate economic data which will lead model builders to obtain rather biased and perhaps even useless results.

While the spirit of this result is broadly consistent with the findings of Levis Kochin, and Alan Blinder and the author, there is one disturbing feature of Crotty's work. In particular, Crotty, following Henri Theil, posits that policy makers choose instrument settings by minimizing a quadratic loss function subject to known linear constraints, i.e., we are in a certainty-equivalence world. For such a case, however, Blinder and I have shown that model builders will encounter none of the difficulties to which Crotty alludes. The purpose of this note is to examine this discrepancy. To anticipate our results, we find that Crotty's formal demonstration is flawed by a simple statistical confusion and that in this specific context, systematic policy making presents no problems for the model builder.

## I. The Basic Model

Following Crotty, we denote the vectors of instrument and goal variables by $X$ and $Y$, respectively. The desired values of these variables are given by $X^*$ and $Y^*$. The policy problem is to choose $X$ so as to minimize

$$(1)\quad W = \alpha'(X - X^*) + \beta'(Y - Y^*) + 1/2[(X - X^*)'A(X - X^*) + (Y - Y^*)'B(Y - Y^*)]$$

subject to

$$(2)\qquad Y = RX + S$$

where (2) is the reduced form of the economy and for the moment we follow Crotty in assuming $S$ to be a set of fixed parameters.

This minimization problem is solved by substituting (2) into (1) and differentiating with respect to $X$ to yield the first-order condition

$$(3)\quad \alpha + A(X - X^*) + R'\beta + R'B(RX + S - Y^*) = 0$$

It will be noted that (3) does not involve $Y$, but Crotty substitutes $Y$ for $RX+S$ to get

$$(4)\quad \alpha + A(X - X^*) = - R'\beta - R'B(Y - Y^*)$$

which is then rewritten as[2]

* Professor of Economics, Princeton University. I would like to thank my colleagues Alan Blinder, Gregory Chow, and Richard Quandt for helpful comments.

[1] See Gregory Chow for a good review of optimal policy. A good example of the reaction function approach is contained in Richard Froyen.

[2] I have followed Crotty in assuming that the inverse in (5) exists. My equation (5) corresponds to equation (6) in Crotty.

(5) $Y = \delta - (R'B)^{-1}AX$

where $\delta = -(R'B)^{-1}(\alpha + R'\beta) + Y^* + (R'B)^{-1}AX^*$

Crotty next observes that we now have two relationships, i.e., (2) and (5), which must be satisfied, and that coefficients of a regression relating $Y$ to $X$ will not be very illuminating since they will in general reflect both relationships. More particularly, he draws the analogy with the conventional supply and demand identification problem to suggest that empirical estimates obtained by regressing $Y$ on $X$ will be dominated by whichever relationship is relatively more stable. Crotty attempts to illustrate these points in the context of a simple two goal-two instrument example. Basically, what he does is to write out (5) explicitly and show that it is different from (2). Crotty then states that if we regress $Y$ on $X$ and "assume that the regression coefficients are estimates of the optimality conditions" (i.e., (5)), then we can "judge the extent of the maximum specification bias" (p. 1027). As we shall see in a moment, one is hardly free to "assume" anything of this sort, and in fact the entire "bias" problem raised by Crotty is invalid.

## II. Statistical Difficulties

As should be clear from this brief summary of his model, Crotty's main point is a statistical or econometric one. This suggests there should be some stochastic elements in the problem. They are, of course, already implicit in $S$ which is properly regarded as a random variable reflecting both uncontrolled exogenous variables and error disturbances (loosely speaking, the residuals). Following the certainty equivalence results of Theil, Crotty has replaced this random variable with its expected value, but it will be illuminating to introduce explicitly this random element. To bring out the consequences of this most clearly, we reexamine Crotty's findings in the context of the simplest possible problem—namely, one goal and one instrument.

The object is then to minimize[3]

(6) $w = (y - y^*)^2 + a(x - x^*)^2$

subject to

(7) $y = rx + \bar{s}$

where $\bar{s}$ is the expected value of $s$ and the "true" reduced form is

(8) $y = rx + s$

Carrying out the minimization yields an optimal $x$ given by

(9) $$x = \frac{ax^* + r(y^* - \bar{s})}{a + r^2}$$

Let us now consider regressing $y$ on $x$ where $x$ is given by (9) and we have a series of observations on both variables over time. For simplicity we assume that $\bar{s}$ is constant over the sample.[4] Furthermore, the natural presumption concerning the desired values $x^*$ and $y^*$ is that they vary nonrandomly over the sample although Crotty seems to suggest they could be constant over time.[5] From (9), this means that $x$ is deterministic and therefore it is certainly uncorrelated with the random variable $s$ in (8). Consequently, the regression $y = rx + s$ satisfies all the assumptions of least squares and consequently has all the desirable regression properties.[6] In particular, the coefficient of $x$ in such a regression should be an unbiased estimator of "the" multiplier $r$.

What this demonstrates, then, is that reduced form (or, for that matter, structural) estimation in the face of a Theil-type policy maker is perfectly straightforward. In particular, since $x$ is uncorrelated with $s$ there is no question of simultaneous equations bias. But what of Crotty's argument suggesting this possibility? As will be readily apparent, the problem with Crotty's line of reasoning is that his "extra equation" is not really

[3] For further simplification, the linear terms present in (1) are ignored in (6).

[4] This still allows for $s$ to represent both uncontrollable exogenous variables and error disturbances, but abstracts from possible trends in these exogenous variables. This is for convenience only and has nothing to do with the basic point I shall make.

[5] If both $x^*$ and $y^*$ are constant, then $x$ will be as well and one would hardly be tempted to use it as an independent variable in a regression.

[6] If $x^*$ and $y^*$ are random, then all that is required is that they be independent of $s$.

extra at all.

To see this, recall that the equation in question, (5), was obtained by replacing $RX+S$ in (3) with $Y$. There are two difficulties with this procedure. First, it is not quite correct since, as is clear from (9) what really appears in (3) is $RX+\bar{S}$ which is not $Y$. One can, of course, make the proper substitution. In the present simple case (3) takes the form

$$(10) \quad a(x - x^*) + r(rx + \bar{s} - y^*) = 0$$

Using the fact that $rx=y-s$, (10) can be rewritten as

$$(11) \quad y = y^* - \frac{a}{r}(x - x^*) + (s - \bar{s})$$

which is the corrected analog of (5).

The more important difficulty concerns the proper interpretation of (11) (or (5)). While (11) is a perfectly valid equation, the basic point is that it is a contrived and highly artificial one which is not independent of the reduced form. The easiest way to see this is to solve (9) for either $x^*$ or $y^*$ and substitute back into (11). In either case this will yield $y=rx+s$, demonstrating that (11) need not concern us.

Put another way, there is only one relationship between $y$ and $x$ which is present and that is the reduced form $y=rx+s$. Equation (11) is simply a related equation which involves two *additional* variables, $x^*$ and $y^*$.

One might, of course, estimate (11) in its own right to yield an estimate of $a/r$. This would require data on $x^*$ and $y^*$ which is generally not available. If it were, however, one could do better still by estimating (9) which must fit *perfectly*. Clearly, the ratio of the coefficients of $x^*$ to $y^*$ would give an exact estimate of $a/r$. Consequently, (11) is even superfluous from this point of view.[7]

In short, as far as the model builder is concerned, the "extra" equation is a red herring, pure and simple.

## III. Summary

This note has shown that in a Theil-type world, regressing endogenous target variables on "controlled" instrument variables will lead to unbiased estimates of the reduced form. The kinds of difficulties alluded to by Crotty, based on vague appeals to simultaneous equations problems, simply do not arise. There is nothing the policy maker does which can produce the statistical problems (correlations between instruments and disturbances) which would be needed to justify Crotty's claims. This is not to say that these problems could not arise in other circumstances, but this has been treated rather fully in the article by Blinder and the author.

[7] Equation (11) could be relevant if one is interested in the nature of the policy maker's preferences, embodied here by the value of $a$ in (6). If $x^*$ and $y^*$ were not known precisely, an exact estimate of $a/r$ would not be available. One could then fit (9) or (11), the choice depending on the nature of the errors-in-variables assumptions, to get an estimate of $a/r$ and use the reduced form estimate of $r$ to obtain an estimate of $a$. This is, in fact, the procedure followed by Anne Friedlaender.

# Specification Error in Macro-Econometric Models: The Influence of Policy Goals—Reply

By JAMES R. CROTTY*

Stephen Goldfeld's conclusions that the analysis of my article is "flawed by a simple statistical confusion" and that "the extra equation is a red herring pure and simple" are based on a set of assumptions which are virtually the opposite of the ones I worked with, and depend on an excessively restrictive interpretation of what is implied by the use of the Theil certainty equivalence framework. Under the assumptions stated in my article, my conclusions remain valid. It is Goldfeld's new assumptions that create the "errors" he then discovers in my paper.

The policy problem that I modelled was one in which the state had relatively firm policy targets and adjusted its policy instruments in response to shifts in the expected values of uncontrolled variables. In order to emphasize the potential problem, I assumed that $X^*$ and $Y^*$ were constant, so that $X$ was chosen to minimize equation (1), the quadratic loss function, as $\bar{S}$, the expected value of $S$, shifted from period to period.[1] As I stated in the article, "$S$ clearly changes every period" (p. 1027). But I used the symbol $S$ to denote the policy maker's certainty-equivalent forecast of $S$, i.e., Goldfeld's $\bar{S}$. My policy examples all contained the same assumptions. "Instrument movements would . . . counterbalance other forces tending to move the goal variables away from their desired values" (p. 1029) represents a typical sample from my discussion. Following Theil, I assumed that the policy maker behaved as if $\bar{S}$, the expected value of his subjective probability distribution (or forecast distribution) of $S$, was known with certainty, but *not* that the forecast distribution or $\bar{S}$ never shifted or changed over time.[2]

Goldfeld reverses these assumptions to describe and analyze a fickle policy maker in a world of constant expected values of uncontrolled variables, the very opposite of my assumptions and a relatively uninteresting case at that. He argues that the "natural presumption" is the $X^*$ and $Y^*$ vary nonrandomly over the sample and, "for simplicity," that $\bar{S}$ is constant over the sample. Only for the case where $\bar{S}$ is constant is Goldfeld's conclusion in footnote 5 that the constancy of $X^*$ and $Y^*$ implies the constancy of the policy instruments $X$ correct. In footnote 4 Goldfeld suggests that the assumption that $\bar{S}$ is constant is "for convenience only," but with respect to the problem addressed in my article, this is not so.

To see this, define $\epsilon_t = s_t - \bar{s}_t$.[3] Here $\epsilon$ is a random variable with an expected value of zero and constant variance, and the "true" reduced form is $y = rx + \bar{s} + \epsilon$. Under Gold-

* Assistant professor of economics, University of Massachusetts at Amherst. I am grateful to Raford Boddy and James Kindahl for helpful comments. Any errors, of course, are my responsibility.

[1] Goldfeld's notation and equation numbering will be used throughout, except where specifically noted.

[2] Rereading the original article, the only place I can find where Goldfeld could conceivably have been misled concerning my treatment of $\bar{S}$ was on page 1026 where I referred to $\bar{S}$ as a vector of "fixed elements." Here I followed Theil in viewing the noninstrument variables as uncontrolled and treated as if their values were known with certainty over the fixed planning horizon for the purpose of making the *first period's decisions*. In the article I had in mind a one-period, moving, fixed-horizon model and it is probably easiest to see the general problem under this simplifying assumption. Even if the planning horizon were assumed to be extremely long, the estimates of $\bar{S}$ elements for future periods would change as new information became available to the policy maker each period and in any case the current period values of the uncontrolled variables would not be expected to remain constant or unchanging from period to period. Furthermore, the rest of the article makes my treatment of $\bar{S}$ so clear that I find it difficult to understand Goldfeld's mix-up.

[3] Goldfeld switches from capital to small letters in going from the general statement of the problem to his one goal, one instrument example.

feld's assumptions, $x$ cannot be correlated with $\bar{s}$ because $\bar{s}$ is a constant, and $x$ is uncorrelated with $\epsilon$ by definition. The problem I addressed has thus been defined out of existence. If we return to my simplifying assumptions that $x^*$ and $y^*$ are constants but that $\bar{s}$ shifts from period to period, Goldfeld's conclusions are untenable. Rewriting his equation (9) as:

$$(9') \quad x = \left(\frac{a}{a+r^2}\right)x^* + \left(\frac{r}{a+r^2}\right)y^* - \left(\frac{r}{a+r^2}\right)\bar{s}$$

it is clear that $x$ is a linear function of $\bar{s}$ and therefore, contrary to Goldfeld's assertion, it is highly correlated with $s$ because $s=\bar{s}+\epsilon$.

Rewrite his equation (11) as:

$$(11') \quad y = \left(y^* + \frac{a}{r}x^*\right) - \frac{a}{r}x + \epsilon$$

In (11′), $x$ is uncorrelated with $\epsilon$. Therefore, a regression of $y$ on $x$ (the explicit case considered in my article and the one which typically arises in econometric studies designed to estimate policy instrument impact multipliers), will yield coefficients which are functions of both the reduced form impact multipliers, represented here by $r$, and the preference function parameters represented by $a$. Under the assumptions used in my article to show the extent of the maximum specification error, the regression coefficients will be unbiased estimates of the optimality condition, i.e., of $a/r$ in equation (11′). Therefore, almost all studies to date do have a potentially serious identification problem caused by the (omitted) influence of the preference function. In other words, if we adhere to the assumptions of my article, my conclusions are valid as originally stated.[4]

The specific estimation problem analyzed here is present to some degree as long as any controlled or uncontrolled variables are omitted from the reduced form regression and could be quite severe in Andersen-Jordan type instrument-goal regressions. Moreover, the analysis presented provides insight into some econometric difficulties involved in the estimation of the full reduced form inclusive of the uncontrolled variables—a problem not specifically addressed in my article. Suppose one regressed a goal variable against all relevant instrument and uncontrolled variables. As can be seen by inspection of equation (9′), if $X^*$ and $Y^*$ were constant over the sample, the $X$ variables would be linear combinations of the $\bar{S}$ variables and the data matrix might be very nearly singular. If $X^*$ and $Y^*$ varied over the sample, but varied significantly less than did $\bar{S}$, all the $X$ variables would be highly correlated with the $\bar{S}$ variables and with each other because of the preference function. The regression would still be riddled with multicollinearity and it might be quite difficult to disentangle the relative influences of the various independent variables.

Thus it seems reasonable to conclude that the econometric problem discussed in my article was not a "red herring" and that Goldfeld himself created the "errors" he found in my work.

[4] Partly because model builders have been unconcerned with this issue, we have as yet little or no hard econometric information concerning policy preference functions. In footnote 7 Goldfeld suggests that a satisfactory procedure for the estimation of preference function parameters has been presented by Anne Friedlaender. Her work in this area has been exceptionally creative but she is justifiably cautious concerning the robustness of her estimates and the reliability of her estimation procedures. See Boddy and the author for a discussion of some of the problems involved in the Friedlaender procedure, and the author for an alternative procedure which overcomes some limitations of her approach but shares many of the same difficulties.

# Commodity Trade and Factor Mobility: Comment

*By* TERUTOMO OZAWA*

In a recent paper in this *Review*, Melvyn Krauss presented an interesting case of factor mobility under the assumption that two countries have an identical factor endowment but differ from each other in tastes. A pattern of factor movements required under this set of assumptions is shown to be determinate in contrast to the basic indeterminacy involved in a situation that assumes differences in factor endowments but identical tastes in two countries.

To prove his point that there is only one unique pattern of factor mobility, Krauss starts by drawing from the origin of a two-factor endowment (capital and labor) diagram two rays representing "the factor endowment ratios in the two countries that correspond to the production vectors . . . required for the mirror image solution" (p. 801) in such a manner that each ray symmetrically deviates from the initial common factor endowment ratio line from the origin. He then proves with the help of a parallelogram the exact amounts of labor and capital to be transferred between the two countries.

Intuitively we know that such factor endowment ratio rays must exist. Yet we are not in a position to tell the exact locations of such rays unless we first know the exact amounts of labor and capital to be moved between the two countries. Although Krauss's arbitrary way of drawing such rays does not invalidate his proof, it seems more logical as a geometrical proof that we directly find the exact amounts of two factors to be transferred in a manner shown below, since only after we have done so, can the rays used by Krauss be derived.

The initial common factor endowment box is shown by $O_yCO_xL$ in Figure 1. The equilibrium production point achieved under free trade is indicated by point $P$. Let us subtract the amount of labor-intensive good $Y$ which the home country would export

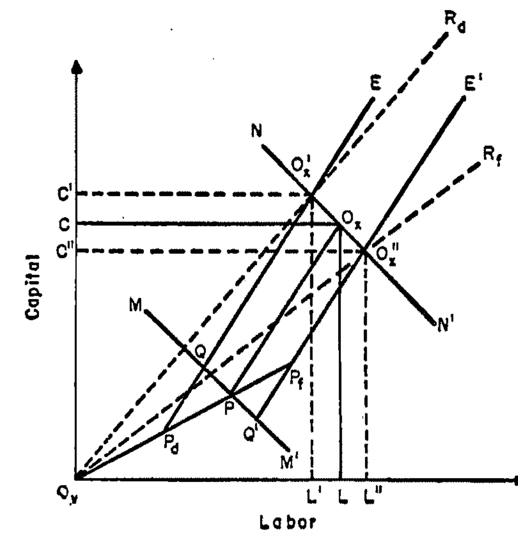

FIGURE 1

under free trade, namely $PP_d$. Draw a line $P_dE$ parallel to $PO_x$ and indicate the amount of capital-intensive good $X$ which the home country would import under free trade, namely $P_dQ$. Then draw a line $MM'$ connecting $Q$ and $P$. The home country's "commodity trade triangle" is $PP_dQ$. We can similarly construct the foreign country's commodity trade triangle, $PP_fQ'$, and the line $P_fE'$.

Next draw a line $NN'$ through point $O_x$ parallel to the line $MM'$, and identify its intersections with $P_dE$ and $P_fE'$ as points $O_x'$ and $O_x''$, respectively. Since $PQ=PQ'$, $O_xO_x'$ must equal $O_xO_x''$. We have thus found that the home country must "import" $CC'$ of capital and "export" $L'L$ of labor, while the foreign country imports $LL''$ of labor and exports $CC''$ of capital, and that any other pattern of factor movements is impossible. We are now in a position to draw the rays which are used by Krauss, as shown by dotted lines $O_yR_d$ and $O_yR_f$, by connecting $O_y$ and $O_x'$ for the home country and $O_y$ and $O_x''$ for the foreign country, respectively.

# Commodity Trade and Factor Mobility: Reply

By Melvyn B. Krauss*

Terutomo Ozawa's demonstration of the relationship between the commodity trade triangle, the factor trade triangle, and the equilibrium factor endowment ratio rays in two countries that initially trade with one another because of differences in tastes, is both logically correct and geometrically interesting. But while I admire his elegant proof, I must disagree with his assertion that "we are not in a position to tell the exact locations of [the factor endowment ratio] rays unless we first know the exact amounts of labor and capital to be moved between the two countries" (p. 668). This assertion not only runs counter to the general mathematical fact that the solution of a general equilibrium system requires that all unknowns be simultaneously determined, but as a specific proposition is demonstrably false as well.

It is proved below that given the initial equilibrium commodity trade triangles, the equilibrium factor endowment ratio rays in the two countries can be determined without *explicitly* considering the exact amounts of labor and capital to be moved between the two countries. In Figure 1 (a simplified version of my earlier Figure 2), the initial common production vector is $OP$ with $OZ_f$ the consumption vector in the foreign country and $OZ_d$ the consumption vector in the home country. The respective equilibrium triangles thus are $C_fFP$ and $C_dDP$, and the equilibrium commodity price ratio given by the slope of $C_fPC_d$.

By the Stolper-Samuelson relation the factor price ratio is known once the commodity price ratio is known; and given factor prices, the optimal factor-intensity ratios $OR_x$ and $OR_y$ also are known. In Figure 2, point $E$ represents the common factor endowment

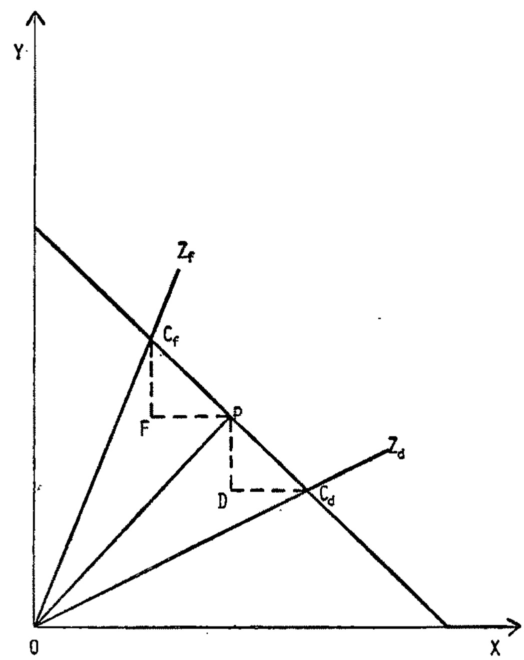

Figure 1

point in the two countries. By vector addition, the common factor allocation points $P_x$ and $P_y$ are determined. The ratio of $X$ production to $Y$ production is reflected by the slope of the straight line connecting points $P_x$ and $P_y$. This ratio is equal to the slope of $OP$ in Figure 1.

For factor mobility to cut off all goods traded in this case, the production vectors in each country must coincide with the respective consumption vectors—that is, the foreign production vector must coincide with $OZ_f$ and the domestic production vector must coincide with $OZ_d$. This implies that at constant international prices factor mobility must increase the ratio of $X$ production to $Y$ production in the domestic country and reduce that ratio in the foreign country. The precise ratios of $X$ production to $Y$ production in both countries that are required for

* Visiting research professor, Institute for International Economic Studies, Stockholm. The paper was written while I was visiting associate professor of economics, Stanford University.

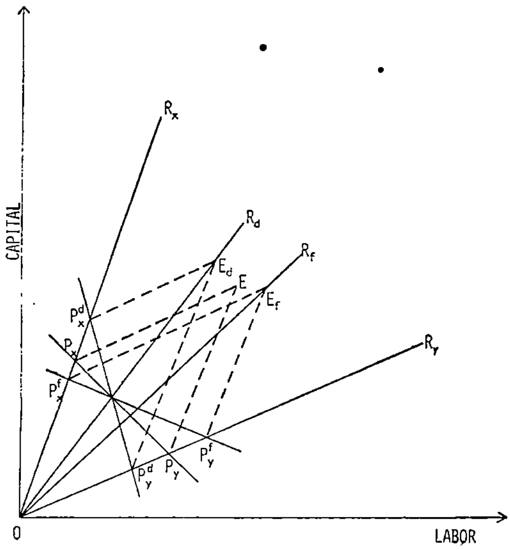

FIGURE 2

equilibrium with factor mobility are known, since the consumption vectors in both countries are known. The ratio corresponding to $OZ_d$ is assumed to be reflected by the slope of $P^d_xP^d_y$ in Figure 2, since the slope of $P^d_xP^d_y$ indicates a higher ratio of $X$ production to $Y$ production than the slope of $P_xP_y$. Similarly, the ratio corresponding to $OZ_f$ is assumed to be reflected by the slope of $P^f_xP^f_y$, which indicates a higher ratio of $Y$ production to $X$ production than the slope of $P_xP_y$.

Given the production ratio lines $P^d_xP^d_y$ and $P^f_xP^f_y$, and the factor-intensity ratios $OR_x$ and $OR_y$, the factor endowment point $E_d$ consistent with $P^d_x$ and $P^d_y$ and the factor endowment point $E_f$ consistent with $P^f_x$ and $P^f_y$ are determined. Points $E_d$ and $E_f$ are not necessarily the equilibrium factor endowment points, since $P^d_x$, $P^d_y$, $P^f_x$, and $P^f_y$ are not necessarily the equilibrium factor allocation points (the slope of $P^d_xP^d_y$ is the equilibrium production ratio but $P^d_x$ and $P^d_y$ need not represent the equilibrium absolute outputs of $X$ and $Y$ in the home country). But both $E_d$ and $E_f$ must lie on the equilibrium factor endowment rays in their respective countries. Hence the equilibrium factor ratios $OR_d$ and $OR_f$ are determined without explicit consideration of the exact amounts of labor and capital to be moved between the two countries. Rather than being arbitrarily drawn, as Ozawa claims, the rays $OR_d$ and $OR_f$ in my earlier Figure 3 are determined from the commodity trade triangle under the assumptions of the Heckscher-Ohlin-Samuelson model.[1] Except for certain expositional differences, Ozawa's and my own proof are substantially the same.

[1] Given $OR_d$, $OR_f$, and $E$, the equilibrium pattern of factor flows can be determined by my earlier Figure 3. Once the equilibrium factor endowments are determined for each country, the equilibrium factor allocation points also are determined by the technique demonstrated in Figure 2.

# Can Trade Widen the Difference Between Factor Rewards? Another Look at the More-Goods-Than-Factors Case

By DOUGLAS B. STEWART*

Since publication of the seminal articles of Jan Tinbergen, Paul Samuelson (1949, 1953), and James Meade it has become increasingly clear that the traditional international trade propositions associated with a two-good two-factor world generally do not hold unchanged in a three-good two-factor world. Moreover, the modifications required to extend those propositions to the three-good world have proven so far to be neither very intuitive nor straightforward.[1] These difficulties have been evidenced in the trade theory literature by continuing and nontrivial disagreements on exactly how the three- and two-good worlds differ. In this context the important and clashing papers by A. H. Land and Harry Johnson (1967) stimulated further work and debate on the conditions for factor-price equalization. The latest word here seems to be the work of Jaroslav Vanek and Trent Bertrand.

In addition to factor-price equalization, a second major question was debated in the Land-Johnson exchange. Land argued by means of an example that free trade in a three-good two-factor world could cause factor-price ratios to diverge from their autarkic values. Johnson (1967) argued that Land's example was subject to certain inconsistencies and, therefore, factor-price ratios necessarily converge with trade. Strangely, this question has received no further analytical attention, although the correctness of Johnson's argument was asserted by both parties in a later exchange between Bertrand and Johnson (1970). The purpose of this note is to show that Johnson's argument on the possibility of diverging factor rewards is incorrect.

To set the stage, consider two countries both of which have endowments of capital and labor which are to be efficiently employed in the production of some mix of goods $X$, $Y$, and $Z$. Both countries face the same constant-returns-to-scale production technology. We assume country 1's endowment is relatively labor abundant and $Z$ is always the labor-intensive good while $X$ is always capital intensive. Finally, we assume positive demand for each good in each country at all relevant prices.

The behavior of a number of variables relevant under the above assumptions can be graphically analyzed. Following Land's Figure 6 (p. 141), Figure 1 here shows both countries in equilibrium in autarky and with free trade. The subscripts $iT$ and $i$ refer to country $i$ with and without trade, respectively. Given the equilibrium commodity prices in autarky and taking $X$ as numeraire, the $Y_1$ and $Z_1$ isoquants represent the quantities of $Y$ and $Z$ equal in value to one unit of $X$ in country 1. By constructing the convex envelope to the $X$, $Y_1$, and $Z_1$ isoquants we obtain the unit iso-revenue curve $xfez_1$. The equilibrium wage-rental ratio is then given by the slope of the iso-revenue curve where it is intersected by the ray $k_1$ representing country 1's factor endowment ratio. Thus $W_1$ is the unit cost line and its points of tangency with the $X$, $Y_1$, and $Z_1$ isoquants determine the optimal factor intensities in each sector; for example, the ray $of$ indicates the optimal capital-labor ratio for the production of $X$ in country 1.

The situation in country 2 is depicted similarly. Note that the equilibrium autarkic prices must be such that all three

* San Diego State University. I wish to thank Chulsoon Khang, Murray Kemp, Harry Johnson, and Jagdish Bhagwati for their helpful suggestions and encouragement on an earlier draft. I have also benefited from the comments of an anonymous referee and the managing editor. All errors here are my own.

[1] See John Chipman's survey of modern trade theory which nicely gives separate treatment to the unequal goods and factors cases in each topic area. Also see the appendices to Murray Kemp's first and third chapters which carefully generalize the Stolper-Samuelson, Samuelson-Rybczynski, and Factor-Price Equalization theorems to any number of goods and factors.

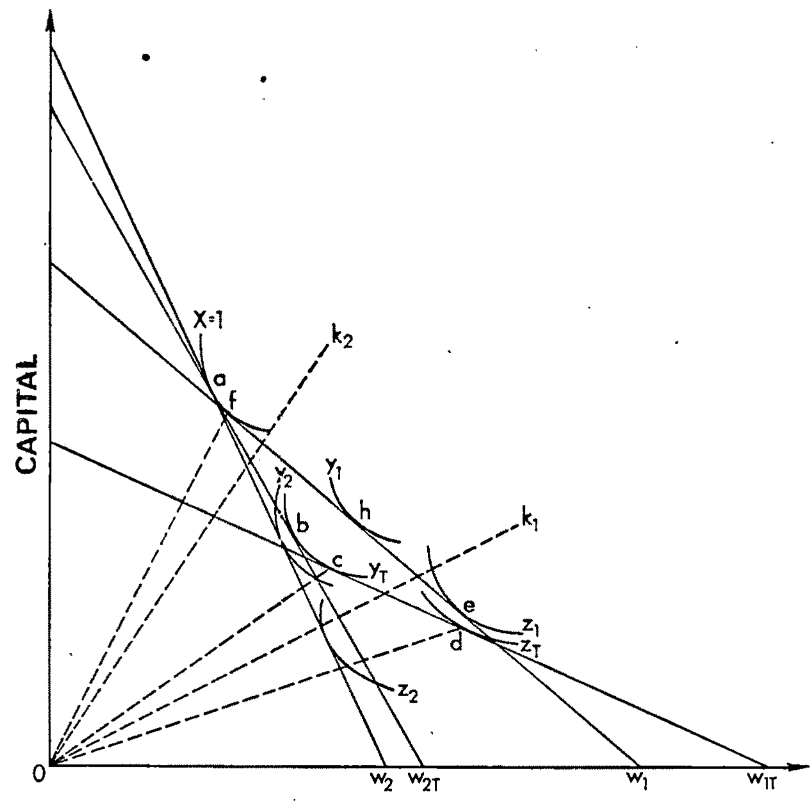

FIGURE 1

unit-value isoquants are tangent to the isocost line since all goods must be produced. Note also that the lower the price, the greater the unit-value quantity. Thus Figure 1 illustrates the case where both $Y$ and $Z$ are more expensive (relative to $X$) in country 2 than in country 1 in autarky. It follows, then, that with free trade the equilibrium terms of trade must be such that the unit value isoquants $Y_T$ and $Z_T$ lie between the pretrade unit value isoquants of the two countries. In the case illustrated in Figure 1 both countries face the unit iso-revenue curve $xabcdz_T$ in trade equilibrium. Given their respective factor endowments we see country 1 will produce only $Y$ and $Z$, and will have the wage-rental ratio given by the slope of $W_{1T}$, while country 2 will only produce $X$ and $Y$ with the wage-rental ratio given by the slope of $W_{2T}$. With trade the wage-rental ratio has fallen in each country and it has fallen more in country 1, the country with the lower pretrade wage-rental ratio. Therefore, factor-price ratios have diverged with trade, and Figure 1 illustrates the possibility as argued by Land.[2]

Johnson (1967) claims that with free trade the factor-price ratios must not only converge but one must fall and one must rise, and, thus Land's example is not a legitimate possibility. He argues as follows. Suppose the wage-rental ratio in country 2 falls with trade and in trade equilibrium it produces only the two relatively capital-intensive goods and does not produce $Z$. Now if the wage-rental ratio also falls in country 1,

[2] Land's Figure 6 (p. 141) does not exactly match her verbal argument. In her diagram the higher wage-rental ratio has fallen more than the lower one with trade. Thus they have converged rather than diverged as was intended.

which is the labor abundant country, it can cease production of $X$ and specialize in the two labor-intensive goods only if its production of $Z$ declines from the pretrade equilibrium. But this is impossible, claims Johnson, since it implies that after trade, 1) world production of $Z$ is less than before trade, and 2) country 1 is producing less of the good intensive in its relatively abundant factor (Johnson, 1967, p. 286 and p. 287, fn. 1).

Johnson's analysis of the changes brought about by trade is quite correct, yet he has not proven that any contradiction arises from them. From statements in his 1967 article as well as in his 1970 exchange with Bertrand it is clear that he sees some inconsistency between general demand conditions and the production mix determined by the supply side for the equilibrium terms of trade in Land's example. However, the assumed regular demand conditions cannot tell us what has happened to world demand for any of the commodities since no one commodity becomes either cheaper or more expensive relative to both remaining commodities as long as the terms of trade are between the pretrade prices. In particular, for the case at hand, the price of $Z$ in country 1 rises with trade. Therefore, declining world demand for $Z$ is possible, and, contrary to Johnson's claim, declining production of $Z$ raises no contradiction.[3]

Notwithstanding the above point, there are two potential inconsistencies in examples like Land's, and although her example avoids both it can be instructive to consider them briefly. First, there are some terms of trade between the pretrade prices at which one good would not be produced in either country regardless of their factor endowments. This would be inconsistent with the assumption of positive demand for each good and, hence, such terms of trade could not be equilibrium values. For example, in Figure 1 if trade caused the price of $Z$ to fall only slightly in country 2 and the price of $Y$ to rise only slightly in country 1, the unit value $Y$-isoquant would lie above the unit isorevenue curve and production of $Y$ would not be viable in either country. Second, the assumed factor endowments may make some potential equilibrium terms of trade inconsistent with world production of all three goods. For the pattern of production shown in Figure 1 to emerge it is required that the endowment rays $k_1$ and $k_2$ lie within the respective cones *cod* and *aob*. If, for example, country 1 had a less labor-abundant endowment so that the ray $k_1$ passed to the left of tangency point $h$, a rising rather than a falling wage-rental ratio would be required to induce country 1 to specialize in $Y$ and $Z$.[4]

Returning to Johnson's second point against Land's example, he claims it is impossible for country 1 to produce less of $Z$ with trade, as that result "contradicts the assumption that country 1 is led by free trade to expand the production of the good in which its factor endowment gives it a comparative advantage" (p. 287, fn. 1). But Johnson's "assumption" here is not an axiom of accepted trade theory. In the two-good two-factor world it is a readily established *result* since with free trade the price of the good in which a country has a comparative advantage must rise relative to the price of the one other good in that country and, hence, more of the good will be produced in that country. However, in the three-good two-factor world of Land's example the price of $Z$ in country 1 rises relative to the price of $X$, but falls relative to the price of $Y$. Thus, increased production of $Z$ does not necessarily follow.

In conclusion, Land's example is not subject to any inconsistencies as claimed by Johnson, and thus the divergence of factor

[3] Indeed, we could construct the demand conditions with $Z$ so strongly inferior (but non-Giffen) as to insure declining demand. However, I do not claim $Z$ inferiority is necessary for this outcome. Lower demand for $Z$ could result from various demand features such as: $Z$ highly price elastic in country 1; $Z$ highly complementary with $Y$ in country 1; $Z$ highly price inelastic in country 2; $Z$ strongly complementary with $X$ in country 2.

[4] Bertrand has used this example in correcting Johnson's (1967) treatment of factor-price equalization. In the same note he accepts Johnson's (1967) argument against diverging factor prices. And it seems at least a possibility that he was led to that acceptance by failing to note this crucial difference between his example and Land's.

rewards remains a possibility in a three-good, two-factor, two-country world. Moreover, the pattern of production and trade seems very reasonable. Free trade allows country 1 to concentrate its labor-intensive endowment in production of the two most labor-intensive goods. However, in doing so it must adjust the relative production levels of these two goods in order to maintain full factor-employment. This adjustment is such as to reduce the production of $Z$ and increase production of the good of intermediate factor intensity. Note also that the trade pattern agrees with the Heckscher-Ohlin result as country 1 must export $Z$ and country 2 must export $X$ in trade equilibrium.[5]

[5] Of course the standard Heckscher-Ohlin theorem does not hold in this model. For consideration of other possible trade patterns, see James Melvin (1968, 1971, 1972) and the author (1971, 1972).

# Factor Demand with Output Price Uncertainty

*By* RICHARD HARTMAN*

The effects of output price uncertainty on a competitive firm's supply and factor demands have recently been explored under the assumption that all decisions are made before the price is observed. Agnar Sandmo has shown that a risk-averse, competitive firm with a nonrandom cost function will produce a smaller output if the price is random than it would if the price were known with certainty to equal its mean. Raveendra Batra and Aman Ullah and I have extended the analysis by considering the effects of output price uncertainty on factor demands. Among other things, Batra and Ullah show that the firm will choose its inputs to minimize the cost of producing whatever level of output is chosen. This result, combined with the Sandmo result that the presence of uncertainty reduces output, implies that the effects of uncertainty on factor demands depend on what effect the decreased output due to uncertainty has on the cost minimizing levels of inputs. Except for the rare case of inferior factors, the presence of uncertainty reduces factor demands. Finally, it is clear from these analyses that if the firm is risk neutral, the uncertainty has no effect on supply and factor demands.

In this paper I relax the assumption that *all* inputs are chosen before the output price is observed. My conclusions show that the results noted above are really rather sensitive to that particular assumption. A simple two-input, one-output model of the firm is employed. One of the inputs, which I call capital, is quasi fixed in the sense that it must be chosen before the output price is observed. The other input, which I call labor, is variable since it is not chosen until the output price is observed. Clearly, this implies that the level of output is not determined until its price is known. Although labor may be a poor name for the variable input in view of the recent discussions of its "quasi-fixed" character, it seems apparent that in many situations there are inputs which can be varied on short notice.

By allowing a variable input in this sense we considerably alter the situation facing the firm. If, after observing the output price, it turns out that the firm made a "poor" choice regarding the quasi-fixed factor, it is able to partially "adjust" by choosing an appropriate level of the variable input. This ability to make adjustments for what, *ex post*, appears to be a poor decision is totally lacking if all inputs must be chosen before the uncertainty is resolved.

In Section I the basic model is presented. In Section II the analysis for a risk-neutral firm is carried out, and Section III contains an example. In Section IV the analysis is extended to a risk-averse firm. The final section contains some brief concluding comments.

## I. The Basic Model

Let us consider a price-taking firm which produces an output $Q$ using capital $K$ and labor $L$ as inputs. These variables are related by a production function

$$(1)\qquad Q = F(K, L)$$

which has positive marginal products,[1]

$$(2)\qquad F_1(K, L) > 0, \qquad F_2(K, L) > 0$$

and is strictly concave,

$$(3)\qquad F_{11}(K, L) < 0, \qquad F_{22}(K, L) < 0$$
$$F_{11}(K, L)F_{22}(K, L) - F_{12}^2(K, L) > 0$$

We take the capital input to be quasi fixed while the labor input is completely variable. By this we mean that the capital

* Assistant professor of economics, University of Washington, Seattle. I am indebted to an anonymous referee for helpful comments.

[1] Subscripts denote partial differentiation with respect to the corresponding argument.

input must be chosen before the output price $p$ is observed, but that the labor input is not chosen until after it is observed. It is assumed that the firm has some subjective probability distribution regarding $p$ before it is actually observed. Finally, we assume that the prices of the capital input $c$ and of the labor input $w$ are known with certainty.

Since the labor input is chosen after the capital input has been determined and after the output price has been observed, it is clear that labor will be chosen to maximize short-run profits

$$pF(K, L) - wL \tag{4}$$

The first-order condition for this optimization is

$$pF_2(K, L) - w = 0 \tag{5}$$

which can be solved for the optimal labor input

$$L^* = L^*(K, p, w) \tag{6}$$

Substituting $L^*$ into (4) gives the short-run profit function

$$g(K, p, w) = pF(K, L^*(K, p, w)) - wL^*(K, p, w) \tag{7}$$

giving maximal short-run profits as a function of the capital input, the output price, and the wage rate.

Before proceeding, we note some facts which will be used in what follows. The envelope theorem[2] implies that the derivative of $g(K, p, w)$ with respect to the output price is the short-run supply function, which we shall denote by $Q^*$,

$$\frac{\partial g}{\partial p}(K, p, w) = F(K, L^*(K, p, w)) = Q^*(K, p, w) \tag{8}$$

Similarly,

$$\frac{\partial g}{\partial K}(K, p, w) = pF_1(K, L^*(K, p, w)) \tag{9}$$

Moreover, differentiating (5) implicitly with respect to $K$ and $p$ gives

$$\frac{\partial L^*}{\partial K}(K, p, w) = -F_{12}/F_{22} \tag{10}$$

and

$$\frac{\partial L^*}{\partial p}(K, p, w) = -F_2/(pF_{22}) \tag{11}$$

If the firm hires its labor optimally in the short run, its long-run profits are

$$\pi(K, p, w, c) = pF(K, L^*) - wL^* - cK = g(K, p, w) - cK \tag{12}$$

At the time the capital input is chosen, $\pi$ is clearly a random function since $p$ is then a subjective random variable. In the following section it is assumed that the firm chooses its capital input to maximize the expected value of long-run profits. In Section IV we generalize by assuming the firm maximizes the expected utility of profits for some strictly concave von Neumann-Morgenstern utility function.

## II. The Risk-Neutral Case

In this section we assume the firm is risk neutral in the sense that it chooses the capital input to maximize the expected value of long-run profits,

$$Eg(K, p, w) - cK \tag{13}$$

An obvious implication of this assumption is that all uncertainty results we derive in this section arise from the non-linear nature of the technology rather than from risk aversion.

The first-order condition for the optimal capital input is

$$E\frac{\partial g}{\partial K}(K, p, w) = c \tag{14}$$

and the second-order condition is satisfied since $F$ is strictly concave. Indeed, using (9) and (10) we have

$$E\frac{\partial^2 g}{\partial K^2} = E\left[pF_{11} + pF_{12}\frac{\partial L^*}{\partial K}\right] = E[p(F_{11}F_{22} - F_{12}^2)/F_{22}] \tag{15}$$

Using (3), this clearly implies

[2] Paul Samuelson, pp. 34–35, gives a good discussion of the envelope theorem.

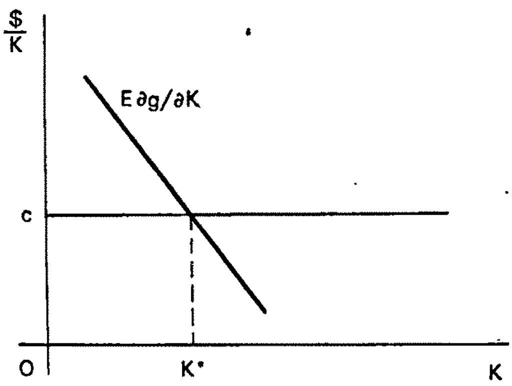

FIGURE 1

$$(16)\qquad E\frac{\partial^2 g}{\partial K^2}(K, p, w) < 0$$

The optimal capital input $K^*$ is shown graphically in Figure 1.

We now examine the effects of increased uncertainty on the demand for the capital input. The notion of increased uncertainty used in this section is the mean preserving spread recently studied by Michael Rothschild and Joseph Stiglitz. Operationally, a mean preserving spread is obtained by adding a random variable with conditional mean zero to the original random variable. Thus, we shall be examining the effects of replacing the random variable $p$ by $p+Z$ where $Z$ is a random variable with $E(Z|p)=0$. The notion of a mean preserving spread clearly includes both moving from one uncertain situation to another which is more uncertain as well as moving from a certain situation to an uncertain one. The result used is that the expected value of a convex (concave) function increases (decreases) as its argument undergoes a mean preserving spread. (See Rothschild and Stiglitz, p. 237.)

We determine the effects of increased output price uncertainty on the capital input by examining the behavior of $E\partial g/\partial K$ as $p$ undergoes a mean preserving spread. The Rothschild and Stiglitz results imply that if $\partial g/\partial K$ is convex (concave) in $p$, the mean preserving spread increases (decreases) $E\partial g/\partial K$ for any value of $K$. From Figure 1 it is clear that any increase (decrease) in $E\partial g/\partial K$ leads to an increase (decrease) in the optimal capital input.

To determine conditions under which $\partial g/\partial K$ is convex or concave in $p$ we differentiate twice. Using (9) and (11), we find,

$$(17)\qquad \frac{\partial^2 g}{\partial K \partial p} = F_1 + pF_{12}\partial L^*/\partial p = F_1 - F_2\frac{F_{12}}{F_{22}}$$

$$(18)\qquad \frac{\partial^3 g}{\partial K \partial p^2} = -F_2\frac{\partial(F_{12}/F_{22})}{\partial L}\frac{\partial L^*}{\partial p}$$

Since $\partial L^*/\partial p > 0$, it follows that

$$(19)\qquad \frac{\partial^3 g}{\partial K \partial p^2} \gtrless 0 \quad \text{as} \quad \frac{\partial(F_{12}/F_{22})}{\partial L} \lessgtr 0$$

An equivalent set of conditions can be derived in terms of the short-run supply curve, equation (8). Indeed, differentiation gives

$$(20)\qquad \frac{\partial^2 g}{\partial K \partial p} = \frac{\partial}{\partial K}\left(\frac{\partial g}{\partial p}\right) = \frac{\partial Q^*}{\partial K}(K, p, w)$$

$$(21)\qquad \frac{\partial^3 g}{\partial K \partial p^2} = \frac{\partial^2 Q^*}{\partial K \partial p}(K, p, w)$$

Thus

$$(22)\qquad \frac{\partial^3 g}{\partial K \partial p^2} \gtrless 0 \quad \text{as} \quad \frac{\partial^2 Q^*}{\partial K \partial p} \gtrless 0$$

Since $\partial^3 g/\partial K\partial p^2 > 0$ implies $\partial g/\partial K$ is convex in $p$, it is clear that increased output price uncertainty increases $E\partial g/\partial K$ and therefore increases the optimal capital input provided that $\partial(F_{12}/F_{22})/\partial L < 0$, or, equivalently, provided that $\partial^2 Q^*/\partial K\partial p > 0$. Similarly, increased output price uncertainty decreases $E\partial g/\partial K$ and therefore decreases the optimal capital input provided that $\partial(F_{12}/F_{22})/\partial L > 0$, or, equivalently, provided that $\partial^2 Q^*/\partial K\partial p < 0$. Since the labor input decision and therefore the output decision are made after the uncertainty is resolved, the increased uncertainty will affect these decisions only through its effect on $K$.

In view of (10), it is clear that for any given output price, a larger capital input will increase or decrease the demand for labor depending on the sign of $F_{12}$. There is nothing in our assumptions about the production

function, however, to give $F_{12}$ a determinate sign. Thus, for any $p$ realized *ex post*, greater uncertainty in the distribution of $p$ *ex ante* may increase or decrease the demand for labor depending on whether the increased uncertainty increases or decreases the capital input and also on the sign of $F_{12}$.

Recall that with expected profit maximization, the assumption that all inputs are chosen before the price is observed implies that uncertainty has no effect on the output or on the inputs. The fact that uncertainty plays a role in the model considered here is not surprising, though, since the firm is operating in a different environment. Indeed, if after the output price is observed, the capital input turns out to have been a poor choice, the firm is able to compensate partially by suitably choosing the labor input. Obviously, the firm could not do this if the labor input were also chosen before the price is observed. If the firm can compensate for what *ex post* turns out to have been a poor decision, it seems intuitively clear that uncertainty (which is related to the size of the possible *ex post* error in the capital input) should affect the capital input decision and that this effect should depend, possibly among other things, on the ease with which capital and labor are substitutable. The example in the next section shows that the mathematical results derived above are consistent with these intuitive conclusions.

## III. An Example

To get some additional feeling for the content of the results in the previous section, let us examine the strictly concave $CES$ production function,

$$Q = [aK^{-\beta} + bL^{-\beta}]^{-\mu/\beta} \tag{23}$$

where $a>0, b>0, \beta>-1, \beta\neq 0$, and $0<\mu<1$. The parameter $\mu$ is a measure of returns to scale. The elasticity of substitution $\sigma$ is given by

$$\sigma = 1/(1+\beta) \tag{24}$$

Rather than examine $\partial(F_{12}/F_{22})/\partial L$, it is more convenient to consider $\partial(F_{22}/F_{12})/\partial L$. Obviously, the sign of $\partial(F_{22}/F_{12})/\partial L$ is opposite that of $\partial(F_{12}/F_{22})/\partial L$. Some rather tedious but straightforward manipulations give

$$\frac{F_{22}}{F_{12}} = \frac{b}{a}\left(\frac{\mu-1}{\mu+\beta}\right)\left(\frac{L}{K}\right)^{-(\beta+1)} - \frac{(\beta+1)}{(\mu+\beta)}\frac{K}{L} \tag{25}$$

Differentiating with respect to $L$, we find

$$\frac{\partial(F_{22}/F_{12})}{\partial L} = \frac{\beta+1}{\mu+\beta}\left[(1-\mu)\frac{b}{a}\frac{L^{-(\beta+2)}}{K^{-(\beta+1)}} + \frac{K}{L^2}\right] \tag{26}$$

Since $\mu<1$, the term in square brackets is positive as is $\beta+1$. Therefore $\partial(F_{22}/F_{12})/\partial L$ has the same sign as $\mu+\beta$. Substituting $\beta=(1/\sigma)-1$ we find that the sign of $\partial(F_{22}/F_{12})/\partial L$ is the same as the sign of $(\sigma\mu+1-\sigma)$. It follows that the sign of $\partial(F_{12}/F_{22})/\partial L$ is the same as the sign of $(\sigma-1-\mu\sigma)$. Therefore,

$$\frac{\partial(F_{12}/F_{22})}{\partial L} \gtrless 0 \qquad \text{as } \sigma \gtrless (1-\mu)^{-1} \tag{27}$$

This is illustrated in Figure 2. In region $A$, $\partial(F_{12}/F_{22})/\partial L>0$ and increased uncertainty in the output price decreases the optimal capital input. In region $B$, on the other hand, increased uncertainty increases the optimal capital input. This suggests that with sufficiently easy substitutability between capital and labor, increased uncertainty decreases the optimal capital input since little is lost by waiting until the uncertainty is resolved and hiring labor.

As the production function approaches constant returns to scale (as $\mu\rightarrow 1$), increased uncertainty leads to a larger capital input. This can be explained in terms of a fact noted by Walter Oi; namely, since the profit function is convex in $p$, increased uncertainty will increase its expected value. With constant returns to scale, both $L^*(K, p, w)$ and $g(K, p, w)$ are homogeneous of degree one in $K$. In this case $\partial g/\partial K$ is independent of $K$ and is, in fact, a per unit of capital profit function. Under these conditions $\partial g/\partial K$ is convex in $p$, and increased uncertainty increases its expected value. We have excluded the case of constant returns to scale

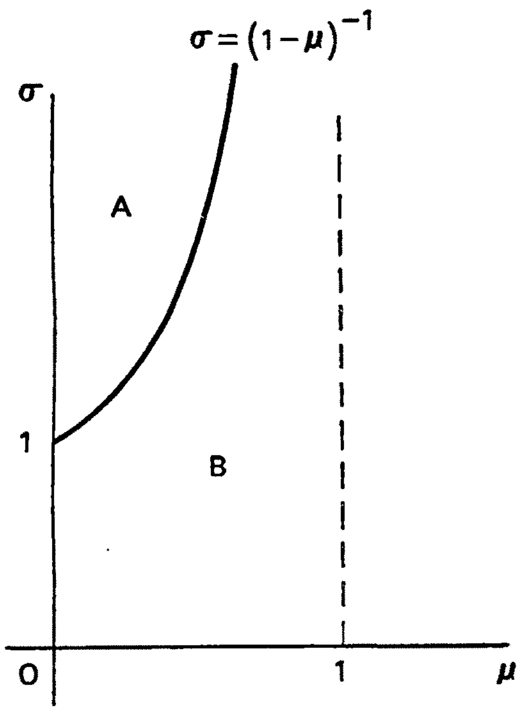

FIGURE 2

from consideration since the model considered here would not have determinate factor demand functions. However, when we are "close" to constant returns to scale we would expect increased uncertainty to have an effect on $E\partial g/\partial K$ similar to that with constant returns to scale.

As noted above, for any $p$ realized *ex post*, greater uncertainty in the distribution of $p$ *ex ante* may increase or decrease the demand for labor depending on the sign of $F_{12}$ and on whether the increased uncertainty increases or decreases the capital input. For the *CES* production function we are using as an example,

$$(28)\quad F_{12} = ab\mu(\mu+\beta)(aK^{-\beta}+bL^{-\beta})^{-(\mu/\beta+2)} \cdot (KL)^{-(\beta+1)}$$

$F_{12}$ clearly has the same sign as $(\mu+\beta)$, and this in turn has the same sign as $(\sigma\mu+1-\sigma)$. Thus,

$$(29)\quad F_{12} \gtrless 0 \quad \text{as} \quad \sigma \lessgtr (1-\mu)^{-1}$$

Figure 2 is again applicable. In region $A$, $\sigma > (1-\mu)^{-1}$ and $F_{12} < 0$. Now, in region $A$ increased uncertainty reduces the capital input, and since $F_{12} < 0$ the reduced capital input results in a larger labor input for any realized $p$. In region $B$, $\sigma < (1-\mu)^{-1}$ and $F_{12} > 0$. In this region the increased uncertainty increases the capital input, and since $F_{12} > 0$ the increased capital input results in a larger labor input for any realized $p$. For the *CES* example, increased output price uncertainty *ex ante* leads to a greater labor input *ex post* for any realized price except on the boundary between regions $A$ and $B$ where there is no change.

## IV. The Risk-Averse Case

In this section we assume the firm is risk averse. It maximizes the expected utility of profits,

$$(30)\quad EU(\pi) = EU[g(K, p, w) - cK]$$

where $U$ is a strictly concave von Neumann-Morgenstern utility function,

$$(31)\quad U'(\pi) > 0 \quad \text{and} \quad U''(\pi) < 0$$

Rather than examine the general case of a mean preserving spread, we simply compare the capital input in a certain situation with that in a situation involving a "small" amount of uncertainty.

Let $Ep = \bar{p}$, and let $\bar{K}$ be the optimal capital input if the price is known to be $\bar{p}$ with certainty. Thus $\bar{K}$ is the solution to

$$(32)\quad \frac{\partial g}{\partial K}(\bar{K}, \bar{p}, w) - c = 0$$

In the uncertain case, the firm maximizes (30). The first-order condition for this optimization is

$$(33)\quad EU'(\pi)\left[\frac{\partial g}{\partial K}(K, p, w) - c\right] = 0$$

The second-order condition is

$$(34)\quad EU''(\pi)(\partial g/\partial K - c)^2 + EU'(\pi)\partial^2 g/\partial K^2 < 0$$

and this is certainly satisfied since $U''(\pi) < 0$ and $\partial^2 g/\partial K^2 < 0$ by (16). The optimal capital

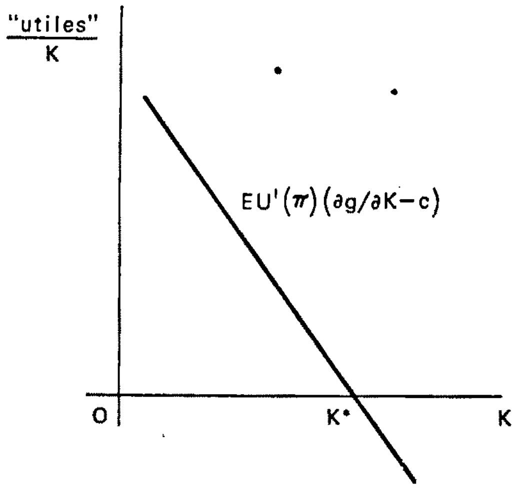

FIGURE 3

input with uncertainty, $K^*$, is shown graphically in Figure 3.

We now determine how $K^*$ and $\overline{K}$ differ. Suppose we insert the certainty capital input $\overline{K}$ in the left-hand side of (33). It is clear from Figure 3 that the certainty capital input is less than (greater than) the capital input with uncertainty if

$$(35)\quad E\left\{U'[g(\overline{K}, p, w) - \overline{K}c] \cdot \left[\frac{\partial g}{\partial K}(\overline{K}, p, w) - c\right]\right\}$$

is greater than (less than) zero. Our approach is to determine whether (35) is positive or negative.

Expanding the expression within braces in (35) around $p=\bar{p}$ and taking account of (32) gives

$$(36)\quad \left[U'(\pi)\frac{\partial^2 g}{\partial K \partial p}\right](p-\bar{p}) + \left[2U''(\pi)\frac{\partial g}{\partial p}\frac{\partial^2 g}{\partial K \partial p} + U'(\pi)\frac{\partial^3 g}{\partial K \partial p^2}\right]\frac{(p-\bar{p})^2}{2} + \dots$$

where all the terms in square brackets are evaluated at $(\overline{K}, \bar{p}, w)$. Taking the expectation of this expression, we find that (35) can be approximated by[3]

$$(37)\quad \left[2U''(\pi)\frac{\partial g}{\partial p}\frac{\partial^2 g}{\partial K \partial p} + U'(\pi)\frac{\partial^3 g}{\partial K \partial p^2}\right] \cdot \frac{Var\,(p)}{2}$$

where again the term in square brackets is evaluated at $(\overline{K}, \bar{p}, w)$ and where $Var\,(p)$ is the variance of the random variable $p$.

Now, by (8) $\partial g(\overline{K}, \bar{p}, w)/\partial p = Q^*(\overline{K}, \bar{p}, w)$ which is certainly positive. Differentiating again, $\partial^2 g/\partial K\partial p = \partial Q^*(\overline{K}, \bar{p}, w)/\partial K = (F_{22}F_1 - F_{12}F_2)/F_{22}$ by (9) and (11). None of our assumptions about the production function give this a determinate sign although one would generally expect it to be positive. This is certainly true for the *CES* production function considered above, as can be shown by some rather tedious calculations. Finally, $\partial^3 g/\partial K\partial p^2 = \partial^2 Q^*(\overline{K}, \bar{p}, w)/\partial K\partial p$ can be either positive or negative. In Section II we showed that it has the sign of $[-\partial(F_{12}/F_{22})/\partial L]$. (See equations (19) and (22).)

If $\partial Q^*/\partial K$ is positive and $\partial^2 Q^*/\partial K\partial p$ is negative then (37) is negative, and the presence of uncertainty reduces the optimal capital stock. In terms of the example involving the *CES* production function, this corresponds to being in region $A$ in Figure 2; and, as we showed in Section III, the smaller capital input due to uncertainty in this region leads to a larger labor input for any realized price. In the unlikely situation where $\partial Q^*/\partial K$ is negative and $\partial^2 Q^*/\partial K\partial p$ is positive, the uncertainty increases the optimal capital stock. In the rather likely situation where both $\partial Q^*/\partial K$ and $\partial^2 Q^*/\partial K\partial p$ are positive, the expression can be of either sign depending on the relative magnitudes of the terms. For the *CES* production function example, this corresponds to being in region $B$ in Figure 2. However, if $U''$ is sufficiently small in magnitude, the $\partial^2 Q^*/\partial K\partial p$ term will dominate and the capital input in the uncertain situation will be larger than in the

[3] Note that I have used the first-order condition under certainty, (32), to simplify the second-order term in (36). Thus, (37) is a valid approximation only for small amounts of uncertainty.

certain situation. If the capital input is larger in the uncertain case, we know from the analysis of Section III that for a *CES* production function this implies a larger labor input and a larger output for any realized price.

These results can be compared with those obtained when both inputs are chosen before the price is observed. In that case we have the Sandmo result, noted in the introduction, that the presence of uncertainty reduces output. Moreover, since the *CES* production function is homothetic, the reduction of output due to uncertainty will certainly reduce both of its factor demands.

## V. Concluding Comments

The results of Section II are particularly strong in that they include the effects of increasing uncertainty as well as the effects of moving from a certain to an uncertain situation. Since the firm is risk neutral in Section II, the uncertainty results derived there have nothing to do with risk aversion. They arise because the firm can partially compensate for what, *ex post*, appears to be a poor decision regarding the capital input by suitably choosing the labor input. I stress that the possibility of doing this is absent if all inputs must be chosen before the uncertainty is resolved.

The results of Section IV are much weaker in that we only compare a certain situation with one involving a small amount of uncertainty. The situation considered in Section IV is rather complicated since the uncertainty effects discussed in Section II frequently run counter to the uncertainty effects arising from risk aversion. However, the analysis does show that the effects discussed in Section II may well dominate the risk aversion effects in many cases, and thus lead to rather different results than those derived under the assumption that all inputs are chosen before the uncertainty is resolved.

# On the Design of Managerial Incentive Structures in a Decentralized Planning Environment

*By* JOHN P. BONIN*

In a recent issue of this *Review*, Liang-Shing Fan presents a bonus scheme intended to induce a manager to report true performance capabilities to a planner. Such properties are extremely desirable for the decentralized planning procedures presently under discussion in several industrial socialist countries. Of current interest is a system called "planning from below," hereafter *PFB*, in which managers self-impose performance norms rather than receive targets from the planner (see Yevsey Liberman's discussion of the profitability norm). Incentives to induce a manager to report and strive for maximal performance are crucial in such a system. This paper considers informational and motivational properties of Fan's scheme and a similar piecewise linear bonus scheme in the decentralized *PFB* environment. For the general stochastic case, Fan's scheme is shown to yield somewhat peculiar norm-reporting results but to possess desirable motivational features.

In *PFB*, as in other decentralized planning environments, the planner interacts with the managers during the decision-making process. Information is initially dispersed so that detailed knowledge about any individual production technology is available only to the manager. The planner uses his knowledge of economic interdependencies and the overall goals of the system, along with any information he receives from the manager, to influence economic activity. The managerial incentive structures are designed in advance by the planner to coax the desired behavior. However, the distinguishing characteristic of *PFB* is that the manager imposes a performance norm upon himself which replaces planner-determined targets in evaluating and rewarding his actual performance. Consequently, the planner seeks to design incentive structures which motivate both norm prediction and performance representing the true capabilities of each manager.

In what follows, the scenario is a single planning period with intertemporal phenomena ignored. Input supply uncertainties make actual performance a random variable when the manager must determine his optimal norm. Although no input delivery plan is available prior to norm reporting, the planner may use the information from the norms to coordinate destinations and dates of delivery for intermediate commodities. Both managerial incentive schemes considered below are piecewise linear functions of actual performance with a kink discontinuity at the reported norm, i.e., the self-imposed target. The manager is assumed to be risk neutral so that he maximizes expected bonuses when calculating his optimal norm. The information and motivational results derived for both bonus schemes are not sensitive to any properties of the manager's probability distribution characterizing supply uncertainties.

In the next section, Fan's symmetric bonus scheme is shown to be preferable to other kink discontinuous ones which penalize deviation of performance from the target level (see Wayne Leeman). Section II considers a piecewise linear bonus scheme which allows nonsymmetric prediction error costs. This incentive scheme permits manipulation of relative prediction error costs so that a manager can be coaxed to take any amount of downside risk desired by the planner. Thus, the planner gains useful information about the expected fulfillment of norms and

can enforce some control on the *PFB* environment. The conclusion summarizes the major results and suggests a possible extension of this method to consider intertemporal phenomena in a different environment.

### I. Fan's Bonus Scheme

So that what follows may be interpreted in various institutional settings, the performance variable will be denoted $X$. In Fan's scheme $X$ would be profit, while in Leeman's it would be output. The manager's knowledge about technology and supply uncertainties is represented by a probability density function $f(X)$ defined for positive values of $X$, a random variable. Maximization of expected bonuses conditioned by $f(X)$ yields the optimal self-imposed target. In Fan's stochastic example, the norm reported is equal to the mean, median, and mode of a simple discrete probability distribution.[1] Hence, interpretation of normal capacity is simple and the incentive-unbiased result for norm reporting straightforward in both the deterministic and the stochastic case. However, when $f(X)$ is any arbitrary density function, we show the optimal norm under Fan's scheme to be the median of $f(X)$.

To derive Fan's optimal norm, rewrite his equation (2), p. 227, as

$$(1) \qquad B = \alpha(X - \epsilon|X - X_0|)$$

where $\alpha>0$, $1>\epsilon>0$, and $|\ |$ denotes absolute value.[2] With bonus written in this fashion, $\epsilon|X-X_0|$ can be interpreted as the nonnegative cost of a norm prediction error for any performance level $X$. It is clear why the manager will always report true capacity in the deterministic case first considered by Fan. Since the minimal value of $\epsilon|X-X_0|$ occurs when $X=X_0$, reporting and achieving true capacity $X'$ yields the maximum bonus $\alpha X'$. The same deterministic behavior is elicited from the bonus scheme suggested by Leeman, p. 436. Contrary to Leeman's assertion on p. 438, bonus schemes that reward overfulfillment of targets need not lead the manager to understate capacity. Indeed, Fan's scheme is such an example, at least in the deterministic case.

In most stochastic environments the definition of normal capacity is not obvious so that Leeman's statement is difficult to evaluate under uncertainty. Interestingly enough, Fan's scheme induces the manager to always report the median of $f(X)$ as the optimal norm. The median would surely be a possible candidate for normal capacity, therefore suggesting a stochastic counterexample to Leeman's assertion. Under uncertainty, expected bonus is written,

$$(2) \qquad E(B) = \alpha[E(X) - \epsilon E(|X - X_0|)]$$

The manager maximizes (2) with respect to $X_0$, given $f(X)$, to determine the optimal norm $X_0^*$. This is formally equivalent to minimizing, with respect to $X_0$,

$$(3) \qquad E(|X - X_0|) \equiv \int_{X_0}^{\infty} (X - X_0)f(X)dX - \int_0^{X_0} (X - X_0)f(X)dX$$

Differentiating (3) with respect to $X_0$ and solving the first-order condition for a minimum yields

$$(4) \qquad F(X_0^*) = \tfrac{1}{2}$$

where $F(X)$ is defined to be the cumulative distribution of $X$. The second derivative of (3) is $2f(X_0)$, which is always positive. Hence, $X_0^*$ determined by (4) minimizes (3). Now $X_0^*$ is simply the median of $f(X)$ by definition. The optimal norm for the Fan manager to report in any stochastic environment is the median of the probability distribution over performance values.[3]

[1] The distribution used by Fan is $f(X')=.5$, $f(X'+\delta)=.25$, and $f(X'-\delta)=.25$ where $X'$ is normal capacity.

[2] In Fan's equation (2), it is obvious that $\epsilon<1$ is envisioned. The rationale for such restriction surfaces when we examine the problem of performance concealment once a target is determined.

[3] The result in Fan's case, when the prediction error is a symmetric piecewise linear function with a single kink at the norm, is completely independent of characteristics of the probability distribution $f(X)$. Some care must be taken to conceptualize the median in discrete cases, but the median, suitably defined, is the optimum performance predictor for the entire class of probability distributions under Fan's scheme.

For purposes of comparison, it would be useful to know what norm the manager rewarded by Leeman's scheme would report in similar circumstances. Unfortunately, no general result can be shown. The various conditions on $f(X)$ under which a symmetric non-linear penalty function for prediction error yields simple norm predictors are given by Clive Granger, pp. 202–03. Although no obvious comparison can be made for norm reporting, Fan's scheme can be shown to be a considerable improvement over Leeman's in motivating performance.

An extremely desirable property of Fan's scheme is that for any *ex ante* prediction, bonuses are maximized at the *ex post* realized value of the performance variable, denoted $X'$.[4] Even if the planner cannot effectively monitor the performance variable, as would likely be the case with profits, the manager gains nothing by concealing performance capabilities. If the predicted norm is not achievable, i.e., $X' < X_0^*$, the maximum bonus is acquired by reporting $X'$ and receiving payment of $\alpha[X' - \epsilon(X_0^* - X')]$. Any other $X < X'$ would generate less bonus. If capacity is initially underestimated, i.e., $X' > X_0^*$, the maximum bonus in Fan's scheme is $\alpha[X' - \epsilon(X' - X_0^*)]$, as long as $\epsilon < 1$. Any other feasible performance $X < X'$ would yield a lower bonus, since the reduction in prediction error cost is less than proportionate to the reduction in $X$.

In contrast, for Leeman's scheme, any initial underestimation of capacity would induce the manager to conceal the higher realized performance, since bonus for performance at norm level exceeds bonus at above-norm levels. This property is most undesirable when the planner cannot easily monitor performance. Because Fan's scheme rewards for overfulfillment, no such motivational problems occur. Rather, the major role of the norm is to convey information to the planner about expected performance. Would the planner prefer to know some statistic other than the median for the purpose of coordinating intermediate transactions? If so, can a bonus structure be formulated which possesses the desirable motivational properties yet elicits different information? The next section addresses the issue of designing optimal bonus structures in *PFB*.

## II. The Planner's Strategy

In a different planning environment, Michael Keren has analyzed the interaction of planning agents when managerial bonuses depend on the fulfillment of a target set by the planner. Crucial to Keren's results is the characterization of optimal managerial performance as a simple function of the imposed output target. Bonus for overfulfillment would severely complicate his analysis. In *PFB*, the target is self-imposed and bonus for overfulfillment is crucial for stimulating performance. In what follows, we attempt to capture the interaction of agents in the *PFB* environment without sacrificing desirable motivational properties.

A piecewise linear bonus scheme with nonsymmetric prediction error cost is considered. By adjusting the weights applied to penalties for misestimating performance, the planner can coax the manager to report a safe or a strenuous norm. By differentiating managerial bonus structures across firms, the planner can impose any desired degree of risk on the overall fulfillment of reported targets. If output norms are reported, the resulting self-imposed production plan can be tuned to any level of tautness. The planner knows in advance the probability that each manager attaches to the attainment of his reported norm. Thus, the planner's risk preference is effectively transmitted to the manager through the bonus scheme with no consequent motivational problems in norm reporting or performance. The planner's strategy is more subtle in *PFB* situations, but the manager is nonetheless manipulatable by judicious design of the incentive structure.

If symmetric costs of prediction error are not imposed, the piecewise linear bonus structure is written

[4] Fan asserts that managers "will strive to attain their target profits set by the planning authority" (p. 226). What becomes clear is that the target in Fan's scheme has no influence on performance. For this reason, I have considered the problem in the *PFB* environment. Indeed, the planner seems to have no role in Fan's scheme. Interestingly, Fan's assertion is correct for Leeman's scheme!

$$(5) \quad B = \begin{cases} \alpha[X - a(X - X_0)] \text{ when } X \geqq X_0 \\ \alpha[X + b(X - X_0)] \text{ when } X \leqq X_0 \\ \text{where } \alpha > 0,\ 1 > a > 0 \\ \text{and} \qquad 1 > b > 0 \end{cases}$$

Then,

$$(6) \quad E(B) = \alpha E(X) - \alpha\left[a\int_{X_0}^{\infty}(X - X_0)f(X)dX - b\int_{0}^{X_0}(X - X_0)f(X)dX\right]$$

Maximizing (6) with respect to $X_0$ is equivalent to minimizing the term in square brackets. The optimal norm is determined as a function of $a$ and $b$. In particular, with $F(X)$ as previously defined,

$$(7) \qquad F(X_0^*) = \frac{a}{a+b}$$

Now, as $a \gtreqless b$, the optimal norm, $X_0^* \gtreqless X''$, the median of $f(X)$. The planner can influence the norm reported by weighting the prediction error costs differently.

Intuitively, when $a$ is large relative to $b$, more serious penalties in terms of foregone earnings are incurred for misestimating the norm on the low side. Consequently, the manager accepts more downside risk and reports a norm which is strenuous compared to that reported in the symmetric case. However, the restrictions on the coefficients indicate that bonus still increases with target overfulfillment. Consequently, given any self-imposed target, the manager will always report the highest possible level of performance, i.e., the realized value of $X$. Thus, this generalized kink discontinuous piecewise linear bonus scheme is exploitable by the planner in *PFB*. A plan resulting from self-imposed targets can reflect any risk of underfulfillment desired by the planner. However, bonus is positively related to performance so that no incentive to conceal above-norm performance exists.

The usefulness of adjusting the coefficients in (5) is exemplified by considering a class of density functions intuitively representative of *ex ante* supply uncertainties in the *PFB* economy. Let $f(X)$ be unimodal and negatively skewed so that $\overline{X}$ the mean $< X''$ the median $< X'''$ the mode.[5] Intuitively, $X'''$ is normal achievable capacity if expected input supplies are forthcoming. Based on previous experience, the manager calculates input estimates which have a high probability of being fulfilled. However, unexpected problems may develop which affect the quantity and timing of input supplies. Bottlenecks causing anything from slight inconvenience to disastrous consequences for the production capability of certain managers can occur with positive probability.

To adjust the riskiness of any plan for intermediate flows determined from reported norms, the planner may prefer some managers to self-impose targets different from the median. For density functions with the assumed skewness, Fan's manager understates normal (modal) capacity and overstates the expected mean value of performance, i.e., $\overline{X} < X_0^* < X'''$. For the nonsymmetric bonus structure in (5), the planner can coax a norm closer to the mode or the mean by judiciously adjusting the ratio $a/b \equiv r$. When $r > 1$, $X_0^* > X''$, and when $r < 1$, $X_0^* < X''$. As long as $r$ is sufficiently close to one, the optimal norm more closely approximates the mode in the first case and the mean in the second case.

An economic interpretation of the relative cost ratio $r$ is rather cumbersome. It is the ratio of the opportunity cost per unit of above-norm performance (in terms of bonus that would have been paid had performance been correctly estimated by the norm) to the penalty cost of each unit of below-norm performance. The planner by adjusting $r$ affects the norm reported. Consequently, the planner can induce the manager to accept any amount of downside risk by increasing the relative opportunity cost of above-norm performance.

The manipulatory property of the bonus scheme makes designing differentiated incentive structures an important planner's strategy in the decentralized *PFB* environment. Consider an example where $X$ represents

[5] Keren, p. 482, suggests that the same skewness is intuitively justifiable as a characterization of supply uncertainty in a centrally planned economy.

output level and the economic system consists of a group of interdependent firms. The planner attempts to formulate a consistent input delivery plan based on his knowledge of intermediate flows, perhaps estimated from previous input-output coefficients. At the same time, the planner has quantified the goals of the system as relative weights on final commodities. When input-output coefficients are known with certainty, Michael Manove describes an algorithm by which production units can be ranked according to the importance of their own product to aggregate final output. High priority firms often produce a commodity which is used extensively as an input throughout the system. Consequently, a shortage of this commodity would reverberate throughout the system. Firms producing final commodities are at the bottom of the ranking. One could conjecture that the fineness of the priority partition depends solely on the quality of the planner's information about interdependencies. Here I refer only to high and low priority firms to illustrate the way in which the planner can manipulate the self-imposed targets in *PFB*.

By setting $r$, the planner determines in advance the probability that the reported norm will be fulfilled or overfulfilled. By the definition of $r$ and (7), the optimal norm is determined from

$$F(X_0^*) = \frac{r}{r+1} \tag{8}$$

The probability that norm $X_0^*$ is at least fulfilled is then given by

$$1 - F(X_0^*) = 1 - \frac{r}{r+1} = \frac{1}{1+r} \tag{9}$$

By setting $r<1$ for high priority firms, the planner knows that the norm reported has a better than 50 percent chance of being met. Hence, the output reported would be a relatively safe estimate of the aggregate availability of that commodity for use as an input by other firms. On the other hand, $r>1$ induces the manager to take more downside risk. Hence, the norm reported will be underfulfilled more than half the time.

The planner may then use his knowledge of interdependencies to assign the differentiated $r$'s across priority classes. Managers of high priority firms could be induced to report relatively safe targets which in turn would help insure adequate input supplies. Low priority firm managers could be coaxed to impose relatively strenuous norms upon themselves. Moreover, the planner can impose his risk preference on the entire plan. Indeed, by increasing all $r$'s, the planner decreases the likelihood that each individual norm is fulfilled. Hence, such a self-imposed plan would be more risky. A comparison of the planner's strategies according to some average of all $r$'s weighted by priority class, call it $\bar{r}$, would index *PFB* "plans" according to tautness. Therefore, the optimal degree of plan tautness, common to the central planning literature, applies to decentralized *PFB* environments as well.

A complete analysis of plan tautness in *PFB* requires a theory explaining the manager's formation of his expectations about performance levels. Clearly, tauter plans affect the probability of obtaining inputs on time. Supply uncertainties were the primary basis for formulating a probability distribution about performance levels. Therefore, any information a manager might obtain about the expected degree of overall tautness $\bar{r}$ would be used to characterize $f(X)$. Given our assumptions about dispersion of information and the type of vertical communication between the manager and the planner, such information would be learned from past experience. Perhaps a sequential model with managerial subjective probabilities formed by adaptive expectations could adequately address this problem.

## III. Conclusion and Extension to Other Environments

In a decentralized informationally dispersed stochastic environment, the piecewise linear bonus scheme with a kink discontinuity at the target possesses desirable properties. Fan's scheme, a special case in which costs of prediction error are symmetric, yields maximum feasible performance for any target since it rewards overfulfillment. At the same time, the manager reports neither a strenuous nor a safe norm, the latter con-

jectured by Leeman to result when bonus for overfulfillment is paid. Instead, for any probability distribution over performance, the manager reports the median. In contrast, Leeman's bonus scheme requires more structure on the probability density function to yield simple norm-reporting results, but more importantly it induces concealment of any above-norm performance.

Interesting interactions between the planner and the manager arise when nonsymmetric prediction error costs are allowed. By adjusting the ratio of the opportunity cost for underestimating performance to the penalty cost for below-norm performance, denoted $r$, the planner can coax a safe or strenuous norm from any manager. In all cases, the incentive to maximize performance given any self-imposed target is retained. The nonsymmetric bonus scheme may be safely manipulated by the planner to impose his own risk preferences on an entire physical production plan determined by the managers themselves. Increases in all $r$'s, or perhaps an increase in an appropriately weighted index $\bar{r}$, indicate a tauter plan. In this case, the probability of managers achieving self-imposed output targets falls, with possible effects on the entire system's ability to balance intermediate transactions. Nonetheless, by judiciously designing the managerial incentive schemes according to his knowledge of economic interactions, the planner can coax managers to respond to the goals of the system in *PFB*.

Despite remarks to the contrary (see p. 227), Fan does not allow the infamous ratchet effect to influence norm reporting or actual performance. To introduce the ratchet effect requires explicit consideration of the interaction between the manager's performance and the planner's strategy for intertemporal target variation.[6] Both in *PFB* and in Fan's model, current norms and performance do not affect the probability of target fulfillment or overfulfillment in any future period. Such dependence led Keren to conjecture the importance of the ratchet effect when bonus is paid for overfulfillment in the jump discontinuous case (see Keren, p. 471, fn. 5). However, the structural similarity of the problem of norm reporting with point estimate prediction in stochastic decision making suggests a potentially fruitful line of attack on this more complex bonus structure in a different planning environment.

[6] Sam Gindin discusses the ratchet problem in a two-period deterministic situation for a special type of target variation. Intuitively, when the bonus structure is jump discontinuous at the target, the manager is more interested in safe targets.

# The Dynamics of Inflation in Latin America: Comment

By ROGER R. BETANCOURT*

In a recent article in this *Review*, a statistical analysis of aggregate data for sixteen Latin American countries leads Robert Vogel to the following conclusion: "The most important result of the present study for this controversy [monetarist-structuralist] is that a purely monetarist model, with no structuralist variables, reveals little heterogeneity among Latin American countries, in spite of their extreme diversity" (p. 113). One purpose of this paper is to show that this inference is inappropriate given the results presented in Vogel's paper. Moreover, the appropriate inference of heterogeneity among Latin American countries sheds no light on the monetarist-structuralist controversy. For no monetarist would argue that the same monetarist model must apply to every Latin American country. Instead of dwelling on the controversy, this note focuses on answering two of the questions which arise from the appropriate interpretation of Vogel's results: given the monetarist model used by Vogel, are there patterns in the differences of behavior among the Latin American countries? Since the answer to this question is yes, then: what do these patterns indicate about the nature of the inflationary process in Latin America?

## I

In order to facilitate the exposition a brief review of the underlying model, equation (6) in Vogel's paper, is necessary. This model relates the rate of inflation $P'_t$ to the rate of change in the money supply ($M'_t$), the rate of growth of income ($Y'_t$), and the lagged change in the rate of inflation ($P'_{t-1}-P'_{t-2}$) as follows:

$$(1) \quad P'_t = k + dM'_t + eM'_{t-1} - (1+a)Y'_t + b(P'_{t-1} - P'_{t-2})$$

where $k$ is expected to capture trends in velocity; $d$ and $e$ capture the current and lagged adjustment of prices to changes in the money supply, respectively; $a$ indicates the effect of real income on the ratio of real balances held to real income; and $b$ captures the effect of the expected costs of holding real balances.

Vogel arrives at the conclusion previously quoted by applying the above monetarist model to all Latin American countries. He estimates the model introducing country dummies for all the slope coefficients. His own $F$-test rejects the null hypothesis that the same model (same slope coefficients) applies to all Latin American countries at the 1 percent level. But the author proceeds to ignore this result because the test only "barely" rejects the null hypothesis! Since the probability of type I error (rejecting the null hypothesis when it is true) is only 1 percent whereas the probability of type II error (accepting the null hypothesis when it is false) is likely to be much larger, the dismissal of this result is totally unwarranted on statistical grounds. Consequently, no substantive conclusion can be said to follow from the dismissal of this result. The appropriate conclusion which follows from the test is that there is heterogeneity among Latin American countries in the coefficients of the variables in the model.

## II

This section presents the result of attempts to find patterns in these heterogeneous results. A look at Table 3 of Vogel's paper, p. 108, which provides the individual country regressions, yields little information on this issue because the variability in the results makes it difficult to detect any patterns. Notwithstanding, Vogel's discussion as well as the basic data presented in his Table 1, p. 103, seem to suggest that the countries fall into three clearly identifiable groups and

* Associate professor of economics, University of Maryland. I thank R. Vogel for a listing of his data and L. Radey for her research assistance. The computer Science Center at the University of Maryland provided support for the computations.

it may be possible to identify patterns by comparing the between group results. The three clearly identifiable groups are: high inflation (*H.I.*) countries (Argentina, Uruguay, Brazil, Chile, and Bolivia); moderate inflation (*M.I.*) countries (Paraguay, Colombia, Peru, and Mexico); and low inflation (*L.I.*) countries (Nicaragua, Ecuador, Honduras, Costa Rica, Guatemala, Venezuela, and El Salvador).

This grouping provided the point of departure in my search for the patterns in the coefficients that the data supported. The null hypothesis that the slope coefficients were the same across all countries was rejected at the 1 percent level when tested against the alternative that the slope coefficients were the same within a group and were different between groups ($F^{8}_{231}=6.2461$). However, the null hypothesis that the coefficients only differ between groups was rejected at the 1 percent level when tested against the alternative that the slope coefficients differ for all countries ($F^{52}_{179}=2.1527$).

Since the data rejected the restriction that the slope coefficients differ only between groups, Argentina was taken out of the high inflation groups and its slope coefficients were allowed to be different.[1] The null hypothesis that the slope coefficients differ only between groups was rejected at the 1 percent level when tested against the alternative that the slope coefficients differ between the (new) groups plus Argentina ($F^{4}_{227}=11.276$). Moreover, the null hypothesis that the slope coefficients differ between the (new) groups plus Argentina could not be rejected at either the 1 percent or the 5 percent level when tested against the alternative that the slope coefficients are different for all countries ($F^{48}_{179}=1.3274$). Thus, the grouping modified to allow the coefficients for Argentina to be different yields the pattern that the data support.

## III

The results of the pooled regressions allowing the coefficients to differ between groups are presented in Table 1 for both the grouping which includes Argentina among the high inflation countries (second block) and the grouping which treats Argentina separately (first block).

Note that the main features of the results are the same in both parts of the table. First, the impact of increases in the rate of growth of the money supply, either current or lagged one year, on the rate of inflation is substantially larger in both high and moderate inflation countries than in low inflation countries. (The null hypothesis of no difference in the impact is rejected using a two sided $t$-test at the 10 percent level in three of the four cases in part *A* and in two of the four cases in part *B*.) Secondly, the impact of the rate of growth of income on the rate of inflation differs among the three groups of countries. For example, in the high inflation countries this coefficient is small, and not significantly different from zero at the 10 percent level. On the other hand, in the moderate inflation countries this coefficient is significantly different from zero but not significantly different from (minus) unity using a two-sided $t$-test at the 10 percent level whereas the same type of test in the low inflation countries yields the result that this coefficient is significantly different from both zero and (minus) unity. Finally, the coefficient of the lagged changes in the rate of inflation tends to be small and statistically insignificant. The only exception is the high inflation countries in part *A* of the table where the estimated coefficient is significantly different from zero at the 10 percent level.

One of the most striking results in Table 1 is the magnitude of the estimated coefficient for Argentina of the rate of growth of income. This estimate is much larger than the estimates for any of the groups as well as significantly different from zero at the 1 percent level. Since the individual country regressions indicated that the same might be

[1] Initially Venezuela was taken out of the low inflation group and its slope coefficients were allowed to be different. However, the null hypothesis that the slope coefficients differ only between groups when tested against the alternative that the slope coefficients differ between the (new) groups plus Venezuela yielded a very low $F$ ratio, i.e., $F^{4}_{227}=.08$. Both Argentina and Venezuela were chosen because they seemed to differ the most from the rest of the group in their socioeconomic characteristics.

[a] One or two asterisks indicates that the coefficient is significantly different from zero at the 10 percent or 1 percent level, respectively, using a two-tailed test.

The first block presents the results for the pooled regression with common intercept allowing the slope coefficients to differ between groups and for Argentina. The intercept was positive and insignificant at the 10 percent level ($R^2=.8740$; $\bar{R}^2=.8675$).

The second block presents the results for the pooled regression with common intercept allowing the slope coefficients to differ between groups. Again the intercept was positive and insignificant at the 10 percent level ($R^2=.8516$, $\bar{R}^2=.8438$).

[b] The three groups are defined as in the text except for the high inflation group ($H.I.$) which excludes Argentina.

[c] The three groups are defined in the text.

[d] These are the results for the pooled regression with common intercept and not allowing the slope coefficients to differ. It is the same as one of Vogel's regressions and the intercept is negative and significantly different from zero ($R^2=.8195$, $\bar{R}^2=.8165$).

true for Uruguay, the pooled regression was run treating both Argentina and Uruguay separately. The estimate of the coefficient of the rate of income growth for Uruguay was also much larger than for any of the groups and significantly different from zero at the 1 percent level. Interestingly enough, the results for the three groups and Argentina were quite similar to those reported in Table 1.

These results indicate how the inflationary process in Latin America differs between the three groups of countries, for example, in the impact of the rate of growth of the money supply and the rate of growth of income. They also indicate how the inflationary process differs even within the high inflation group of countries, for example, in the impact of the rate of growth of income for Argentina and Uruguay. Moreover, these differences are not very sensitive to minor changes in specification. For instance, suppressing the lagged change in the rate of inflation leads to a new set of estimates for the pooled regressions such that in the twenty-one possible comparisons (taking all elements of the table together) the largest difference between the old and the new results is .037.[2] While more elaborate or alternative theoretical and econometric specifications will affect the magnitude of the point estimates, they are not likely to obliterate the differences; on the contrary, they are likely to introduce new sources of differences. Instead of searching for these additional differences in the context of more elaborate models,[3] I conclude by raising the question: what explains the differences already observed in the inflationary process between these groups of Latin American countries?

Answering the above question requires, in my opinion, a detailed comparative analysis of the countries in the different groups over the sample period. In particular, such an analysis might be able to ascertain whether the low inflation countries have refrained from using monetary policy consistently to promote growth or resolve social conflicts and whether the opposite is true for moderate and high inflation countries. It would also be of interest to ascertain if this difference in policies, assuming that it exists of course, is due to favorable external circumstances, conscious design, or the nature of the social, political, and economic environment prevailing in these countries. Finally, a detailed comparative analysis may also help explain

[2] Similarly, correcting for heteroskedasticity hardly affects the patterns in the point estimates.

[3] It doesn't follow that we consider this area of further research useless or unimportant; but, given the data limitations for cross-country analysis, the main elaborations worth exploring can't be implemented except for some individual countries; for example, see A. C. Pastore.

the association between the high rates of growth over the period and inflation in the moderate inflation countries.

# The Dynamics of Inflation in Latin America: Comment

By EDMUND J. SHEEHEY*

In a recent issue of this *Review*, Robert Vogel extended to sixteen Latin American countries a technique used by Arnold Harberger to examine the chief causes of Chilean inflation. On the basis of pooled regressions for the sixteen countries, he concluded that with little heterogeneity, the different rates of inflation cannot be put to structural differences but must be attributed to varying rates of expansion of the money supply. Only monetary variables are employed and the link between inflation and the rate of money supply growth rests essentially on $\bar{R}^2$ so high as to leave little of the variation in the rate of price increase for other variables to explain. This note contends that in coming to such broad conclusions on the basis of only monetary variables, Vogel has committed an error that the Harberger model was designed to avoid. Some regressions based on Argentine data are presented by way of illustration.

As a partial justification for using only monetary variables, Vogel states the Harberger model is essentially monetarist. In his original study, however, Harberger focused specifically on the problem of multicollinearity between changes in the money supply and the wage rate. He suspected that the long history of Chilean inflation consisted of instances when increases in the quantity of money had brought rising prices in the absence of wage increases, other instances when wages had pushed up prices without being "financed" by expansion of the money supply, and still others when inflation had been accompanied by wages and prices rising together. Regression analysis cannot sort out these instances, he asserted, " . . . but it can give some indications of their relative importance, and can surely distinguish between the extreme positions that deny the explanatory power of either wage changes or monetary changes, once the other is taken into account" (p. 228). Thus Harberger contended that if either monetary changes or wage changes are excluded, the regression analysis might not be able to distinguish between these extreme positions.

A formulation such as Vogel's, using money supply changes and lagged values of the rate of inflation, can capture the variation in prices resulting from: 1) current and past instances in which money supply changes alone have driven up prices; 2) current and past instances in which monetary and structural variables have risen in step; and 3) past instances in which structural variables alone have been at work. The only instances that it clearly will not capture are those in which current structural variables have operated without accompanying money supply changes.

Vogel's high $\bar{R}^2$ indicate that these instances have been few relative to all others. However, because Vogel's model will attribute to monetary factors the variation in prices due to both current structural causes which have been financed by increases in the money supply and past causes which have affected the lagged price variable, these $\bar{R}^2$ cannot say anything about the relative importance of structural and monetary factors. The Harberger model is designed to identify the relative inflationary impact of structural and monetary factors when each has operated alone. If it is true that in the majority of instances both have operated together and that in an important number of instances, each has forced up prices on its own, then either a totally monetary model, such as Vogel's, or a totally structural one will leave only a small portion of the variation in prices unexplained. Their relative importance as independent inflationary forces will only show up in an equation which uses both sets of factors.

*Sources:* See the author. With the exception of real supply for the years 1950 to 1966 which is taken from Diaz-Alejandro, p. 534, all data are from official publications of the Argentine Republic.
*Note:* All data are percentage changes (denoted by primes) in semiannual averages. The dependent variable is the wholesale price index; $M$ is currency plus demand deposits; $Y$ is real supply, defined as gross domestic product plus imports; $P_{t-1}$ is lagged wholesale prices; $EXR$ is the exchange rate, defined as total peso trade divided by total dollar trade; and $W$ is the wage rate. The $t$-values are given in parentheses below each coefficient; $\bar{R}^2$ is the multiple correlation coefficient adjusted for degrees of freedom; $SE$ is the standard error of the estimate; and $D.W.$ is the Durbin-Watson statistic. Beginning with the second half of 1950, there are 43 observations for each regression.

Based on Argentine data for the period 1950 to 1971, the regressions in Table 1 alternatively present extreme monetarist and structuralist models and one that combines the two. The dependent variable is the wholesale price index and all data are semiannual averages. In the first equation, a formulation similar to Vogel's would seem to reinforce his monetary hypothesis. Current and lagged changes in the money supply, the current change in real supplies, and the rate of inflation from the previous period explain almost 60 percent of the variation in the rate of growth of prices. The combination of positive and negative money supply coefficients supports the hypothesis of Adolpho Diz that the response in Argentina to money supply increases has been an initial overshooting with a sharp deceleration a year or more later. The Durbin-Watson statistic gives no indication that significant variables have been omitted.

Equation (2), however, employs only structural variables and confirms precisely the opposite view. The hypothesis underlying this formulation is that wage and exchange rate increases are the active inflationary agents and the money supply is passively increased in order to avoid a serious shortage of liquidity. While devaluations have their main effect through an almost immediate rise in the price of tradeable goods, the impact of wage increases is spread out over the following year.[1] All three coefficients are significant at well above the 5 percent level and most of the inflationary impact of wages comes with a lag of six months. The $\bar{R}^2$ is far higher than that of the monetary model and the Durbin-Watson statistic is in the acceptable range.

Equation (3) employs both sets of variables as a test of the relative importance of Harberger's three sets of instances. The coefficient for $M_t$ is still significant at about the 5 percent level, but both it and that for lagged prices are greatly reduced in size and significance. The performance of the structural variables argues that the inflationary pressure they have exerted on their own has been far more important than that of the money supply.

These results serve to reinforce Vogel's own evidence of errors in the specification of his model. They show that high $\bar{R}^2$ for a purely monetary formulation are by no means inconsistent with even higher ones for a purely structural model. For Argentina the use of monetary and structural variables together shows the course of rising prices as alternatively propelled by demand and cost pressures with the latter apparently playing the greater role. If Vogel is correct in concluding that the inflationary process in Latin America is fairly homogeneous, then the results for Argentina may well give an accurate description of that process.

[1] For a structuralist model of inflation that would justify this formulation, see Ronald Findlay. See also Carlos Diaz-Alejandro.

# The Dynamics of Inflation in Latin America: Reply

*By* ROBERT C. VOGEL*

Roger Betancourt and Edmund Sheehey have offered interesting comments on my recent article on inflation in Latin America. Since each of these comments has a rather different focus, they are dealt with independently, first Sheehey's comment and then Betancourt's. In discussing Betancourt's comment, predictions of inflation based on coefficients estimated in my earlier article are compared with actual rates of inflation in Latin America in the 1970's.

The empirical work in my earlier article focuses on extending the Harberger model to sixteen Latin American countries by means of pooled time-series cross-section regressions, while Sheehey's comment concentrates on a single country by essentially replicating the earlier empirical work of Carlos Diaz-Alejandro and Adolfo Diz on Argentina. In attempting to build a case for his statistical analysis, Sheehey misinterprets my article at several key points. First, my conclusions with respect to the monetarist-structuralist controversy do not rest essentially on high $\bar{R}^2$s, as Sheehey asserts, but rather on limited heterogeneity. This is clearly stated in my article, p. 113, and quoted by Betancourt, but recognition of this point would make Sheehey's statistical analysis largely irrelevant, since his analysis is concerned only with Argentina.

Second, the essentially monetarist nature of the Harberger model is, as Sheehey states, a partial justification for my omission of structural variables. However, Sheehey neglects to mention what is made very clear in my article, p. 106: the primary reason for not including wages and exchange rates is that comparable data do not exist for a sufficient number of Latin American countries.[1] To assemble and analyze such data could provide a major contribution to the literature on the monetarist-structuralist controversy, but it would also require extraordinary effort.

Third, Sheehey asserts that my article reaches broad conclusions on the monetarist-structuralist controversy. On the contrary, my article, p. 113, emphasizes the difficulty of reaching such conclusions by pointing out that even with roughly similar findings, Harberger (1963), Diaz-Alejandro (1965), and Diz reach quite different conclusions on the relative importance of monetary and structural causes of inflation. As indicated in my article, p. 113, and discussed below, a principal issue is whether wage rates or the money supply is the autonomous variable, and my suggestions for further research emphasize the importance of investigating this issue, as well as the potential usefulness of adding structural variables to the model.

Although Sheehey claims to be following Harberger's approach and criticizes my article for failing to do so, he in fact fails to follow Harberger in two very important respects. First, Sheehey's lagged price variable is not the explanatory variable used by Harberger or in my article (see pp. 105–06). Contrary to Sheehey's interpretation, my extension of the Harberger model does not involve using the lagged rate of inflation to explain the current rate of inflation. Harberger (1963, pp. 225–27) is very clear that it is the change in the expected rate of inflation which changes the expected cost of holding money and hence affects the rate of inflation. Accordingly, Harberger and I use the lagged change in the rate of inflation as an explanatory variable, whereas Sheehey uses simply the lagged rate of inflation.[2] Thus the equation estimated by Sheehey contains a lagged dependent variable and may be viewed as a

* Associate professor of economics, Southern Illinois University at Carbondale.

[1] Another reason given in my article, but also overlooked by Sheehey, is the rather limited importance of structural variables in the findings of Arnold Harberger (1963), Diaz-Alejandro (1965), and Diz.

[2] Diz, pp. 114–15, constructs a series for exogenous changes in inflationary expectations, while Diaz-Alejandro (1965) omits all lagged variables from his reported regressions.

lagged adjustment model.[3] This view gives a rather different interpretation to the coefficients of Sheehey's explanatory variables and, in particular, to the patterns of response over time.

Second, Harberger (1963, pp. 227–29) emphasizes the use of an autonomous wage rate as an explanatory variable, whereas Sheehey apparently uses a realized, *ex post* wage rate.[4] The importance of using an autonomous wage rate should be clear: the change in a realized, *ex post* wage rate will be closely correlated with inflation unless inflation has a significant impact on real wages, a position which is not widely held.[5] Sheehey's equation also includes the lagged change in the wage rate which, it might be argued, could not be influenced by the current rate of inflation, but such an argument overlooks the likely correlation between leads and lags of the same variable. In particular, Diaz-Alejandro (1970, p. 376) finds a correlation of .44 between the current change in the wage rate and the change in the wage rate lagged two (six-month) periods. Sheehey suggests that multicollinearity between changes in the money supply and changes in the wage rate may present a problem in determining the cause of inflation, but a more basic problem is which is the autonomous variable. Both Harberger (1963, p. 245) and Diaz-Alejandro (1965, pp. 123–24) explore the correlation between leads and lags in the money supply and wage rates in their attempts to resolve this issue, but Sheehey does not deal with this issue.

Since Diaz-Alejandro and Diz had previously applied the Harberger model to Argentina, Sheehey's comment on my article may be viewed as primarily a comment on these earlier studies. Curiously, however, Sheehey does not point out that his findings are strikingly different from those of Diaz-Alejandro (1965) and Diz. In contrast to the predominance of structural variables in Sheehey's findings, monetary variables are at least as important as structural variables in Diaz-Alejandro's (1965) results, and Diz finds that monetary variables are clearly dominant. These differences may be due to differences in the definitions of certain variables or to differences in the time periods covered.[6] However, this is primarily an issue between Sheehey and Diaz-Alejandro and Diz, and does not seem to warrant further discussion here.

Betancourt's comment makes what could have been a significant contribution to understanding patterns of inflationary behavior in Latin America. However, the findings from his empirical work are marred by a serious statistical flaw which will be discussed below. In addition, Betancourt misinterprets the conclusion of my article, p. 113. He is incorrect in asserting that I ignore the existence of heterogeneity in slope coefficients among Latin American countries, and the quote which he selects from my article to illustrate his point even states that there is heterogeneity. The point which my article does make in stating clearly that there is significant heterogeneity at the 1 percent level is that "the $\overline{R}^2$ obtained by allowing all coefficients to differ among countries is only .03 higher than the $\overline{R}^2$s obtained in the pooled regressions in Table 2" (p. 109). This result, that allowing for heterogeneity among Latin American countries brings such a relatively small improvement in the explanatory power of the Harberger model, seemed to me quite surprising at the time the article was written. Moreover, it still seems to me quite surprising considering the widely differing inflationary experiences of Latin American countries and the importance frequently attributed to structural differences.

Contrary to Betancourt's argument, my article never implies that a "monetarist would argue that the same monetarist model must apply to every Latin American coun-

[3] As pointed out by Marc Nerlove and Kenneth Wallis, Durbin-Watson statistics are no longer appropriate when lagged dependent variables are introduced.

[4] Sheehey in fact nowhere defines his wage variable, but since he cites Diaz-Alejandro (1970) as the source for some of his data, it can probably be assumed that he uses Diaz-Alejandro's wage variable.

[5] See, for example, Harberger (1964, pp. 325–29).

[6] For unexplained reasons, Sheehey extends his study two years beyond mine, but he does not go back before 1950, despite the fact that both Diaz-Alejandro (1965) and Diz do.

try." It is indeed clear that monetarists would not argue that it is *necessary* for all Latin American countries to have identical coefficients; for example, monetarists have found income elasticities of the demand for money which differ widely among countries. However, the lack of heterogeneity in a monetarist model could be a *sufficient* reason for rejecting the structuralist position and accepting the monetarist view. In short, Betancourt has confused necessary and sufficient conditions.

Despite his attack on the empirical work in my article, Betancourt has failed to follow proper statistical procedures in reaching his own conclusions. It would have been an important contribution if Betancourt had found three distinct groups of Latin American countries with homogeneous coefficients within each group.[7] Unfortunately, Betancourt's own $F$-tests reject this outcome at the 1 percent level of significance. However, he then goes on to experiment with the data without acknowledging that under such conditions tests of significance no longer have the same meaning.[8] On the basis of undefined socioeconomic characteristics, Betancourt separates Argentina and Venezuela from their respective groups, and he then puts Venezuela back in its group to achieve the results which best suit his purposes. Subsequently, Betancourt also separates out Uruguay along with Argentina because of their large negative coefficients for income. However, for reasons which he does not mention, he fails to separate out Colombia which has a larger negative coefficient for income than Uruguay. Given this experimentation with the data, the standard statistical tests are no longer applicable, and it is not clear what can be concluded about similarities and differences in inflationary behavior. Almost inevitably some groupings of Latin American countries will provide so-called significant patterns, but this is not the appropriate procedure for hypothesis testing.

The data generated by Latin American countries since 1969 present an unusual opportunity to test the applicability of the Harberger model under greatly changed circumstances. The 1970's, particularly 1973 and 1974, have brought dramatic increases in the rate of inflation in most Latin American countries, and these changes have been accompanied by lengthy discussions of imported inflation and various structural problems. It is thus important to inquire to what extent the Harberger model with coefficients estimated on the basis of data for the period 1950–69 can explain Latin American inflation in the 1970's. In particular, the predictive power of the coefficients based on pooled regressions can be compared with the predictive power of the coefficients based on individual country regressions and on Betancourt's grouping of Latin American countries.

The May 1976 issue of *International Financial Statistics* provides data for 70 of the 80 possible observations (sixteen countries over five years) for comparing actual and predicted inflation from 1970 through 1974. When the predicted rate of inflation is calculated using the coefficients from the individual country regressions reported in Table 3 of my article, the actual rate of inflation is underpredicted by more than 8 percent on the average, while the coefficients from Betancourt's groupings yield an average underprediction of more than 4 percent. On the other hand, the coefficients from the pooled regression (with common intercept) in Table 2 of my article underpredict the rate of inflation by less than 2 percent on the average. In terms of mean square error, the coefficients from the pooled regression and from Betancourt's groupings yield almost identical results, while the mean square error for the coefficients from the individual country regressions is almost twice as great. Thus the coefficients from the pooled regres-

[7] As Betancourt indicates, his division of Latin American countries into three groups is based on my categories, p. 102. However, Betancourt fails to mention that the patterns which he discusses in the third section of his comment had already been noted in my article, p. 108.

[8] Michael Lovell (1974) examines other aspects of such experimentation which he terms "data-grubbing." Lovell has also pointed out to me that the coefficients for lagged rates of inflation can be interpreted in the context of second-order difference equations (see Lovell, 1975, pp. 410–14); and examination of the coefficients in Tables 2, 3, and 4 of my article reveals no examples of explosive behavior.

sion perform somewhat better than the alternatives in predicting Latin American inflation in the 1970's, and it is particularly interesting to note that only the predictions based on the pooled regression do not substantially underpredict the recent upsurge of inflation in Latin America.

# The Relationship between Relative Prices and the General Price Level

*By* Daniel R. Vining, Jr. and Thomas C. Elwertowski*

"If one great group of commodities varies pretty uniformly in one direction, and another in a different direction (or even in the same direction but in a markedly different degree), then the task of restoring the level of prices can no longer be regarded as a purely objective *quaesitum*, a currency problem."
*F. Y. Edgeworth*

It is very nearly a truism among neoclassical economists that the public is wont to confuse changes in the general price level with relative price changes. Correspondingly, one might speak of the independence between the two as one of the central postulates of the neoclassical tradition.

William Stanley Jevons was among the first to identify this basic dichotomy in economic life as well as to attempt to explain the ordinary citizen's seeming incapacity to understand it:

It is almost impossible, too, for any person to detect the effects of the change in the standard in his own personal affairs. Besides the interference of changes in prices and profits and activity of trade, which affect most persons, each individual has his own fluctuations of prosperity and adversity. If his income is not variable, at least his expenditure is more or less so. There are a hundred items of expenditure, some increased, some diminished, and among the variety of unmeasured circumstances, it is impossible for him to *feel* the very slow and measured change of 20 or 30 percent, spread over twenty or thirty years. If his receipts are variable and increasing, he enjoys the consciousness of prosperity, and probably attributes it complacently to his own abilities and deserts. If his income consists of fixed dividends or rents, he receives the same pieces of money as before, and has no thought that they are not what they were. *It is when he comes to pay his household bills that he can alone feel the difference. And then the difference seems to arise from the deficient harvest, from the growth of population, from the extortion of tradesmen, from anything rather than the change of a British sovereign fresh from the Mint. Value is the most invisible and impalpable of ghosts, and comes and goes unthought of while the visible and dense matter remains as it was.* [p. 75, last italics added]

Jevons' diagnosis of this misperception as due to the very gradual rise in the cost of living, however, has been badly undermined by recent events: the ordinary citizen persists, in the face of rates of decline in his dollar's purchasing power of as much as 12 percent annually, in attributing this decline to the abnormal behavior of *certain* prices. How little progress has been made since Jevons' day on the part of the public towards accepting a revision of this view of inflation is suggested by the preoccupation of contemporary economists, in their public addresses and popular writings, with the explication of this simple dichotomy between relative prices and the general price level:

*Milton Friedman:* . . . what of oil and food to which every government official has pointed? Are they not the immediate cause of the price explosion? Not at all. It is essential to distinguish changes in *relative* prices from changes in *absolute* prices. The special conditions that drove up the prices of oil and food required purchasers to spend more on them, leaving less to spend on other items. Did that not force other prices to go down or to rise less rapidly than otherwise? Why should the *average* level of all prices be affected significantly by changes in the prices of some things relative to others? [1974, p. 73]

*Alan Greenspan:* I think that there is a general fiscal-financial-monetary cause of inflation which essentially overrides all other

considerations. Put another way: I do not believe that, in the longer run, the general price level is determined by the sum of its parts. . . . The relationship between the price of steel, for example, and the price of wheat is a relative concept—that is, it is determined by the relative supplies and demands, and the absolute price level of each is not determined by that relationship, but by the aggregate price level. Algebraically, we know of course that if we define all relative prices—that is, the relationship of one price to all others—and state the total price level, all individual prices are algebraically calculable. I submit that is a bit more than a statistician's calculation; it is something not terribly different from the process by which our price system is determined. [p. 2]

*Edgar Fiedler:* Despite the seriousness of the inflation problem, it is not well understood. I am particularly conscious, for example, of the widespread confusion between inflation, which reflects the general level of prices, and price changes for individual commodities. Most people will point to the price increase for fuel oil or rice or scrap steel, each of which has doubled in the past year, and call it inflation. But that is no more valid than pointing to soybeans or pocket calculators, all of which can be bought today for less than last year, and calling it deflation. Thus, it is important to remember that inflation is what happens to all prices, on the average. When we forget that point we forget the fundamental nature of inflation—and then we start to think about corrective policies that tend to treat the symptoms of the problem rather than its cause. [pp. 2–3]

It is the thesis of this paper that the popular folklore in fact enjoys ample justification in the data; it shall be shown that the behavior of the general price level is related in a statistically systematic manner to the behavior of individual prices relative to each other. To establish this thesis, of course, we must first make more precise what is meant by the contrary notion that the general price level is independent of relative price behavior.

A recent essay in this *Review* by Robert Lucas provides us with the necessary formalization of this notion of independence to test it on the incomparably rich body of data available on prices in this country. The article is set apart from previous attempts in the neoclassical school to represent mathematically this dichotomy in that it allows relative prices to vary. Previous work (see, for example, Don Patinkin) depicted relative prices as constant and, therefore, since they never shift, obviously and trivially independent of changes in the general price level. It does not require an elaborate analysis of price data to know that the hypothesis of relative-general price independence in this form must fail. Lucas' innovation is to represent this independence in the language of probability theory: the movement in the general price level over time, the mean of the distribution of a population of individual prices in the Lucas model is independent of (in the sense that it has no effect on) the remaining parameters and form itself of this distribution; and in the latter is captured our notion of "relative price behavior." Unlike the form the hypothesis takes under Patinkin's hands, there is no a priori reason to expect (except for the persistence of popular feeling to the contrary) Lucas' hypothesis not to fit the facts; that is, that the two forms of variation, one of the general price level over time and the other of individual prices relative to each other at a particular time specified probabilistically will have any relationship.

To summarize Lucas' model, let

$$P_{it} = P_t + z_t \tag{1}$$

where $P_{it}$ is the logarithm of the price of the $i$th good at time t, $P_t$ is the logarithm of the general price level at time t and a random variable, and $z_t$ is also a random variable, but independent of $P_t$. The difference $P_{it}-P_t$, then, is the logarithm of the relative price of good $i$, and in contrast to Patinkin's model is a random variable rather than a constant. In the Lucas model, this random variable is assumed to be normally distributed with mean 0 and variance $\tau^2$ and to be the same for all goods, $i=1, \ldots, k$; and $P_t$ is likewise assumed to be normally distributed, but with mean $\overline{P}_t$ and variance $\sigma^2$. Thus, the variance in individual prices (we shall henceforth mean by "prices" their logarithmic values) around their mean $P_t$ is a constant, $\tau^2$, and is therefore independent of the degree of variability $\sigma^2$ in the general price level $P_t$ around its trend, $\overline{P}_t$. The form of the dis-

tribution of individual prices is likewise constant and unrelated to the behavior of $P_t$. In short, the familiar constancy of relative prices in neoclassical economics is translated into a constancy in the mode of variation in these prices.

It turns out that there is strong statistical evidence that the two parameters $\tau^2$ and $\sigma^2$ move together, that is, as $\sigma^2$ increases (as the general price level becomes more unstable or less predictable relative to its trend value $\bar{P}_t$), so does $\tau^2$ (the dispersion in relative prices increases), and vice versa. There is somewhat weaker evidence that the form of the distribution of individual prices itself varies with $\sigma^2$. To demonstrate this dependence of $\tau^2$ and of the form of the distribution upon the magnitude of $\sigma^2$, it is necessary to translate Lucas' assumption, (1), into a statement about the changes in relative and general prices from one period to the next, since the more accessible data on the prices of goods are those giving those goods' price *changes* (i.e., indices relative to some base year) rather than their actual values in dollars and cents per unit of merchandise. To do so, we proceed with a simple transformation of equation (1):

$$(2)\quad P_{i,t+1} - P_{i,t} = P_{t+1} - P_t + z_{t+1} - z_t$$

$$(3)\quad [(P_{i,t+1} - P_{i,t}) - (P_{t+1} - P_t)]^2 = (z_{t+1} - z_t)^2$$

The expected value of the left-hand term of (3) is the expected variance of the one-period changes in $P_{it}$, $i=1, 2, \ldots, k$, around their mean change $(P_{t+1}-P_t)$. Thus, if $E(z_{t+1}z_t)=0$, as it is assumed to be in the Lucas model,

$$(4)\quad \mathrm{Var}\,(P_{i,t+1} - P_{i,t}) = E(z_{t+1} - z_t)^2 = 2\tau^2 = \gamma^2$$

That is, the variance in the one-period changes in $P_{it}$ around their mean $(P_{t+1}-P_t)$ should be roughly constant; and, since constant, unrelated to the degree of variability in the mean change. Since for large $\sigma^2$, this latter variability will be correspondingly large; (4) in effect says that $\gamma^2$ is invariant under shifts in the parameter $\sigma^2$.

An analysis of the behavior of both wholesale and retail prices over the period 1948–74,

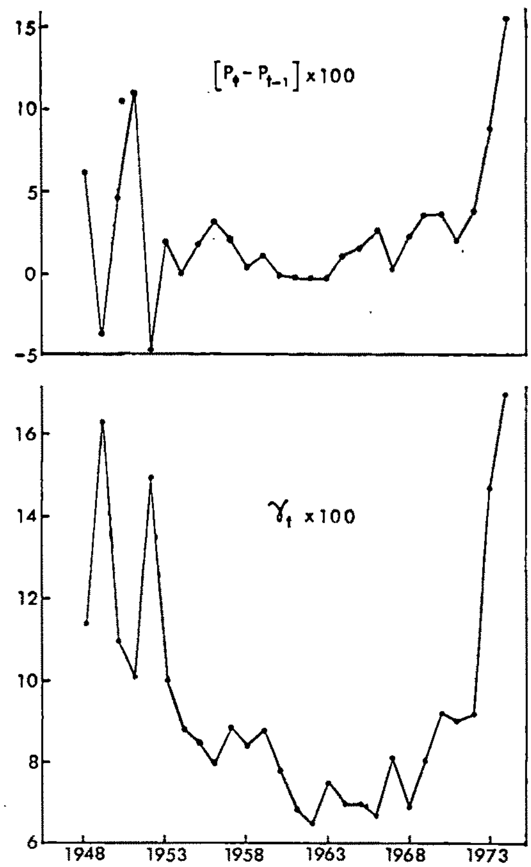

FIGURE 1. A comparison of $\gamma_t$ (the standard deviation in individual price changes at time t) and $(P_t-P_{t-1})$ (the average price change at time t) for the individual items of the Wholesale Price Index, 1948–74

however, reveals changes in $\gamma^2$ which are obviously in close association with the degree of general price change instability prevalent at time t, or $\sigma^2$. Consider first Figure 1, constructed from the components of the Wholesale Price Index (*WPI*). With the achievement of general price change stability in the late 1950's and early 1960's, the dispersion in individual price changes experiences a significant decline from its average level in the late 1940's and early 1950's, a period of great instability in the general rate of inflation. Subsequently, with what has come to be known as the Vietnam inflation, the standard deviation in these price changes rises to its original level—and beyond, with the energy and food scarcities of the early 1970's. Fur-

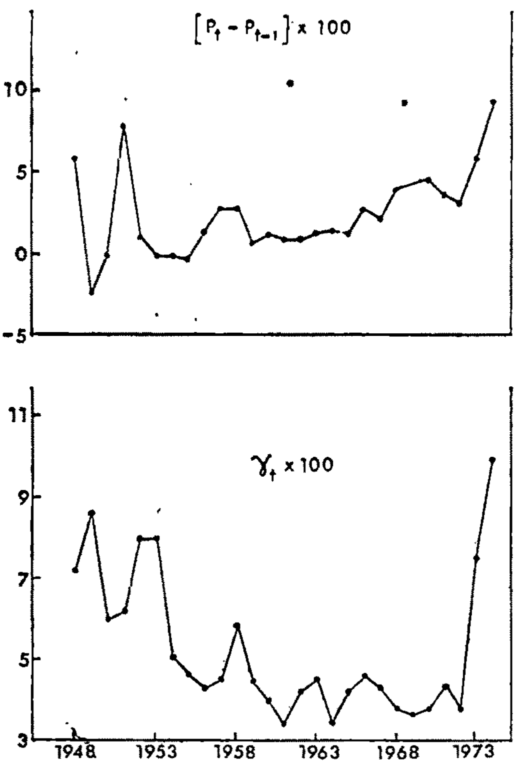

FIGURE 2. A comparison of $\gamma_t$ (the standard deviation in individual price changes at time t) and $(P_t - P_{t-1})$ (the average price change at time t) for the individual items of the Consumer Price Index, 1948–74

thermore, the transition from instability to stability in the inflation rate (i.e., from high to low $\sigma^2$), which is represented graphically as a gradual horizontal straightening in the line connecting the observations $P_{t+1}-P_t$, is characterized by a similarly gradual settling down of the dispersion in individual price changes $\gamma_t$.

The prices used to construct this figure are the price indices of the components of the *WPI* at the item (or 8 digit) level for each year between 1947 and 1974; the names and codes of these items are available from the authors. The basic data are available on tape (*WPI* Subfile 2002) from the Bureau of Labor Statistics (*BLS*). For any given year, the number of commodities for which a previous year's price index is available (and therefore for which $P_{i,t+1}-P_{i,t}$ may be calculated, as this difference is the logarithm of the ratio of the indices published by the *BLS*) varies between one and two thousand, with the smaller sample sizes at the beginning of the period of study and the larger at the end. All calculations have been performed on the unweighted first differences of the logarithms of the annual averages of these indices. Similar calculations were performed for a sample of commodities for which an unbroken series of price indices existed from 1947 to 1974 (795, in all); the resultant figure was found to be identical in form to that of Figure 1, although the individual values of $\gamma$ and $(P_{t+1}-P_t)$ for any given year tended to be somewhat different.

Figure 2 is identical to Figure 1, except that it has been constructed from the components of the Consumer Price Index (*CPI*) and thus represents retail rather than wholesale price behavior. Again, one notes high relative price change dispersion in the two episodes of general price change instability at the beginning and end of the period, 1948–74, and low relative price change dispersion in the one episode of general price change stability in the middle of this period. There does seem to be a delay relative to the behavior of wholesale prices in the rise of $\gamma_t$ with the onset of general price change instability in the late 1960's. The basic pattern, however, seems to be the same for both wholesale and retail prices.

The prices used to construct this figure are the price indices comprising the *CPI*, again at the individual item or 8 digit level and again available on tape from *BLS* (*CPI* Subfile 2001). The samples here are much smaller than those available for wholesale prices, varying between 110 in 1948 and 311 in 1973. As with our analysis of wholesale prices, calculations were performed on the unweighted first differences of the logarithms of the annual average price indices of those items for which two successive years' observations exist. We also performed these calculations on a sample of items for which an unbroken series of prices existed from 1947 to 1974 (there are 102 such items); the resultant figure is again identical in form to Figure 2.

Moreover, this relationship between general price change instability and relative price change dispersion seems to be a persistent feature of the American economy. As long ago as 1927, Frederick Mills, in his ex-

haustive study on wholesale price variation, observed that the dispersion in price changes in individual commodities increases with general or average price instability.[1] The reader is referred to page 284 of Mills where, after a long and fruitless attempt to relate this dispersion to a number of other aspects of general price behavior, such as its direction of change and even its absolute level, he uncovers a strong association between the absolute change in the general price level from one year to the next and the dispersion in relative price changes, or $|P_{t+1}-P_t|$ and $\gamma_{t+1}$. Since general price *change* instability (high $\sigma^2$) typically is closely associated with periods of general price instability (inflation or deflation, or high $|P_{t+1}-P_t|$), Mills' results and those represented graphically in Figures 1 and 2 are seen to be expressions of one and the same phenomenon.

In addition, the *shape* of the distribution of individual price changes, assumed in the Lucas article to be stable over time, is in fact highly variable and almost never of normal and infrequently of even symmetrical form. Rather, it is generally a highly skewed and asymmetrical distribution; and there are at least suggestions in the data that the direction of skew is the same as the direction of change in the rate of inflation (a high positive skew has been a particularly prominent feature of the current inflation). That is, if the general rate of inflation is climbing, then there tends to be a positive skew to the distribution, with most commodities' price changes below the mean (the rate of inflation) and a few above but generally at a great distance from it. On the other hand, if the general rate of inflation is falling, then the skew is typically a negative one with the majority of price changes greater than the mean and only a few below, but again generally at a great distance from this mean. The degree of skew is particularly pronounced during periods of rapid changes in the average rate of inflation. More stable periods, on the other hand, are characterized by distributions more nearly symmetrical. Their shapes, however, diverge from the normal in being much more peaked than would be expected if the samples were drawn from normal populations. (Tables 1 and 2 give the summary statistics, including those of kurtosis and skewness, for the retail and wholesale price change distributions of the years, 1948 through 1974.)

The latter feature, of course, is well known to students of speculative prices; indeed, that price changes, both speculative and otherwise, are distributed with significant amounts of kurtosis has been well known since the early teens of this century (see the papers by Benoit Mandelbrot and Wesley Mitchell). The presence of skewness in these distributions as well as their variability of form, and the suggestion of a systematic relationship between these two aspects of relative price variation and the mean of this distribution, i.e., the change in the general price level, has also been well documented, again by Mills.

The gradual settling down of the dispersion and form of the distribution of relative price changes with general price change stability (which corresponds here, and may always, to general price stability, i.e., constant $P_t$) may be what Friedman had tacitly in mind (although it seems to have been forgotten in the passage from his *Newsweek* column quoted above) when he recommended stable monetary growth on the grounds that it provides a stable background for the "other fluctuations": "It [the Federal Reserve] should limit itself to seeing to it that the stock of money grows at a steady rate month in and month out, year in and year out. This would provide a stable background

[1] Adopting Mills' approach and methodology, Frank D. Graham, in a book first published in 1930, uncovered a similar relationship between individual price change dispersion and general price instability during the German hyperinflation of the early 1920's (pp. 175–77). And an intercountry comparison of inflation rates and standard deviations in relative prices for 15 European countries by Herbert Glejser shows, again, an unmistakably strong relationship between the two. Glejser, however, seems to have employed *unlogged* price indices for different commodity groups (divided by the overall price index) as his basic observations. For lognormal variables, the standard deviation is known to have a positive relationship with the mean, though the variance in the logarithms of these variables remains stable. In this paper, we have shown the latter also to be positively related to the mean of the logarithms. We are indebted to Robert Barro and Lawrence Klein, respectively, for bringing our attention to these references.

TABLE 1—DESCRIPTIVE STATISTICS OF WHOLESALE PRICE CHANGE DISTRIBUTIONS, 1948–74

| Year | Mean[a] | Standard[b] Deviation | Skewness[c] | Kurtosis[d] | Sample Size |
|---|---|---|---|---|---|
| 1948 | .0625 | .1149 | −1.130 | 7.208 | 1159 |

[a] Let $P_{it}$ be the logarithm of the price index of commodity $i$ for year t, $\Delta P_{it}=P_{it}-P_{i,t-1}$, and $k$ the number of commodities. Then the mean price change $\Delta P_t$ is given by

$$\Delta P_t = \frac{1}{k}\sum_{i=1}^{k} \Delta P_{it}$$

[b] $$\gamma_t = \sqrt{\frac{1}{k}\sum_{i=1}^{k} (\Delta P_{it} - \Delta P_t)^2}$$

[c] $$\frac{\frac{1}{k}\sum_{i=1}^{k} (\Delta P_{it} - \Delta P_t)^3}{\gamma_t^3}$$

[d] $$\frac{\frac{1}{k}\sum_{i=1}^{k} (\Delta P_{it} - \Delta P_t)^4}{\gamma_t^4} - 3$$

[e] Indicates that a coefficient of skewness this large or larger could have been generated by a sample of size $k$ from a normal distribution with mean $\Delta P_t$ and standard deviation $\gamma_t$ with probability greater than .01. That is, only these observations are remotely consistent with the hypothesis of a normal distribution where the third moment is identically zero. None of the kurtosis statistics (again, their expected values are zero, if the underlying distribution being sampled from is normal) are consistent with a normal hypothesis. For details on normality tests using the third and fourth sample moments, see G. Snedecor and W. Cochran (1972).

for the other fluctuations" (Friedman, 1959, p. 623).[2] With stable growth in the money

[2] Raymond Bye interprets Mills' empirical discoveries explicitly in this fashion:

The proponents of plans for stabilizing the general price level are fully aware that different prices move up and down unevenly, in response to the myriad influences of demand and supply that affect particular commodities and they know better than to offer their proposals as a panacea which would correct all price disparities. This has been made perfectly clear in the writings of Irving Fisher and others. But the stabilizers rightly regard fluctuations in the level of prices arising from monetary changes as one serious cause of internal price disturbances. Mills' findings support rather than upset this view. [p. 47–48]

TABLE 2—DESCRIPTIVE STATISTICS OF RETAIL PRICE CHANGE DISTRIBUTIONS, 1948–74

a, b, c, d, e: See Table 1.

stock and, presumably as a consequence, a steady rate of inflation, the incessant fluctuations in relative prices normal to any developing economy with evolving tastes and technology are allowed to reach and maintain their "natural" level, i.e., they are no longer exaggerated by erratic movements in the monetary sector of the economy. It is interesting to note that what is perhaps the most appealing justification for a constant and unvarying expansion of the monetary base, namely, its elimination of artificially induced instability in the prices of products relative to each other, has yet to receive a formalization in economic theory: the link between the two kinds of instability, i.e., that of general and relative prices, remains a simple empirical regularity.

The increase in relative price change dispersion with general price change instability may also explain, in part, the hostility on the part of a large class of citizenry to price inflation, a resistance that some economists find irrational unless the inflation is accompanied by declines in real incomes, a comparatively rare event until recently. ("One man's price is another's income; when buyers pay more, sellers receive more. The inflation may proceed unevenly, so that some workers, consumers, and property owners lose while others gain; such relative distributional changes are always occurring, inflation or no inflation." James Tobin, p. 33.) If general price change instability is highly correlated with and accompanied by price inflation, and if dispersion in individual price changes widens in such periods, however, then a general atmosphere of higher risk and insecurity is the result, a cost of inflation in addition to that associated with the general depreciation of the currency over time which is the exclusive subject of Armen Alchian and

Reuben Kessel's study of its effects. That is, while the individual is more likely to experience a very large change in his price relative to that of all prices during periods of inflation, he is also more likely to experience a very small one relative to the average. The prevalence of positive skewness in such periods, whereby the majority of price changes are below the average price change (which may serve as a first approximation to changes in costs) would perhaps accentuate this preference for general price stability in a risk-averse population.[3] The widespread attraction of policy makers to price and wage controls may also be interpreted as a response, in some inchoate fashion, to the widening dispersion (and therefore riskiness) associated with inflationary periods. That is, wage and price controls may be a mechanism by which a normal variation in relative price changes is maintained *within* an environment of inflation and not a response to the general rate of inflation, as they are most often interpreted to be by economists (see, for example, James Barth and James Bennett, p. 397).

Indeed, one would hardly expect general price level instability to be the public policy problem that it manifestly is if it didn't have some systematic and predictable effect on the prices that are important to the individual, i.e., the prices of goods that he sells relative to those of the goods that he buys. A passage from J. M. Keynes (1932) makes this point in a particularly explicit way:

Money is only important for what it will procure. Thus, a change in the monetary unit, which is uniform in its operation and affects all transactions equally, has no consequence. If, by a change in the established standard of value, a man received and owned twice as much as he did before in payment for all rights and for all efforts, and if he also paid out twice as much money for all acquisitions and for all satisfactions, he would be wholly unaffected. It follows, therefore, that a change in the value of money, that is to say in the level of prices, is important only insofar as its incidence is unequal. Such changes have produced in the past, and are producing now, the vastest social consequences, because, as we all know, when the value of money changes, it does not change equally for all persons for all purposes. A man's receipts and his outgoings are not modified in one uniform proportion. Thus, a change in prices and rewards, as measured in money, generally affects different classes unequally, transfers wealth from one to another, bestows affluence here and embarassment there and redistributes Fortune's favors so as to frustrate design and disappoint expectation.[4] [pp. 80–81]

However, Keynes' insight seems generally to have been forgotten by the current generation of economists; thus, in contrast to many of his other conclusions, Lucas' remark in an otherwise extremely controversial paper, namely "that there is no reason to expect $\tau$ to vary systematically with demand policies" (1976, p. 39), has gone utterly uncontested.

It is perhaps at least worth remarking that this lack of awareness of the relative-general price relationship is even a contemporary phenomenon among neoclassical economists. As Lucas finds the *lack* of such a relationship entirely to be expected, his earlier counterparts in the neoclassical school declared its *existence* (specifically in their assessment of Mills' contribution) likewise unremarkable and quite consonant with the principles of

[3] A possible implication of this line of thought is that a falling rate of inflation would be more tolerable since the majority of price changes then would lie above the average price change; that is, there would be a greater than 50 percent chance that the rate of increase in the price of your good will exceed the average rate of increase for all goods. Richard Day has used this fact about negatively skewed distributions to explain the observed preference among Mississippi Delta farmers for oats over corn, though the average profitability of the latter exceeds the former. On the other hand, a pronounced skewness in either direction suggests an asymmetry in the distribution of the overall price change across its members that a society probably cannot long tolerate.

[4] Of course, as Tobin points out, "relative distributional changes are always occurring, inflation or no inflation" (p. 33). In not introducing the language of probability, which would have probably been inappropriate in this essay, Keynes constrains himself to write as if relative price change variation is zero in periods of general price stability. He would have been aware of the absurdity of this proposition, and perhaps intended it only as shorthand for the situation outlined here—namely that the variation in relative price changes is more violent in times of inflation.

that school:

> A significant correlation (+.614 for 35 pairs of observations) is found between degree of change—regardless of direction—in the price level and degree of dispersion of prices [page 284]. All that is necessary to adduce in explanation of this correlation is that, in addition to the many influences affecting particular commodities which operate to bring about dispersion of prices even when the price level is constant, active pervasive factors tending to affect all prices will further increase dispersion if different commodities have varying degrees of resistance to their influence. Jacob Viner [pp. 345–46]

Though there is something tautological about Viner's explanation that belies his nonchalance about the phenomenon Mills discovered, this was about as far as such explanations went among those aware of Mills' work. Raymond Bye, for example, ten years after Viner's review article, writes:

> Mills finds that it is the *amount* and not the direction of changes in the price level which affect the degree of internal stability in the price system. When the average movement of prices is violent in either an upward or downward direction, dispersion . . . become[s] greater. Apparently, marked changes in the price level, caused perhaps by monetary factors, seriously disturb the ordinary price relationships between different commodities. This could be inferred from general reasoning, because the incidence of monetary changes would hardly be instantly and evenly diffused through the system of prices. [pp. 37–38]

In fact, the first attempt to formalize, within the neoclassical tradition, an explanation of the phenomenon is in Robert Barro's extension of Lucas' 1973 article. Greatly simplified, Barro's explanation is that for a given random variation in the demands for the various goods making up the economy, a rotation in the supply curves for these goods towards greater inelasticity (brought about by the increased general or average price change instability, as in the Lucas model, where the individual suppliers become less price responsive as prices become more dominated by movements in the general price level) will generate a higher variability in the observed relative price changes. This may be grasped quite readily via the conventional supply-demand curve diagram. If the demand curve varies around some average curve, the steeper the supply curve the greater the variability in the equilibrium price for any given level of demand curve variation.

Barro's is a highly sophisticated effort to account for the observed dependence of heightened relative price change dispersion on general price change instability, relying upon a chain of causality running from general price level change instability to relative price change instability. It purposely ignores the perhaps more acceptable view, at least to the ordinary citizen, that an autonomous increase in relative price change dispersion somehow induces instability in the changes in the general price level. By this view, the latter is simply a symptom of the former, the former being the only item of interest to the citizen. The mechanism of causality might well be that of the neoclassicists, i.e., an increased instability in the money supply process. But the latter would have much less autonomy than is attributed to it by monetarists. This in fact is the tentative explanation put forward by Mills himself in his rejoinder as an alternative to the view of Bye:

> Bye's third principle ($MV+M'V'=PT$) is equally capable of a two-way cause and effect interpretation. Not necessarily is the monetary circulation antecedent, with price changes consequent. Under contemporary conditions, a change in the volume of credit outstanding may result from changes in the prices of individual commodities, changes that may in turn be due to any of an infinity of forces affecting demand or supply conditions. [See Bye, p. 139]

Mills' qualification here, "under contemporary conditions," is of interest, since we have been unable to find any relationship between relative price change dispersion and average price change instability in the data of Jevons (pp. 136–41) on commodity prices in England during the middle 1800's. Variations in the money supply during his day may very well have been autonomous, due as they were to the discovery of gold in remote parts of the world. Crises in the relative price

relationships could not therefore be "papered over" by increased issues of paper currency, leading in turn to a general rise in all prices. And the latter could not therefore in turn be interpreted, except under the contemporary conditions of a credit system under the control of the government, as simply the symptom of abnormal relative price disturbances.

A major challenge to empirical economists would seem to be the discrimination between these two hypotheses, i.e., to determine the direction of causality between individual price change dispersion and general price change instability. Both theories must have testable implications for the data that are available. The theory advanced by Barro may well have; it is at least in the form that one could answer one way or the other. The counter hypothesis to that of Barro has not acquired any more particulars since the original intuition of Mills, quoted above. This would seem to be the first order of business for economists interested in such matters.

# On the Shape of the Trade Indifference Curve: Rejoinder to Batra

*By* MURRAY C. KEMP AND EDWARD TOWER*

Raveendra Batra argues in his reply that our comment on his article is substantially incorrect because "the curvature of the trade indifference curve in the presence of the nontraded good is indeterminate" (p. 252). In this note we demonstrate the correctness of our earlier assertion that, even when there are nontraded goods, the trade indifference curve has the usual curvature.

Let $C=\{c=(c_1, c_2, \ldots, c_n)\in R^n_+ \mid U(c)\geq U_0\}$ be the production possibility set, where $T$ denotes the set of input-output combinations let $Y=\{y=(y_1, y_2, \ldots, y_n)\in R^n_+ \mid (y, \bar{x})\in T\}$ be the production possibility set, where $T$ denotes the set of input-output combinations that are feasible and $\bar{x}$ denotes the given factor endowments. Both $Y$ and $C$ are assumed to be convex. The set of trades which generate levels of utility not less than $U_0$ is simply $E=Y-C$, where $E=\{e=(e_1, e_2, \ldots, e_n)\in R^n\}$ and the $i$th good is exported or imported according as $e_i$ is greater than or less than zero. It is well known that any linear combination of two convex sets must also be convex.[1] Thus $E$ also is convex, and the surface which bounds it, a trade indifference surface when all goods are traded, must have the normal curvature.

Now in restricting our attention to the case in which $m$ goods are not traded, so that $c_i=y_i$, $i=n-m+1, \ldots, n$, we are considering that linear cross section of $E$ determined by $E\cap\Gamma$, where $\Gamma=\{e=(e_1, e_2, \ldots, e_n)\in R^n \mid e_i=0, i=n-m+1, \ldots, n\}$. Since $\Gamma$ is convex ($\Gamma$ is a linear subspace), $E\cap\Gamma$ must also be convex. Since this is simply the set circumscribed by the trade indifference surface when the last $m$ goods are nontradeables, we have proved that the trade indifference surface for an economy which consumes $n$ goods, $m$ of which are nontradeables $(m<n)$, has the normal curvature.

# The Terms of Trade and the Balance of Payments in the Short Run

By Carlos Alfredo Rodriguez*

Several recent models associated with the "monetary approach to the balance of payments" have focused on the role of adjustment to monetary disequilibrium as the crucial factor in explaining the behavior of the overall balance of payments.[1] It is the purpose of this paper to point out a peculiar characteristic of those models regarding the effects of an exogenous change in the price of a tradable good on the balance of payments. It will be shown that under the most likely assumptions, the simple versions of these models predict a short-run improvement in the balance of payments as a consequence of an exogenous increase in the price of any tradable good, whether exportable or importable. I also present an alternative formulation, still within the spirit of the monetary approach, which allows for different short-run effects of a price change on the balance of payments depending crucially on whether the commodity increasing in price is an exportable or an importable good. This alternative formulation, based on the "precautionary" demand for money, allows real cash balances to play the role of a short-run "shock absorber" in order to even out over time the required changes in the level of real expenditures.

## I

Modern work on the monetary approach to the balance of payments originated with Mundell and Johnson.[2] This approach correctly recognizes that in an open economy with fixed exchange rates, changes in the domestic supply of money can be brought about via domestic credit or foreign exchange operations by the monetary authority. This fact plus the assumption that the existing stock of money must be willingly held by individuals implies that in the absence of changes in the domestic credit component of the money supply any increase in the nominal demand for money must be equilibrated through the accumulation of foreign exchange reserves.

Empirical tests of the monetary approach seem to validate its main prediction: after compensation for real income growth differentials, those countries which expand domestic credit at a faster rate than the world average tend to run balance-of-payments deficits.[3] All of these studies are, however, of a long-run nature and follow the theoretical structure developed by Johnson which, among other things, assumes the constancy of all relative prices and an exogenous and known rate of real income growth. Short-run responses of the balance of payments to unexpected changes in relative prices or real income have not, to my knowledge, been the subject of empirical investigation within the framework of this approach. At a theoretical level, however, several papers[4] have concentrated on the dynamic path of the balance of payments following several types of disturbances within the framework of the monetary approach. Although not necessarily common to all of them, the most typical feature of the dynamic models is that, in the absence of domestic credit creation by the monetary authority, the balance-of-payments surplus equals the desired rate of accumula-

* Associate professor of economics, Columbia University. I want to thank George Borts and Rudiger Dornbusch for helpful comments. In a recent paper, Borts and James Hanson have independently arrived at results similar to those presented here.

[1] Among others, Robert Mundell, Jacob Frenkel (1971), Harry Johnson, Rudiger Dornbusch (1973a, b), and Frenkel and the author. See also the forthcoming collection of essays edited by Frenkel and Johnson.

[2] See, however, Frenkel (1975) for references of work on similar lines dating back to the middle 1700's.

[3] See, for example, several of the papers in Frenkel and Johnson.

[4] Dornbusch (1973a), Frenkel (1971), and Frenkel and the author among others.

tion of cash balances by individuals which in turn is taken to be a fraction of the difference between the desired and actual stocks. Thus, assuming that the exchange rate is equal to unity, the balance-of-payments surplus ($B_s$) becomes:

$$B_s = \gamma(M^d - M) \tag{1}$$

where $M^d$ and $M$ represent the desired and actual stocks of nominal cash balances and $\gamma$ is the constant speed of adjustment to the excess stock demand for money.

The desired stock of cash balances is in turn usually assumed to be proportional to the level of nominal income (thus ensuring a unit income elasticity of the demand for real cash balances):[5]

$$M^d = k \cdot Y$$

Nominal income is in turn defined as:

$$Y = \sum_i p_i q_i$$

where $p_i$ and $q_i$ are the nominal price and quantity produced of good $i$.

Assuming that the outputs of all goods produced at home are constant and also traded at fixed world prices,[6] the impact effect of an exogenous change in the world price of one good on the domestic balance of payments is

$$\partial B_s / \partial p_j = k\gamma q_j \geq 0$$

since at the instant of the price change the actual nominal stock of cash balances remains unchanged.[7] Thus, the prediction of this simple model is that an exogenous rise in any price generates a balance-of-payments surplus independently of whether the good in question is imported or exported, provided there is some domestic production of the good (otherwise there would be no effect at all). In particular, this simple version of the monetarist model predicts that a rise in the price of an importable will immediately generate (if at all) a balance-of-payments surplus. The explanation for the surplus is purely monetarist: the rise in the price increases nominal income and thus the demand for nominal cash balances; given the adjustment process formulated, individuals will immediately start accumulating cash balances, which brings about the surplus.

Needless to say, I find that particular result of the simple monetarist model unsatisfactory and in the next section the model is extended in order to allow for a rise in the price of an importable to generate a balance-of-payments surplus or deficit depending on the values of certain parameters, in particular, the volume traded of the good in question and the monetarist effect discussed above.

## II

In this section, I present an alternative formulation to the determination of the balance of payments which relies heavily on the specification of the role of money in the determination of real expenditures and is based on two well-known concepts, Milton Friedman's permanent income and J. M. Keynes' precautionary demand for money.

In Keynes' words, individuals hold money, among other reasons, to "... provide for contingencies requiring sudden expenditure ...". (p. 196). In my interpretation, should such a contingency occur, individuals will use their cash balances to soften the effect of this change on the time pattern of their *real* expenditures. As a proxy for that level of real expenditures which individuals will try to maintain in the short run, I take Friedman's concept of permanent income. This transitory use of cash balances should be independent of the behavior of the individual's long-run desired target money holdings which, also following Friedman, I assume to depend

[5] For a derivation of the above form of adjustment to monetary "disequilibrium" in the context of an intertemporal optimization model and the proof that that particular form *must* imply unit income elasticity of demand for money, see Dornbusch and Michael Mussa.

[6] I am thus ignoring the possibility of existence of nontraded goods in this simple version. An extensive analysis introducing nontraded goods into the monetarist model is done in Borts and Hanson. See also Dornbusch (1973b).

[7] Allowing for substitution in production will not affect this result since the substitution effect of a price change on nominal income is zero, provided that competition and full employment prevail, i.e., $\sum_i p_i \partial q_i / \partial p_j = 0$.

on the individual's permanent income. Should the unexpected event prove to be permanent and, say, reduce the permanent income of the individual, he will modify slowly his pattern of expenditures to accommodate his cash balances to the new long-run desired level; this may imply a further reduction or even accumulation of cash balances depending on whether the initial phase of dishoarding brought them above or below the new long-run desired level.

Algebraically, I postulate the following expenditure function.

$$e = y^p + \gamma(m - ky^p) \tag{2}$$

where all variables are defined in terms of a composite bundle of commodities to be defined below and

$e$ = real expenditures
$y^p$ = real permanent income
$ky^p$ = long-run desired real money holdings
$m$ = actual real money holdings
$\gamma$ = constant speed of adjustment to a stock excess demand for money

According to (2), real expenditures will exceed or fall short of permanent income only to the extent that individuals are not on their long-run demand for money. Although the model presented here could be extended to incorporate other assets alternative to money (possibly also performing the role of short-run shock absorbers), I will for simplicity assume that money is the only available asset and thus expenditures as defined in (2) represent the acquisition of goods by individuals. The term $\gamma(m-ky^p)$ in (2) is not, however, the actual accumulation of real cash balances. In an open economy with fixed exchange rates and no credit creation by the monetary authority, the actual change in the stock of money equals the balance-of-payment surplus ($b_s$), the difference between *current* real income and real expenditures:

$$\begin{aligned} dm/dt &= b_s = y - e \\ &= (y - y^p) - \gamma(m - ky^p) \end{aligned} \tag{3}$$

where $y$ stands for the current level of real income.

There are two main differences between the formulation of the balance of payments presented in (3) and that of the simple version presented in (1): (i) the term $(y-y^p)$ appears as a direct contribution to the balance-of-payment surplus; and (ii) the long-run demand for money depends on permanent rather than current income. Of course, when permanent and current income are equal, both expressions become identical.

The $(y-y^p)$ term in (3) characterizes the shock absorber nature of real cash balances in the short run since, to the extent that the term $\gamma(ky^p-m)$ represents *ex ante* desired accumulation of cash balances, it is clear that the desired rate will differ from the actual rate of accumulation by the full amount of the discrepancy between actual and permanent income.

### A. *Consumption and Production Technology*

Before going into the analysis of short- and long-run effects of price changes on the balance of payments we need to specify the units in which the real magnitudes in (2) are measured. This is particularly important in this model since one of the real variables, $y^p$, will be assumed to be unresponsive to any price change in the short run and thus the units in which it is measured become crucial. Obviously, the more important step here is the selection of the correct price level. In order to avoid problems which are unessential to the analysis and to provide an unambiguous definition of the price level it will be assumed that all goods are demanded in fixed proportions irrespective of income levels or relative prices. I also retain the assumption made in the last section that the outputs of all goods domestically produced are constant. These two assumptions will allow us to concentrate on macro-economic issues which will in any case be present in a more complete model where substitution effects are also accounted for.

The demand pattern is thus represented by:

$$C_i/C_j = a_i/a_j, \quad i, j: 1, \ldots, N, \text{ all } a \text{ constant}$$

and

$$\sum_i p_i C_i = E$$

where $C_i$ = demand for good $i$
$E$ = nominal expenditures
$p_i$ = nominal price of good $i$

Define the unit consumption basket as that basket that contains $a_i$ units of each good, or $(a_1, a_2, \ldots, a_N)$. The price of that basket is then

$$p = \sum_i p_i a_i$$

which will be our measure of the price level. It follows easily that

$$C_j = a_j \cdot E/p = a_j e$$

where $e$ stands for the number of unit baskets demanded (real expenditures).

On the production side, nominal income is

$$Y = \sum_i p_i q_i$$

and real income, $y$, is correspondingly defined as

$$y = Y/p = \sum_i p_i q_i / \sum_i p_i a_i$$

Real income responds to price changes according to

$$\partial y/\partial p_j = (q_j - a_j y)/p$$

and, if also $y=e$ which implies $C_j = a_j y$, it follows

$$\partial y/\partial p_j = (q_j - C_j)/p$$

which implies that a rise in the nominal price of good $j$ will increase real income if good $j$ is exported or decrease it if the good is imported.

Similarly, real cash balances $m$ are defined as

$$m = M/p$$

and the effect on real cash balances of a price change is given by:

$$\partial m/\partial p_j = -\, m a_j/p$$

### B. *Impact Effect of a Price Change on the Balance of Payments*

I will here maintain the assumption that the country is a price taker in all international markets and that there are no nontraded goods. The impact effect of a change in the price of good $j$ on the balance of payments can be readily obtained by differentiation of (3) holding $y^p$ constant. Starting with an initial situation where $b_s = 0$ and $y = y^p = e$, this derivative is

$$\text{(4)} \quad \partial b_s/\partial p_j = (1/p)[(q_j - C_j) + m a_j \gamma]$$

If the price increase corresponds to an exportable good $(q_j - C_j > 0)$, it is clear that the balance of payments must initially improve since both the increase in current real income (captured by the term $q_j - C_j$) and the reduction in actual real cash balances (captured by the term $m a_j \gamma$) will work towards a surplus. If however the price increase corresponds to an importable, the response of the balance of payments is ambiguous and more likely to be negative the larger the import volume of the good in question. Notice that the expression we have derived incorporates the standard monetarist effect of a price increase reducing real cash balances and thus contributing to a surplus. In addition it considers the full increase in the import bill (export bill) as a contribution to the balance-of-payments deficit (surplus) *independent of monetary considerations.* This latter effect, which has been disregarded so far in the short-run monetarist models, provides a plausible explanation for the observed fact of sharp changes in the prices of importables generating deficits in the balance of payments. However the model is flexible enough and allows for the pure monetarist effect to dominate when the amount traded of the good in question is small but the share of real expenditures on the good and the speed of adjustment to stock disequilibrium are large.

It should be clear from our analysis thus far that those short-run effects on the balance of payments of changes in the import or export bill are due exclusively to the short-run unresponsiveness of real expenditure to changes in the level of real income. As time goes on and individuals revise their permanent income level towards the new prevailing real income, expenditures will adapt and those effects will eventually disappear. This transitional period is the object of dynamic analysis contained in the next section.

### C. *Dynamic Effects of a Price Change on the Balance of Payments*

In deriving the impact effect of a price change I have assumed that permanent in-

come remained constant irrespective of the price change. It is obvious, however, that consumers will eventually have to adapt to this permanent price change and will thus have to modify their permanent income accordingly. How fast permanent income will be revised to the new level will depend on the degree with which individuals believe the price change is permanent and on the nature of the adjustment costs involved in changing the level of real expenditures. Remember we are using permanent income as a measure of that level of real expenditures households wish to maintain in the short run, presumably because there are adjustment costs involved in the process of changing the level of real expenditures. In what follows I will assume, for purposes of exposition only, that permanent income is adjusted through time according to the adaptive process

$$(5) \qquad dy^p/dt = b(y - y^p) \qquad b \text{ constant}$$

Also, from (3), real cash balances adjust through time according to

$$(6) \qquad dm/dt = (y - y^p) - \gamma(m - ky^p)$$

Given the actual value of real income, $y$, (5) and (6) describe the behavior over time of real cash balances (and by implication the balance of payments) and permanent income. The system (5)–(6) is linear and the matrix of the coefficients is

$$\begin{bmatrix} -b & 0 \\ -(1 - \gamma k) & -\gamma \end{bmatrix}$$

for which the trace is always negative and the determinant positive. Thus, the system (5)–(6) is globally stable, meaning that for any initial values for $m$ and $y^p$, both will eventually converge to the unique steady-state values $m^* = ky$ and $^*y^p = y$.

The final approach to the steady state must be asymptotic since the coefficient matrix of the dynamic system is triangular and thus the characteristic roots of the system are both real (and equal to $-b$ and $-\gamma$). The dynamic paths of $m$ and $y^p$ following a rise in the price of an importable are depicted in Figures 1a and 1b. There are two dynamic configurations depending on $(1-\gamma k)$ being

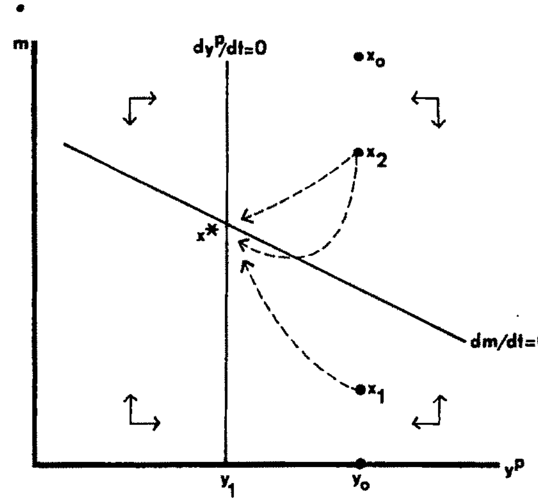

FIGURE 1a.

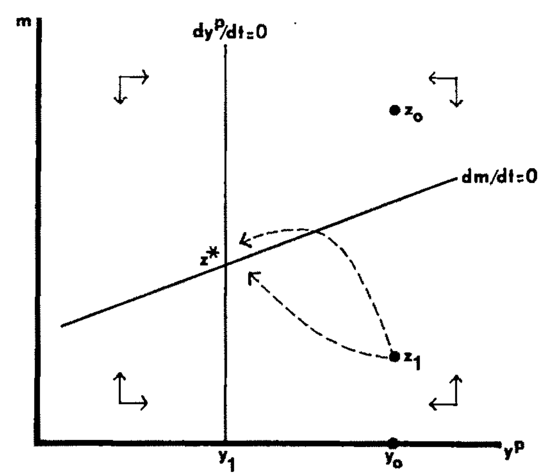

FIGURE 1b

larger or smaller than zero. Figure 1a shows the case where $(1-\gamma k)>0$ while Figure 1b illustrates the case where $(1-\gamma k)<0$. In both cases the schedule $dm/dt=0$ shows the pairs of $(m, y^p)$ for which the rate of change in the stock of real cash balances is zero according to (6). The slope of this schedule is:

$$dm/dy^p = -(1 - \gamma k)/\gamma$$

The vertical schedule $dy^p/dt=0$ shows that only for $y^p = y_1$ (the postprice change level of real income) will permanent income remain unchanged, according to the adaptive

process formulated in (5). The directions of the arrows show the movements of the variables in the plane and are derived from the signs of the coefficients in (5)–(6). Notice that Figure 1b, for which $(1-\gamma k)<0$, corresponds to the extreme situation where the monetary effects are the strongest, even in the short run; in this case the reader can verify from (2) that an increase in permanent income will actually be followed by a *fall* in real expenditures because the increased desired rate of hoarding will exceed the increase in permanent income. It is no surprise that in this case any price increase will generate a surplus when starting from a full equilibrium situation. This can be verified by substituting $ky$ for $m$ and $C_j$ for $a_jy$ in (4) after which the impact effect of a price change on the balance of payments becomes

$$(4') \quad \partial b_s/\partial p_j = (1/p)[q_j - C_j(1-\gamma k)]$$

which is always positive if $(1-\gamma k)<0$.

The initial positions before the rise in the price of the importable good are denoted by $x_0$ and $z_0$ in Figures 1a and 1b, respectively. At $x_0$ or $z_0$, real income was $y_0$ and, since it was a full-equilibrium position, it also was $y^p=y_0$ and $m=ky_0$. Following the price increase, both real income and real cash balances fall instantaneously. The new level of real income is denoted by $y_1$ in both figures. The change in $y$ also shifts the $dm/dt=0$ and $dy^p/dt=0$ schedules to the left such that at their new intersection (points $x^*$ or $z^*$), $m=ky_1$ and $y^p=y_1$. We can get an idea about the magnitude of the initial fall in real cash balances by noticing that the price rise may generate a surplus or a deficit in the case of Figure 1a and a surplus in Figure 1b. Since a surplus corresponds to an initial position where $dm/dt>0$, this corresponds to a fall in $m$ to points such as $x_1$ or $z_1$ in Figures 1a or 1b, respectively. If the price rise generates an instantaneous deficit in the balance of payments, the fall in $m$ must leave the system in an initial position where $dm/dt<0$, at a point like $x_2$ in Figure 1a. It is easy to see in the case of Figure 1a that if the initial impact effect is to bring the balance of payments into surplus, it will continue in surplus until the new steady state is reached (both $m$ and $y^p$ will remain in the region where $dm/dt>0$). If, however, the impact effect is to bring the balance of payments into deficit there are two possible outcomes: (i) it continues all the way into deficit until the new steady state is reached; or (ii) in later stages the deficit turns into a surplus which eventually becomes zero as the steady state is reached. In the case of Figure 1b, the initial surplus may be followed in later stages by a deficit.

An increase in the price of an exportable must be always followed by a balance-of-payments surplus although in later stages the surplus could turn into a deficit. This latter case could happen if expenditures do not adjust fast enough to the increased real income and thus more real cash balances accumulate than desired in the new steady state. The decumulation of those excess cash balances gives rise to the deficit in the later stages.

# The Distribution of State Incomes: Differential Growth of Sectoral Employment

By DONALD MITCHELL SMITH AND E. JAMES JENNINGS*

The degree of income concentration varies significantly among countries and among states of the United States. It is commonly accepted by economists that the concentration of income is less unequal in high income economies. The relation between low income concentration and high aggregate income is ascribed to such factors as the distribution of property income, the education of low income workers, and the relative size of the nonagricultural sector.

An implication of the hypothesized relation between income concentration and the relative size of nonagricultural employment is that intersectoral labor movements decrease income concentration. So far, this implication has not been tested. In this paper, the relation between changes in income concentration and changes in sectoral employment within states of the United States is tested directly.

The findings in this paper confirm the hypothesis that changes in income concentration are related to differential growth rates of sectoral employment within states. Between 1920 and 1950, and between 1950 and 1960, the change in employment of the agricultural vis-à-vis the nonagricultural sector is an important determinant of the change in income concentration. Between 1960 and 1970, the change in income concentration is related to the change in employment in the services sector vis-à-vis the combined agricultural and manufacturing sectors.

## I. Theory

Changes in the concentration of income may result from two major sources. The first source is increased wages such as that which result from an investment of human capital in otherwise low income workers. Ahmed Al-Samarrie and Herman Miller, p. 70, for example, find a strong negative correlation between Gini coefficients and median school years completed.

A second major source of changes in income concentration results from changes in the mix of employment in the economy. The historical decline of agricultural employment in the United States has increased the number of employees who work in manufacturing and services at levels of higher reported income. This hypothesis is weakly verified in a finding by Al-Samarrie and Miller that the Gini coefficient is positively related to labor earnings in agriculture relative to labor earnings in all industries.

Simon Kuznets offers some theoretical justification of the relation between income concentration and the proportion of nonagricultural employment. Kuznets views the aggregate distribution of income as derived from a combination of the income distributions in the rural (agricultural) and urban (manufacturing and service) populations. He stresses not only the difference in average per capita incomes, but also a potential difference in the income distribution between the two sectors (pp. 7, 8). A shift of employment from the agricultural to the nonagricultural sector, argues Kuznets, will increase income inequality because the urban sector exhibits a greater income inequality, and because employees who are left in the agricultural sector continue to receive relatively low incomes.

If the income inequality is not greatly different between the two sectors, however, a shift from a largely agrarian society to an industrial and services society will first cause an increase, and then an eventual decrease,

* Economist, Office of Economic Impact Analysis, Federal Energy Administration, and doctoral candidate, Southern Methodist University, respectively. The ideas in the paper are those of the authors and do not necessarily represent opinions or policies of the federal government.

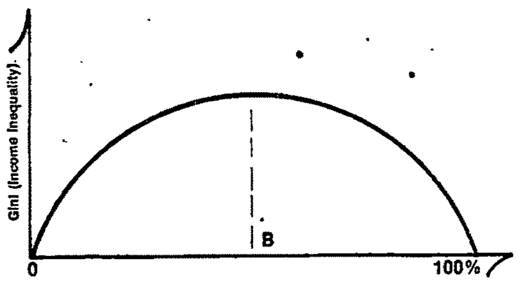

FIGURE 1. PERCENTAGE OF EMPLOYMENT IN THE NONAGRICULTURAL SECTOR

(As the percentage of nonagricultural employment increases from 0 to 100, the degree of income inequality first increases, then decreases)

in income inequality. For the sake of argument, assume complete income equality within each sector, but that income per worker in sector $A$ (agricultural) is less than that in sector $NA$ (nonagricultural). If the economy begins with almost all employment in sector $A$, the income distribution will be equal (the Gini almost zero). As workers transfer to the higher wage $NA$ sector, the distribution of income becomes more unequal (the Gini increases). With continued transfer to the $NA$ sector, most of the employment will be at the high wage level, and the distribution of income will become less unequal. In Figure 1, the Gini coefficient is shown to increase and then decrease as the proportion of nonagricultural employment increases.

Al-Samarrie and Miller's negative empirical relation between the Gini and the proportion of total earnings in the nonagricultural sector is probably due to the fact that most states of the United States were beyond point $B$ in 1950 and 1960, when their cross-section data was collected.

This paper studies only the concentration of income in relation to the relative sizes of employment within sectors of a state's economy. It is assumed that all workers in each sector of a state receive the same wage, although the wage level differs between sectors. Therefore, the distribution of income (measured by wage income per worker) is equal within each sector.[1] The unequal distribution of income within a state (composed of two sectors) is due to the mix of employment and the wage differential between the sectors.

Changes in income concentration over periods when the wage differential between the sectors is approximately constant will be caused by the varying growth rates of the two sectors. The causes of varying growth rates of sectoral employment have been treated at length in the economic literature, and will not be incorporated into this analysis. However, it is implicitly assumed that labor moves between states and between sectors of states in response to wage differentials and other indicators of the prospects for higher income.[2]

## II. Gini Coefficient and Variance of Incomes

Since the focus of this paper is on the relation between the concentration of incomes and the sectoral mix of employment, the concentration of income will be measured from Internal Revenue Service ($IRS$) data on personal incomes. An advantage of the $IRS$ data compared to the U.S. Census of Population data is that transfer payments are excluded. These data are available from 1920, and may be used in an analysis of income concentration of states.

Because the change in the Gini coefficient may be positively or negatively related to a relative increase in nonagricultural employment the analysis will be made through the intervening calculation of the variance of income, measured between two sectors each having a constant but different wage level. The use of the variance allows direct inclusion of the relative size of the two sectors, and will allow mathematical adjustment of the alternating positive and later negative relation between the Gini and the proportion of nonagricultural employment.

The degree of income concentration is conventionally measured by Gini's coefficient of concentration, defined by

[1] Kuznets finds that the difference in income distribution between the agricultural and nonagricultural sectors "in the years after the second world war seems to have disappeared" (p. 8).

[2] Smith, for example, finds such a model consistent with the growth experience of states and sectors of states in the United States. However, Lloyd Ulman finds that labor migration does not induce substantial reductions of wage differentials.

$$(1)\qquad G = \Delta_1/2u_1'$$

where

$$(2)\qquad \Delta_1 = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} | x - y |\, dF(x)dF(y)$$

and $x$ and $y$ are cumulative percentages of income received by each income group, and $u_1'$ is the mean. Following M. G. Kendall and A. Stuart (p. 47), we define

$$(3)\qquad E^2 = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} (x - y)^2 dF(x)dF(y)$$

$$(4)\qquad E^2 = 2u_2$$

where $u_2$ is the variance.

On inspection we note that the difference between $\Delta_1$ and $E^2$ is that one calculation involves $|x-y|$, whereas the other involves $(x-y)^2$. Since $|x-y|$ is a monotonic transformation of $(x-y)^2$, $\Delta_1$ is a monotonic transformation of $E^2$. Furthermore, since $G$ is simply $\Delta_1$ divided by a positive constant, $G$ must be a monotonic transformation of $E^2$, which is equal to twice the variance. Thus $G$ is also a monotonic transformation of the variance.

By the assumption of a single wage in each sector of a state, the variance of a state's income is

$$(5)\qquad V = \frac{L_i(W_i - \overline{W})^2 + L_j(W_j - \overline{W})^2}{L_n}$$

where, in each state,

$\overline{W}$ = mean wage
$W_i$ = wage in sector $i$
$W_j$ = wage in sector $j$
$L_i$ = employment in sector $i$
$L_j$ = employment in sector $j$
$L_n$ = total state employment

It is assumed that wage levels are constant throughout the period under examination. Thus, only the mean wage changes with changes in employment.

The change in the variance is

$$(6)\qquad dV = \frac{L_j}{L_n^2}(W_i - W_j)^2 dL_i + \frac{L_i}{L_n^2}(W_i - W_j)^2 dL_j - 2\frac{L_iL_j}{L_n^3}(W_i - W_j)^2 dL_n$$

There are three components of change in the variance which are variables in this model: $dL_i$ is the change of employment in the declining sector; $dL_j$ is the change in employment in the growing sector; and $dL_n$ is the change in employment in the state which is net migration from another state, and is distributed among the two sectors in the same proportion as the existing mix of employment.

In equation (6) it is clearly seen that an increase in $dL_j$ which equals a decrease in $dL_i$ will bring about a positive or negative change in $dV$, depending on the relative sizes of the coefficients of $dL_i$ and $dL_j$.

In a primarily agrarian economy a positive $dL_i$ equal to negative $dL_j$ will increase $V$, due to $(W_i-\overline{W})>(W_j-\overline{W})$. Therefore, a $dL_j=-dL_i$ will cause a decline in $V$ (or the Gini coefficient). In general, however, interstate migration will affect $dL_i$ and $dL_j$ differentially so that $dL_i=dL_j$ will not be found empirically.

Because $V$ is a monotonic transformation of $G$ we substitute $dG$ for $dV$ in equation (6). The coefficients of $dL_i$, $dL_j$, and $dL_n$ are included as variables in the equation which tests the relation between changes in the Gini and changes in sectoral employment.

$$(7)\qquad dG = \alpha_0 + \alpha_1X_1 + \alpha_2X_2 + \alpha_3X_3 + e$$

where

$$X_1 = (W_{ia} - W_{ja})^2\frac{L_{jb}}{L_{nb}^2}[L_{ic} - L_{ib}]$$

$$X_2 = (W_{ia} - W_{ja})^2\frac{L_{ib}}{L_{nb}^2}[L_{jc} - L_{jb}]$$

$$X_3 = (W_{ia} - W_{ja})^2 2\frac{L_{ib}L_{jb}}{(L_{nb})^3}[L_{nc} - L_{nb}]$$

and $e$ is a vector of randomly distributed error terms having a mean of zero.

The second subscript $b$ is the first year of the time period, $c$ is the last year of the time period, and $a$ is the average of the first and last year's data for the period. For the 1920–50 and 1950–60 periods, the agricultural ($i$) and nonagricultural ($j$) sectors are used to

compute the independent variables. For the 1960–70 period, however, the data are arranged such that the growing sector ($j$) is composed of services, and the declining sector ($i$) is an aggregate of the manufacturing and agricultural sectors.[3]

The arrangement of the data for the first two periods is consistent with the literature pertaining to the historical decline of agriculture in the United States. However, by 1960 the migration from the agricultural sector had diminished considerably. For this reason the growing services sector was isolated from manufacturing. The agricultural sector was combined with manufacturing for empirical practicality.[4]

By inspection of (6) and (7) $\alpha_1$ and $\alpha_2$ are greater than zero and $\alpha_3$ is negative. If $dG$ equalled $dV$ (rather than being a monotonic transformation), $\alpha_1$ and $\alpha_2$ would equal plus one, and $\alpha_3$ would equal minus one. Thus, the null hypothesis is that $\alpha_1$, $\alpha_2 \leq 0$, and $\alpha_3 \geq 0$. Rejection of this null hypothesis will allow acceptance of the alternate hypothesis that $\alpha_1$, $\alpha_2 > 0$; $\alpha_3 < 0$ which will verify the theory.

### III. Empirical Results

In Table 1 the least squares regression coefficients are presented. All coefficients except one are significantly greater than zero and of the expected sign. Thus the model is found to be in general agreement with the hypothesis that the change in the distribution of income is related to changes in sectoral employment.

From equation (6) it is seen that the variables $X_1$ and $X_2$ refer to weighted changes in sectoral employment, with net change in state employment $L_n$ held constant. The variable $X_3$ picks up the change in $G$ due to increased state labor force, with the intersectoral movement held constant.

The coefficient of $X_2$ is not significantly different from zero for the 1960–70 period. This result may be due to the combination of manufacturing and agricultural sectors when one is growing and the other declining simultaneously in some states.

The interpretation of the regression results may be assisted by an example using a single state for the 1920–50 period. The data were arranged so that the Gini coefficient could vary from zero to 1,000. In Alabama, migration from the agricultural sector of 298,900 workers is associated with a decline in the Gini of $-200.2$, when the weight (obtained from Table 1) is multiplied by the coefficient estimate. Similarly, the migration of 425,300 workers to the combined manufacturing and services sector is associated with an increase in the Gini of 231.4.

The relatively low $R^2$ in all equations requires some explanation. In the first place, the income data used in generating the independent variables are based upon only one of the sources of income, namely, labor. Because the proportion of property income varies between states, it may differentially impact state Gini coefficients. Therefore, a portion of variance in state Gini coefficients lies outside the explanatory power of the independent variables. Secondly, there exists a variance of income within sectors which will be incorporated in the Gini coefficient but is kept out of reach of this study by data restrictions. Thirdly, a model using many sectors rather than only two would have captured much more intrasectoral income variance. A fourth factor causing the relatively low $R^2$ may be due to the assumption that wage levels are constant for each sector during the period of analysis. Changing levels of employment may change capital-labor ratios and thus change wage levels. A decrease in wage level in the grow-

[3] A three-sector analysis was found to be impractical for statistical analysis because of the complexity of taking the total differential of the variance when three sectors was included. A regression was run on the agricultural vs. nonagricultural sector for the 1960–70 period. However, this yielded nonsignificant coefficients for $X_1$ and $X_2$.

[4] The data used in calculating the independent variables for 1920 and 1950 came from E. S. Lee et al. In the 1960 and 1970 periods nonagricultural employment and agricultural employment came from the *U.S. Census of Population, General Social and Economic Characteristics*. Manufacturing employment is from the *U.S. Census of Manufactures*, 1960 and 1970. Agricultural and nonagricultural income is from the *Survey of Current Business*, 1960 and 1970. The generation of the Gini coefficients is in accordance with James Morgan. The raw income data are from *Personal Income by States* 1920, 1950, 1960, and 1970, published by the *IRS*.

TABLE 1—REGRESSION COEFFICIENTS[a]

| Independent Variables | Dependent Variables | | |
|---|---|---|---|
| | Agricultural vs. Nonagricultural | | Service vs. Manufacturing and Agriculture |
| | $dG$ 1920–50 | $dG$ 1950–60 | $dG$ 1960–70 |

ing sector would, for example, tend to decrease the unequal distribution of income.

## IV. Conclusion

This paper focuses on one component of the many influences on the concentration of income. Specifically, changes in the sectoral mix of employment are related to changes in the variance of state incomes which are demonstrated to be related directly to changes in Gini's coefficient of income concentration. An increase of employment in the high wage sector may cause an increase or decrease in the variance, depending on the relative size of income payments in the sector. For purposes of statistical testing, changes in sectoral employment are appropriately weighted and then regressed on the change in Gini coefficient.

This simple model, which omits other important influences on income concentration such as property income and the great diversity of incomes within sectors, explains about 10 to 20 percent of the variation of state Gini coefficients.

These results tend to confirm Kuznets' hypothesis that the process of economic growth (involving a shift from an agrarian to manufacturing and service economy) influences the concentration of income. In advanced stages of growth, however, the relatively faster growth rate of services vis-à-vis manufacturing is an important influence on the concentration of income.

Further research in the direction taken in this paper would incorporate the covariation of wage levels with changes in employment. The changing wage levels would then possibly influence the change in income concentration resulting from intersectoral migration.

# Multiperiod Consumption-Investment Decisions: A Correction

By EUGENE F. FAMA*

My 1970 paper attempts to provide a multiperiod setting for hypotheses about investor behavior derived from one-period portfolio models. The main result of the paper is that if the investor is risk averse (his Von Neumann-Morgenstern utility function for lifetime consumption is strictly concave) and markets for consumption goods and portfolio assets are perfect, then the investor's behavior in the market in any period is indistinguishable from that of a risk-averse expected-utility maximizer who has a one-period horizon. William Ziemba has recently pointed out, however, that the proof of the theorem on which this conclusion is based is incomplete. I hope now to give a complete proof.

In the framework of my earlier paper, the consumption-investment decision facing the investor at any time t can be expressed in recursive form as

$$(1)\quad U_t(C_{t-1}, w_t \mid \beta_t) = \max_{c_t, H_t} \int_{\beta_{t+1}} U_{t+1}(C_t, H_t R(\beta_{t+1})' \mid \beta_{t+1}) dF_{\beta t}(\beta_{t+1})$$

$$\text{subject to} \quad 0 \leq c_t \leq w_t, \qquad H_t i' = w_t - c_t$$

Briefly, $H_t$ is the (row) vector of dollars invested in individual securities at time t; $R(\beta_{t+1})$ is the vector of returns realized on individual securities at time t+1 when the state of the world at t+1 is $\beta_{t+1}$; $F_{\beta t}(\beta_{t+1})$ is the distribution function for $\beta_{t+1}$ conditional on $\beta_t$; $c_t$ and $w_t$ are consumption and wealth at time t; $C_t$ is the vector of lifetime consumptions to time t; $i$ is the sum vector; and

$$(2)\qquad w_{t+1} = H_t R(\beta_{t+1})'$$

Finally, for any t, the function $U_t(C_{t-1}, w_t \mid \beta_t)$ shows the maximum expected utility of lifetime consumption if the consumer is in state $\beta_t$ at time t, his wealth is $w_t$, his past consumption was $C_{t-1}$, and optimal consumption-investment decisions are made at time t and at all future decision times.

As in most dynamic programming models, expression (1) represents the decision problem for any time t in terms of a derived objective function, $U_{t+1}(C_t, w_{t+1} \mid \beta_{t+1})$, which is explicitly a function of variables for t+1 and earlier periods, but which in fact summarizes the results of optimal decisions at t+1 and subsequent periods for all possible future events. Thus the recursive relation (1) represents the multiperiod problem as a sequence of "one-period" problems, but at any stage in the process the objective function used to solve the one-period problem summarizes optimal decisions for all future periods. The major result of the 1970 paper is that if the consumer's utility function for lifetime consumption has properties characteristic of risk aversion, then for all t the derived functions $U_t(C_{t-1}, w_t \mid \beta_t)$ also have these properties. From this it follows that each period the consumer behaves as if he were a risk-averse expected-utility maximizer with a one-period horizon. The formal basis for this result is the following:

PROPOSITION: *If* $U_{t+1}(C_t, w_{t+1} \mid \beta_{t+1})$ *is strictly increasing and strictly concave in* $(C_t, w_{t+1})$, *then* $U_t(C_{t-1}, w_t \mid \beta_t)$ *is strictly increasing and strictly concave in* $(C_{t-1}, w_t)$.

PROOF:

Let $c_t^*$, $H_t^*$ and $\tilde{c}_t$, $\tilde{H}_t$ be the optimal values of $c_t$ and $H_t$ in (1) for two vectors $(C_{t-1}^*\ w_t^*)$ and $(\tilde{C}_{t-1}, \tilde{w}_t)$ that differ in at least one element. Let

$$(3)\quad \begin{aligned} \hat{C}_{t-1} &= \alpha C_{t-1}^* + (1-\alpha)\tilde{C}_{t-1} \\ \hat{w}_t &= \alpha w_t^* + (1-\alpha)\tilde{w}_t \end{aligned}$$

* Professor of finance, Graduate School of Business, University of Chicago. I am grateful for the comments of Gary Eppen and Nicholas Gonedes, and for the financial support of the National Science Foundation.

$$\hat{c}_t = \alpha c_t^* + (1-\alpha)\tilde{c}_t$$
$$\hat{H}_t = \alpha H_t^* + (1-\alpha)\tilde{H}_t$$
$$\hat{w}_{t+1} = \alpha w_{t+1}^* + (1-\alpha)\tilde{w}_{t+1} = \alpha H_t^* R(\beta_{t+1})' + (1-\alpha)\tilde{H}_t R(\beta_{t+1})'$$

The strict concavity of $U_{t+1}$ in $(C_t, w_{t+1})$ implies that for $0<\alpha<1$,

$$(4)\quad U_{t+1}(\hat{C}_{t-1}, \hat{c}_t, \hat{H}_t R(\beta_{t+1})' \mid \beta_{t+1}) \geq \alpha U_{t+1}(C_{t-1}^*, c_t^*, H_t^* R(\beta_{t+1})' \mid \beta_{t+1}) + (1-\alpha) U_{t+1}(\tilde{C}_{t-1}, \hat{c}_t, \tilde{H}_t R(\beta_{t+1})' \mid \beta_{t+1})$$

This expression can only hold as an equality when

$$(5)\quad (C_{t-1}^*, c_t^*, w_{t+1}^*) = (\tilde{C}_{t-1}, \tilde{c}_t, \tilde{w}_{t+1})$$

Since $(C_{t-1}^*, w_t^*)$ and $(\tilde{C}_{t-1}, \tilde{w}_t)$ are assumed to differ in at least one element, (5) can only hold when the optimal allocations for two *unequal* wealth levels $w_t^*$ and $\tilde{w}_t$ imply $c_t^* = \tilde{c}_t$. Moreover, although $w_t^* \neq \tilde{w}_t$ and $c_t^* = \tilde{c}_t$ necessarily imply $H_t^* \neq \tilde{H}_t$, if (5) is to hold we must have

$$(6)\quad w_{t+1}^* = H_t^* R(\beta_{t+1})' = \tilde{H}_t R(\beta_{t+1})' = \tilde{w}_{t+1}$$

That is, in spite of unequal allocation vectors $H_t^*$ and $\tilde{H}_t$, the return vector $R(\beta_{t+1})$ leads to equal values of $w_{t+1}^*$ and $\tilde{w}_{t+1}$.

It is reasonable to assume, however, that the joint distribution of security returns is nonsingular so that there are necessarily possible values of $R(\beta_{t+1})$ for which unequal $H_t^*$ and $\tilde{H}_t$ imply unequal $w_{t-1}^*$ and $\tilde{w}_{t+1}$, in which case (4) holds as strict inequality. As long as there is one possible value of $\beta_{t+1}$ for which (4) must hold as a strict inequality, we have

$$(7)\quad \int_{\beta_{t+1}} U_{t+1}(\hat{C}_{t-1}, \hat{c}_t, \hat{H}_t R(\beta_{t+1})' \mid \beta_{t+1}) \cdot dF_{\beta t}(\beta_{t+1})$$
$$> \alpha \int_{\beta_{t+1}} U_{t+1}(C_{t-1}^*, c_t^*, H_t^* R(\beta_{t+1})' \mid \beta_{t+1}) \cdot dF_{\beta t}(\beta_{t+1}) + (1-\alpha)\int_{\beta_{t+1}} U_{t+1}(\tilde{C}_{t-1}, \tilde{c}_t, \tilde{H}_t R(\beta_{t+1})' \mid \beta_{t+1}) dF_{\beta t}(\beta_{t+1})$$
$$= \alpha U_t(C_{t-1}^*, w_t^* \mid \beta_t) + (1-\alpha) U_t(\tilde{C}_{t-1}, \tilde{w}_t \mid \beta_t)$$

Since the consumption-investment decision implied by $\hat{c}_t$, $\hat{H}_t$ is not necessarily an optimal allocation of $\hat{w}_t$

$$(8)\quad U_t(\hat{C}_{t-1}, \hat{w}_t \mid \beta_t) \geq \int_{\beta_{t+1}} U_t(\hat{C}_{t-1}, \hat{c}_t, \hat{H}_t R(\beta_{t+1})' \mid \beta_{t+1}) dF_{\beta t}(\beta_{t+1})$$

so that

$$(9)\quad U_t(\hat{C}_{t-1}, \hat{w}_t \mid \beta_t) > \alpha U_t(C_{t-1}^*, w_t^* \mid \beta_t) + (1-\alpha) U_t(\tilde{C}_{t-1}, \tilde{w}_t \mid \beta_t)$$

Thus $U_t$ is strictly concave in $(C_{t-1}, w_t)$. The monotonicity of $U_t$ in $(C_{t-1}, w_t)$ follows easily from the monotonicity of $U_{t+1}$ in $(C_t, w_{t+1})$, and the proposition is established.

# IN MEMORIAM

## CALVIN BRYCE HOOVER

## 1897-1974

Calvin Bryce Hoover, James B. Duke Professor Emeritus of Economics at Duke University, died June 24, 1974, in his seventy-seventh year. Born in Berwick, Illinois, Hoover received an A.B. degree from Monmouth College in 1922 and the Ph.D. from the University of Wisconsin in 1925. That same year he went to Duke as an assistant professor in the department which remained his academic home until his retirement and death.

Among both graduate and undergraduate students he was known as an outstanding teacher. For many years in the advanced theory courses his students learned to apply previously studied economic principles both to micro and macro problems. His most popular courses, however, were Economic Systems and Economic Functions of the State, to which he brought his extensive experiences with communism and fascism, and with numerous aspects of federal bureaucracy. His academic life included twenty years service as chairman of the department of economics and for ten of those years, as Dean of Duke's Graduate School of Arts and Sciences.

A reading of his autobiography, "Memoirs of Capitalism, Communism, and Nazism," provides understanding of Hoover's insight into the concerns of both the small farmer and the less skilled worker. His own boyhood experiences probably sharpened his interest in the plight of the southern farmer and worker and led to his aiding in the organization of the Committee of the South and to serving for many years as that committee's Director of Research. With Professor Ben Ratchford, he published in 1951 a penetrating monograph, *Economic Resources and Economic Policies of the South.*

Hoover's chief contributions to economic literature were his analyses of the development and operation of Russian communism and German nazism. His first book, *Economic Life in Soviet Russia*, was written after a year spent in Russia during the great Stalinist purges. He was in Germany in 1932–33 during Hitler's rise to power and along with Lord Keynes (a long-time friend of Hoover's) saw that Hitler was using his rearmament program as a weapon to restore full employment and that an underemployed economy, when stimulated, may produce both guns and butter. From his German experiences came his second book, *Germany Enters the Third Reich.*

Having seen totalitarianism at work, Calvin Hoover became an ardent, but never uncritical, believer in more liberal systems. His many books and articles dealing with economic theory, nontotalitarian economies, and with state economic policies were well-reasoned economic analyses, though never to the neglect of critical political factors when pertinent. His writings and numerous addresses always reflected the logic and reasoning of the trained economist.

Hoover's many nonacademic assignments in government in both peace time and wartime drew heavily upon his skills as advisor and administrator. He was proud of his services as a private and noncommissioned officer during the First World War where, according to him, he learned nonacademic language which he could use effectively at the proper time and place.

During the New Deal days he was an economic advisor and administrator under Henry Wallace in the Department of Agriculture. When the United States entered the war, Hoover, because of his experiences in Nazi Germany and the Soviet Union, was recruited by General Donovan for the intelligence service later called O.S.S. He played various roles while serving, eventually becoming head of Northern European operations based in Stockholm. According to one competent observer, "His network was considered the hottest and most professional of all United States' intelligence operation." For his wartime activities Hoover was

awarded the Medal of Freedom by President Truman.

After the war, in 1945, he returned to Berlin where under Generals Clay and Draper, he prepared the Hoover Plan for restoring the German economy, a program at variance with the earlier Morgenthau line to prevent German economic recovery. Later Hoover was one of the principal initiators and developers of the Marshall Plan, which he helped administer as special advisor to the *U.S.* representative in Europe for the Economic Cooperation Administration.

His Duke friends and colleagues called him Bryce and no memorial statement would be complete without some mention of Hoover as a colleague. He could be firm, perhaps even stubborn, but he seldom gave advice without a preface that advice that had to be taken was not worth getting. His enormous fund of always interesting and appropriate stories, together with his warm personality, made him a great companion whether he was discussing economic problems or recounting some of the events of an active life or simply telling stories. And he seldom if ever repeated himself.

The honorary degrees he received from Columbia, Monmouth College, Duke University and Case-Western Reserve and his election to the presidency of the Southern Economic Association, of The Association for Comparative Economies, and of the American Economic Association, showed recognition of an able economist and a devoted public servant.

# NOTES

The eighty-ninth annual meeting of the American Economic Association will be held in Atlantic City, New Jersey, September 16–18, 1976. The Employment Registry and Center will be open from September 15 to 18.

As the annual meeting is being held at an early point in the academic year, it may not be possible to complete all job placement activity through the offices of the Employment Registry and Center. Accordingly, the American Economic Association will hold a special job placement meeting for two days at the O'Hare Hilton in Chicago's O'Hare International Airport, January 7–9, 1977.

---

*Annual Meeting Placement Service*

The Placement Service at the 1976 annual meetings of the Allied Social Science Associations in Atlantic City will begin operation on September 15, the day before sessions begin. Applicants and employers will be able to attend more sessions with a day set aside entirely for labor market transactions. This service will be located at the Convention Placement Center in the Hotel Shelbourne. It will be open from 10:00 A.M. to 5:00 P.M., September 15; 8:30 A.M. to 5:00 P.M., September 16–17; and 8:30 A.M. to 12:00 noon September 18.

---

Economists who are *strongly* oriented toward the humanities, who use humanistic methods in their research, and who will be participating in meetings abroad that are concerned with the humanistic aspects of their discipline are eligible to apply for small travel grants of the American Council of Learned Societies. Grants are likely to cover only lowest cost excursion fares and will rarely exceed 50 percent of full economy-class fares. Specifically, economists may be eligible if (a) they deal with the history of economic thought or economic history, and (b) if their approach is qualitative and descriptive rather than quantitative and statistical. Conferences dealing with the establishment of social policy or legislation are ineligible. The deadlines for applications to be received in the office of the American Economic Association are: meetings scheduled between July and October, March 1; for meetings scheduled between November and February, July 1; for meetings scheduled between March and June, November 1. Application forms may be obtained from C. Elton Hinshaw, Secretary, American Economic Association, 1313 21st Avenue South, Nashville, Tennessee 37212.

---

The History of Economics Society will hold its next annual conference at the University of California, Riverside, on March 24–26, 1977. Persons wishing to present papers should submit an abstract in duplicate together with a separate sheet containing author's name, address, professional affiliation, position, and telephone number; title of paper; and whether or not the author is a member of the Society. The deadline is November 15, 1976. Persons wishing to serve as discussants are invited to submit full information including major areas of interest within the history of economics. All communications regarding the conference should be addressed to President-elect Carl G. Uhr, History of Economics Society, Department of Economics, University of California, Riverside, CA 92502.

---

The Eastern Community College Social Science Association will hold its 1976–77 conference at the Webster Hall Hotel in Pittsburgh, Pennsylvania, April 14–16, 1977. Those interested in presenting papers, participating in panel discussions, or presenting media demonstrations should send an abstract to George H. Skau, Program Chairman, Social Science Department, Bergen Community College, 400 Paramus Road, Paramus, NJ 07562. The deadline is September 30, 1976.

---

The African Studies Program, University of Wisconsin, announces a new journal, *African Economic History*, to be published twice a year. It will focus on recent economic change in Africa as well as on the colonial and precolonial economic history of the continent. Subscriptions are $4.50 to individuals and $7.00 to institutions and organizations outside of Africa ($4.50 for those in Africa), to be remitted in U.S. currency and made payable to the University of Wisconsin. Manuscripts and subscriptions should be sent to The Editors, *African Economic History*, 346B Agricultural Hall, 1450 Linden Drive, Madison, Wisconsin 53706.

---

The Southern Regional Science Association will hold its 1977 meetings in Birmingham, Alabama, on April 14–15, 1977. Scholars interested in presenting papers on any subject involving analysis of the spatial dimensions of human activity are invited to submit one-page abstracts by October 1, 1976 to the program chairman, Professor Shirley F. Weiss, Center of Urban and Regional Studies, University of North Carolina, Chapel Hill NC 27514.

---

*Meetings of Regional Economic Associations*

Eastern Economic Association Meeting, April 14–16, 1977, Hartford, CT.

Midwest Economic Association Meeting, March 31–April 2, 1977, St. Louis, MO.

Western Economic Association Meeting, June 19–23, 1977, San Francisco, CA.

Missouri Valley Economic Association Meeting, February 24–26, 1977, St. Louis, MO.

---

Omicron Delta Epsilon, the International Honor Society in Economics, invites the submission of entries for the ninth year of the Irving Fisher Graduate Monograph and Frank W. Taussig Award Undergraduate Competitions. The Fisher Award consists of $1,000 and publication as a book by Princeton University Press, subject to approval of its editorial board. In addition, the winner will be invited to submit a paper based on the winning entry to the *American Economic Review*. The recommendations of the Final Selection Board of the Competition will be considered by the *Review* in the refereeing process. All finalists will be invited to submit a paper for publication in *The American Economist*. The Taussig Award consists of $100 and publication in *The American Economist*. Entries for the Fisher Award should be submitted to Departmental Selection Committees by January 1, 1977 and entries for the Taussig Award by May 15, 1977. They will be judged by the Selection Board consisting of Professors Frank H. Hahn, Dale W. Jorgenson, Robert M. Solow, Arnold Hahn, Dale W. Jorgenson, Robert M. Solow, Arnold Zellner, and Egon Neuberger (editor). Anyone interested in entering the competition should contact Professor E. Neuberger, Editor, Economic Research Bureau, State University of New York, Stony Brook, NY 11794, for information on entrance requirements.

---

Under a joint program of the Social Science Research Council and the American Council of Learned Societies, fellowships are offered for nine to eighteen months of dissertation research on contemporary Western European affairs. Applications are invited from students in all social sciences and humanities, but particular attention is given to disciplines in which relatively less attention has been devoted to Western Europe, such as anthropology, economics, social psychology, and sociology. Requests for further information and application forms should be sent to Social Science Research Council, Western European Program, 605 Third Avenue, New York, NY 10016.

---

## *Deaths*

William C. Bagley, Jr., associate professor, department of economics, Rutgers–The State University, Feb. 29, 1976.

Earl Crockett, professor of economics, Brigham Young University, Dec. 2, 1975.

Thomas A. Martinsek, professor of economics, Southern Illinois University, Aug. 15, 1975.

Sidney E. Rolfe, professor of finance, Long Island University, and research associate, Center of International Studies, Massachusetts Institute of Technology, Mar. 10, 1976.

Emerson P. Schmidt, former director of economics research, Chamber of Commerce of the United States, Aug. 8, 1975.

Rufus Burr Smith, professor of economics, Rollins College, Apr. 30, 1976.

## *Promotions*

Peter Asch: professor of economics, Rutgers–The State University, July 1, 1976.

Bennett D. Baack: associate professor of economics, Ohio State University.

Ernst Baltensperger: professor of economics, Ohio State University.

D. L. Brito: professor of economics, Ohio State University.

H. S. Burness: associate professor of economics, University of Kentucky, Sept. 1, 1976.

Robert M. Coen: professor of economics, Northwestern University.

Richard S. Cowan, Jr.: professor of business administration and economics, Waynesburg College, Sept. 1975.

Gerald S. Goldstein: associate professor of economics, Northwestern University.

Yukon Huang: associate professor, department of economics, University of Virginia, Sept. 1, 1976.

James E. Jonish: professor of economics, Texas Tech University, Apr. 1976.

Peter A. Koop: associate professor of economics, department of social sciences, King's College, July 1, 1976.

Conway L. Lackman: associate professor of economics, Rutgers–The State University, July 1, 1976.

Alton D. Law: professor of economics, Western Maryland College, Sept. 1, 1976.

John O. Ledyard: professor of economics, Northwestern University.

Dale T. Mortensen: professor of economics, Northwestern University.

Van Doorn Ooms: professor of economics, Swarthmore College, Mar. 1976.

Frederick W. Parkhurst, Jr.: professor of economics, Guilford College, June 1, 1976.

Hugh T. Rockoff: associate professor of economics, Rutgers–The State University, July 1, 1976.

Joseph J. Seneca: professor of economics, Rutgers–The State University, July 1, 1976.

Robert C. Stuart: professor, department of economics, Rutgers–The State University, July 1, 1976.

Bernard L. Weinstein: associate professor of economics and political economy, University of Texas at Dallas, Sept. 1, 1976.

## *Administrative Appointments*

Marcus Alexis: chairman, department of economics, Northwestern University, Sept. 1976.

Robert L. Avinger: dean, Center for Honor Studies Davidson College, July 1, 1976.

Phillippe J. Crabbé: chairman, department of economics, University of Ottawa, July 1, 1975.

Charles W. Hultman: interim chairman, department of economics, University of Kentucky, Jan. 1, 1976.

Peter A. Koop: chairman, department of social sciences, King's College, July 1, 1976.

John L. Madden: associate dean, College of Business

and economics, University of Kentucky, Sept. 1, 1975.

Frederick W. Parkhurst, Jr.: chairman, department of economics, Guilford College, June 1, 1976.

*Appointments*

John A. Andrulis: assistant professor, department of economics, Rutgers–The State University, July 1, 1976.

Charles W. Bausell, Jr., University of Maryland: assistant professor, department of economics, Kent State University, Sept. 1976.

Alberto Bensión: research associate, National Bureau of Economic Research, Apr. 23, 1976.

Bettina Berch, Barnard College: assistant professor, department of economics, Williams College, July 1, 1976.

Joel Bergsman, Congressional Budget Office: International Bank for Reconstruction and Development, May 3, 1976.

Theodore C. Bergstrom: visiting scholar, National Bureau of Economic Research, summer 1976.

Ralph Bradburd, State University of New York-Albany: assistant professor, department of economics, Williams College, July 1, 1976.

Ivan E. Brick: lecturer, department of economics, Rutgers–The State University, July 1, 1976.

Frank A. Camm, Jr., University of Chicago: associate economist, economics department, The Rand Corporation, Sept. 1976.

Stephen W. Chapel, Federal Energy Administration: senior economist, management sciences department, The Rand Corporation, June 1976.

Dov Chernichovsky: visiting scholar, National Bureau of Economic Research, summer 1976.

Douglas Coate: visiting scholar, National Bureau of Economic Research, summer 1976.

Paul H. Cootner: senior research associate, National Bureau of Economic Research, June 1976.

Vittorio Corbo: research associate, National Bureau of Economic Research, Apr. 23, 1976.

Bruce R. Dalgaard, University of Illinois: assistant professor of economics, Lehigh University, July 1, 1976.

John Dennis: research associate, National Bureau of Economic Research, Apr. 23, 1976.

Robert P. Flood: acting assistant professor, department of economics, University of Virginia, Sept. 1976.

Peter M. Garber: acting assistant professor, department of economics, University of Virginia, Sept. 1976.

David M. Gay: research associate, National Bureau of Economic Research, Apr. 23, 1976.

Fred Goldman: visiting scholar, National Bureau of Economic Research, summer 1976.

Daniel A. Graham: visiting research fellow, National Bureau of Economic Research, Sept. 1976.

William H. Greene, University of Wisconsin: assistant professor of economics, Cornell University, Sept. 1976.

Claudio Haddad: research associate, National Bureau of Economic Research, Apr. 23, 1976.

Eric A. Hanushek: research associate, National Bureau of Economic Research, June 1976.

Susan Hegsted, University of Utah: assistant professor of economics, Loyola University of Chicago, Sept. 1, 1976.

J. Stephen Henderson, University of Wisconsin: assistant professor, department of economics, Ohio State University.

John L. Hilley, Princeton University: assistant professor of economics, Lehigh University, Sept. 1, 1976.

Cheng Hsiao: visiting research fellow, National Bureau of Economic Research, Sept. 1976.

Douglas Joines, University of Chicago: lecturer of economics, Loyola University of Chicago, Feb. 1, 1976.

Arthur E. King, Ohio State University: assistant professor of economics, Lehigh University, Sept. 1, 1976.

Anne O. Krueger: senior research staff, National Bureau of Economic Research, Apr. 23, 1976.

I. David Lane: senior research associate, National Bureau of Economic Research, June 1976.

Jeffrey E. Levin: assistant professor, department of economics, University of Kentucky, Sept. 1, 1976.

James D. Libbin: research associate, department of economics, Iowa State University, Dec. 1, 1975.

Glenn C. Loury, Massachusetts Institute of Technology: assistant professor, department of economics, Northwestern University, Sept. 1976.

Stephen A. McCafferty, Brown University: assistant professor, department of economics, Ohio State University.

J. Huston McCulloch: visiting research fellow, National Bureau of Economic Research, Sept. 1976.

James M. McGrann: assistant professor, department of economics, Iowa State University, Jan. 1, 1976.

Roy E. Marsten: research associate, National Bureau of Economic Research, Apr. 23, 1976.

Stephen T. Marston, The Brookings Institution: assistant professor of economics, Cornell University, Sept. 1976.

Patricio Meller: research associate, National Bureau of Economic Research, Apr. 23, 1976.

Marc A. Miles: assistant professor, department of economics, Rutgers–The State University, July 1, 1976.

Jay B. Morrison: senior research associate, National Bureau of Economic Research, June 1976.

Leopold Mureithi: research associate, National Bureau of Economic Research, Apr. 23, 1976.

Mark Pitt: research associate, National Bureau of Economic Research, Apr. 23, 1976.

Richard A. Posner: senior research staff, National Bureau of Economic Research, Apr. 23, 1976.

David H. Pyle: senior research associate, National Bureau of Economic Research, June 1976.

Barr Rosenberg: senior research associate, National Bureau of Economic Research, June 1976.

Jeffrey I. Rubin: assistant professor, department of economics, Rutgers–The State University, July 1, 1976.

Frederic M. Scherer, Federal Trade Commission: professor, department of economics, Northwestern University, Sept. 1976.

T. Paul Schultz: research associate, National Bureau of Economic Research, Apr. 23, 1976.

Robert L. Schweitzer, University of North Carolina at Chapel Hill: assistant professor, department of economics, Kent State University, Sept. 1976.

Leslie Seplaki, Rutgers–The State University: visiting scholar, Harvard Law School, 1976–77.

Linda J. Shaffer, Northwestern University: assis-

tant professor of economics, University of California, Davis, July 1976.

William F. Sharpe: senior research associate, National Bureau of Economic Research, June 1976.

Steven M. Sheffrin, Massachusetts Institute of Technology: assistant professor of economics, University of California, Davis, July 1976.

Gordon R. Storholm: assistant professor, department of economics, Rutgers–The State University, July 1, 1976.

Carl Van Duyne, Stanford University: assistant professor, department of economics, Williams College, July 1, 1976.

W. Kip Viscusi, Harvard University: assistant professor, department of economics, Northwestern University, Sept. 1976.

Harvey Zabinsky: assistant professor, department of economics, University of Kentucky, Sept. 1, 1976.

### *Leaves for Special Appointments*

Christopher Garbcz, University of Missouri, Rolla: economist, Regional Impact Division, Federal Energy Administration, Washington, June 1, 1976–May 31, 1977.

Kurt Hausafus, Oberlin College: vice president and chief economist, Chicago Mercantile Exchange, June 1, 1976.

W. Whitney Hicks, University of Missouri, Columbia: Agency for International Development, Washington, Jan. 5, 1976.

Karel Holbik: chief, Section for Development of Financial Institutions, United Nations, New York Jan. 1976.

Mukul K. Majumdar, Cornell University: Ford Foundation rotation professorship, University of California, Berkeley; Guggenheim Fellowship, Sept. 1976.

### *Resignations*

Christopher C. Barnekov, Jr., Ohio State University, Sept. 1976.

Erwin A. Blackstone, Cornell University: Temple University, Sept. 1976.

Warren L. Coats, Jr., University of Virginia: International Monetary Fund, Jan. 15, 1976.

Stuart I. Greenbaum, University of Kentucky: Northwestern University, July 1, 1976.

Joseph A. McKinney, University of Virginia: Baylor University, May 1976.

Donald L. Martin, University of Virginia: University of Miami, May 1976.

Dennis C. Mueller, Cornell University: International Institute of Management, Berlin, Sept. 1976.

John A. Otte, Iowa State University, Feb. 4, 1976.

Pierre Pestieau, Cornell University: University of Liege, Sept. 1976.

### *Miscellaneous*

William G. Dewald: editor, *Journal of Money, Credit, and Banking.*

Peter O. Steiner, University of Michigan: president, American Association of University Professors, June 1976.

Roy Weinstein: vice president, National Economic Research Associates, Mar. 1, 1976.

## NOTE TO DEPARTMENTAL SECRETARIES AND EXECUTIVE OFFICERS

When sending information to the *Review* for inclusion in the Notes Section, please use the following style:

A. Please use the following categories:

1—Deaths
2—Retirements
3—Foreign Scholars (visiting the USA or Canada)
4—Promotions
5—Administrative Appointments
6—New Appointments
7—Leaves for Special Appointments (NOT Sabbaticals)
8—Resignations
9—Miscellaneous

B. Please give the name of the individual (SMITH, John W.), his present place of employment or enrollment: his new title (if any), and the date at which the change will occur.

C. Type each item on a separate 3x5 card and please do not send public relations releases.

D. The closing dates for each issue are as follows: *March*, November 1; *June*, February 1; *September*, May 1; *December*, August 1.

This announcement supersedes and replaces a letter which was sent annually from the managing editor's office. All items and information should be sent to the Assistant Editor, *American Economic Review*, Box Q, Brown University, Providence, Rhode Island 02912.

# ESSAYS ON HAYEK

**Edited by Fritz Machlup. Foreword by Milton Friedman**

Friedrich A. Hayek, Nobel Laureate in Economic Science 1974

Focusing on one of this century's most influential economic and political thinkers, this book brings together seven original essays presented at a special meeting of the Mont Pelerin Society, plus additional commentary about Hayek and his work.

WILLIAM F. BUCKLEY, Jr.—*The Road to Serfdom: The Intellectuals and Socialism*
GOTTFRIED DIETZE—*Hayek on the Rule of Law*
RONALD MAX HARTWELL—*Capitalism and the Historians*
SHIRLEY ROBIN LETWIN—*The Achievements of Friedrich A. Hayek*
FRITZ MACHLUP—*Hayek's Contribution to Economics*
GEORGE C. ROCHE III—*The Relevance of Friedrich A. Hayek*
ARTHUR SHENFIELD—*Scientism and the Study of Society*

Clothbound, $10.00

**NYU Press**
Washington Square, New York 10003

# Insights: International Economics

**Foreign Trade and International Development**
**Anindya K. Bhattacharya,** Adelphi University
The author considers such issues as international and domestic income distribution, long-term trading trends, and preferential tariff treatment in discussing the progress of less-developed nations. 128pp. $13.50

**The New Internationalism:** Strategy and Initiatives for U.S. Foreign Economic Policy
**Wilbur F. Monroe**
The author conducts an ambitious, knowledgeable investigation, by blocs of countries, into the make-up of a comprehensive foreign economic policy. 256pp. $16.00

**China's Foreign Aid:** An Instrument of Peking's Foreign Policy
**John F. Copper,** University of Maryland
Here is an intriguing analysis of China's economic aid program during the past twenty years and its relationship to foreign-policy goals. 224pp. $17.50

**Latin American Inflation**
**Susan Wachter,** University of Pennsylvania
Unlike other works dealing with inflationary problems of Latin America, Wachter reviews the monetarist-structuralist debate, reformulating the structuralist model for testing. The author subjects data from Chile, Brazil, Argentina and Mexico to rigorous analysis. In Press Fall 1976

# *ANNOUNCING*

# A SECOND JOB PLACEMENT MEETING

**O'HARE HILTON**

**CHICAGO, ILLINOIS**

**January 7, 8, & 9**

As the annual meeting is being held at an early point in the academic year (September 16-18, 1976), it may not be possible to complete job placement activity through the office of the Employment Registry and Center. Accordingly, the American Economic Association will hold a special supplementary placement meeting on January 7, 8, and 9, 1976 at the O'Hare Hilton in Chicago, Illinois. The O'Hare Hilton is located within the airport complex and is within easy walking distance of the terminals.

---

Instructions regarding application submission, job listing submission, and hotel reservations will be available in the October issue of *JOB OPENINGS FOR ECONOMISTS*, the December issue of the *AMERICAN ECONOMIC REVIEW*, and the Secretary's Office (after the September Annual Meeting). In addition, information for interested employers and applicants will be distributed to all Department Chairpersons and to nonacademic employers who have listed openings in *JOE*.
